Pain is the main sensation elicited by stimulation of ocular sensory nerves although tactile sensations are evoked at the conjunctiva and feelings of cold are also evoked by mild cooling of the corneal surface. After repeated noxious stimulation or tissue injury, ocular polymodal nociceptors become sensitized and cause sustained pain and hyperalgesia. They also contribute to local inflammation through the antidromic release of peptide transmitters stored in their peripheral endings ("neurogenic inflammation"). Intact sensory nerve endings, particularly in the corneal epithelium, are subjected to a continuous remodeling. Ocular sensory nerves damaged by accidental or surgical injury or following pathological processes, may also experience long-lasting changes in excitability, giving rise to ocular dysesthesia or neuropathic pain referred to the eye.

Sensations originated at the ocular surface can be explored by esthesiometry. The cornea has an overall higher sensitivity than the conjunctiva. Sensitivity of the ocular surface is reduced by age and by a variety of pathological processes that affect sensory innervation such as herpetic keratitis, some types of corneal trauma and post-infectious conditions, certain hereditary corneal dystrophies and anterior segment or vitreo-retinal surgery, especially scleral buckling operations. Although the principal eye diseases leading to impaired vision – such as retinal pathologies, chronic open-angle glaucoma or cataract – course without pain, pain is a cardinal symptom of inflammatory and traumatic disturbances of

the anterior segment of the eye. Pain is also evoked by various ocular diseases affecting other structures within the globe or orbital tissues, and may become an undesired consequence of ocular surgery. Dry eye, a multietiological condition that leads to alteration of the ocular surface epithelium, is the most common cause of superficial ocular discomfort and pain. Management of ocular pain includes the use of topical anesthetics, cycloplegic agents and anti-inflammatory drugs or ocular patching to reduce peripheral nociceptive input, and systemic analgesics to act on nociceptive pathways at the central nervous system.

1. Anatomy of ocular sensory nerves

1.1 Origin of the ocular sensory nerves

Trigeminal ganglion neurons

The sensory innervation of the eye is provided by primary sensory neurons mainly of small or medium size, clustered in the ophthalmic (medial) region of the ipsilateral trigeminal ganglion (TG). Most ocular sensory neurons are devoted to the cornea and represent about 1.5 percent of the total number of neurons of the TG.¹ The axons of the pseudounipolar trigeminal neurons divide into a peripheral branch that projects to the peripheral target tissues and a central branch that enters the brainstem to reach the trigeminal sensory complex. Based on the size and the presence of a myelin sheath in the peripheral axons, corneal trigeminal neurons can be classified as myelinated (20 percent in the mouse) and unmyelinated (80 percent in the mouse).^{1,2} Myelin content is reflected in the conduction velocity of the peripheral axons (see below).

TG neurons innervating the eyeball contain several neuropeptides, including CGRP (calcitonin gene-related peptide, present in about 50 percent of corneal neurons), the tachykinin substance P (present in about 20 percent), cholecystokinin, somatostatin, opioid peptides, pituitary adenylate cyclase activating peptide (PACAP), vasoactive intestinal peptide (VIP), galanin and neuropeptide Y (NPY), as well as neuronal nitric oxide synthase (nNOS).^{1,3-5}

The ophthalmic nerve and its branches

The peripheral axonal branch of most ocular sensory neurons in humans exits the TG running with the ophthalmic

division of the ganglion, which traverses the superior orbital fissure and then branches into the nasociliary, the frontal and the lacrymal nerves. The nasociliary nerve gives several sensory branches: (1) two long ciliary nerves that reach the eyeball and pierce the sclera, constituting the major sensory output of the eye; (2) the infratrocchlear nerve that innervates the medial aspect of lids, nose, and lacrymal sac; (3) the external nasal nerves; (4) a communicating branch to the ciliary ganglion. The ciliary ganglion is a parasympathetic ganglion located within the orbit that sends 5–10 short ciliary nerves carrying parasympathetic postganglionic fibers, postganglionic sympathetic axons originating at the superior cervical ganglion, and the trigeminal sensory nerve fibers arriving through the communicating branch of the nasociliary nerve to the eye. These mixed, short ciliary nerves enter the eyeball around the optic nerve. The second branch of the ophthalmic nerve is the frontal nerve, which bifurcates into the supraorbital nerve to innervate the upper eye lid and the frontal sinus, and the supratrochlear nerve that provides innervation to the forehead and the upper eyelid. Finally, the third branch of the ophthalmic nerve, the lacrymal nerve, innervates the lacrymal gland and some areas of the conjunctiva and the skin of the upper lid. It also incorporates postganglionic parasympathetic nerve fibers from the pterygopalatine ganglion (Fig. 16.1).

A minor part of the sensory fibers from the eye is conveyed, together with the innervation of the conjunctiva and the skin of the lower eye lid, by the infraorbital nerve, a branch of the maxillary nerve, which in turn constitutes

the second major branch of the trigeminal ganglion (Fig. 16.1).

Trigeminal sensory fibers end in the epithelia, connective tissue and blood vessels of the lids, orbit, extraocular muscles, ciliary body, choroid, scleral spur, sclera, cornea, and conjunctiva – the retina and lens being the only ocular tissues not receiving direct trigeminal sensory innervation.

1.2 Distribution of sensory nerve fibers within the eye

After penetrating the sclera around the optic nerve at the posterior eye pole, long and short ciliary nerves containing a mixture of sensory, sympathetic, and parasympathetic nerve fibers form a ring around the optic nerve, keeping the lamina cribrosa devoid of innervation. Ciliary nerve fascicles travel anteriorly towards the cornea within the suprachoroidal space, giving a few collaterals that provide the sparse innervation of the posterior part of the eye. Along their trajectory to the eye front, these nerve fiber bundles undergo repetitive branching. Some of the nerve fibers innervate the sclera itself, being more numerous in the episcleral tissue; others leave the sclera to enter the choroid, while most nerve filaments continue to innervate the ciliary body, the iris, and the cornea. Most nerve fibers finally form a series of ring meshworks of nerve fibers at the limbus around the cornea – the so-called limbal or pericorneal plexuses.

Nerve filaments entering the choroid are composed of sensory, sympathetic, and parasympathetic axons, that

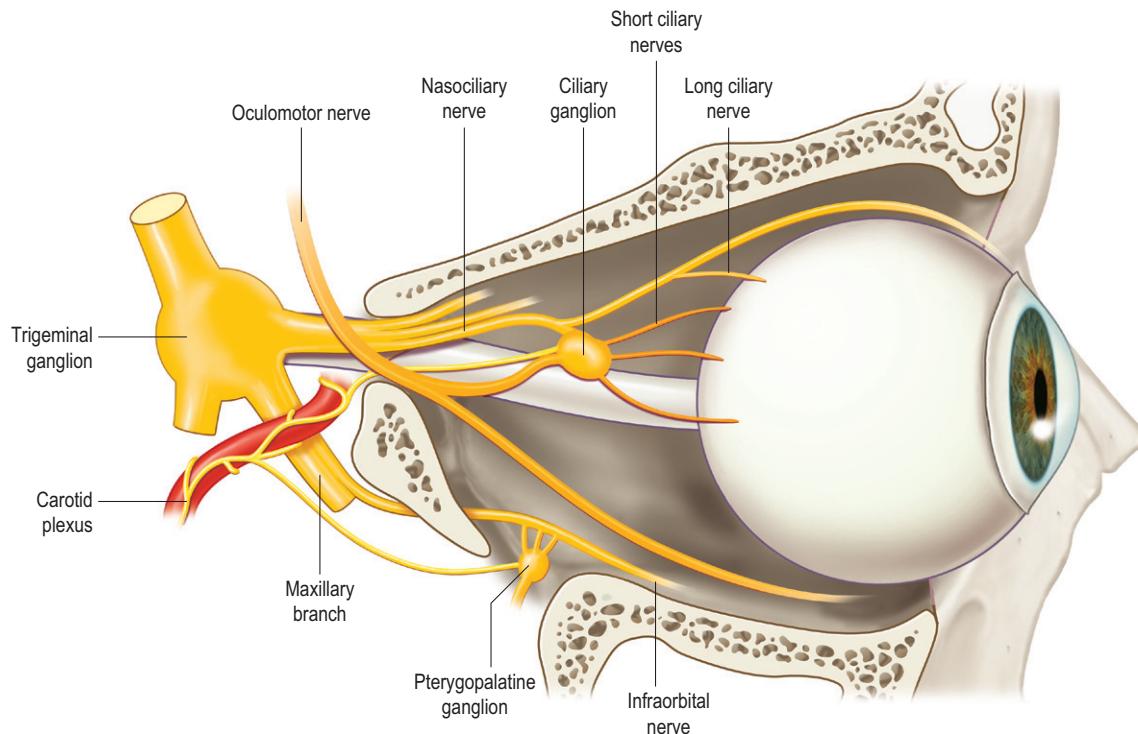

Figure 16.1 Innervation of the eye. Medial view of the orbit showing the sensory and autonomic nerves directed to the eye. The ophthalmic branch of the trigeminal ganglion gives the nasociliary nerve that sends long and short ciliary nerves to the eyeball, the last through the ciliary ganglion. Frontal and lacrimal nerves are not shown in this picture. The trigeminal maxillary branch gives the infraorbital nerve that innervates part of the eye and the lower lid. Sympathetic fibers from the superior cervical ganglion, travelling within the carotid plexus and parasympathetic branches of the ciliary and the pterygopalatine ganglia join short ciliary nerves. (Adapted from Rubin M, Safdieh JE, Netter's Concise Neuroanatomy, Elsevier, 2007.)

branch extensively forming a dense network in which individual parasympathetic ganglion cells are also found.⁶

Limbal plexus nerves supply the sensory and autonomic innervation of the limbal vessels, the trabecular meshwork and the scleral spur. Nerve bundles also form at the root of the iris, a circumferential plexus that gives origin to the iridal innervation. Finally, a variable number of nerve trunks arising from the limbal plexus enter the corneal stroma (corneal stromal nerves). Despite its comparatively small size, the cornea receives a significant portion of the ocular innervation, presenting a nerve density that is estimated to be 300–400 times higher than that of the human fingers or the teeth.^{4,7}

The majority of the nerves directed to the eye are composed by thin, unmyelinated nerve fibers often incompletely surrounded by Schwann cells, while less than 30 percent present a myelin sheath. All branch extensively and terminate as free nerve endings showing small enlargements (varicosities) along their terminal course. In addition, some encapsulated nerve endings similar to Krause and Meissner bodies have been observed in the choroid, in particular near the ciliary body^{8,9} and the iris,¹⁰ and in the episclera and chamber angle but not in the cornea.¹¹

1.3 Architecture of corneal sensory nerves

The corneal innervation is anatomically organized in four levels from the penetrating stromal nerve bundles up to the intraepithelial nerve terminals (Fig. 16.2A).

Corneal stromal nerves

The anatomy of nerve bundles radially entering the corneal stroma is quite similar among mammals varying only in their number (6–8 in rat, 15–40 in cat or dog, about 60 in human).^{12–14} Stromal nerves branch immediately after entering the cornea and run within the stroma as ribbon-like fascicles enclosed by a basal lamina and Schwann cells. Myelinated axons included in stromal nerves (about 20 percent of the nerve fibers) lose their myelin sheath within a millimeter after penetrating the stroma (Fig. 16.2B). The distal branches of this arborization anastomose extensively, forming the anterior stromal nerve plexus, a dense and complex network of intersecting small and medium-size nerve bundles and individual axons with no preferred orientation laying in the anterior 25–50 percent of the corneal stroma, depending on the species, being most dense in the anterior layers. In contrast, the posterior half of the human stroma and the corneal endothelium are devoid of sensory nerve fibers.

In addition to stromal nerve innervation, a small number of small nerve fascicles originating at the limbal plexus and at the conjunctiva superficially enter the peripheral cornea to innervate the perilimbal and peripheral corneal zones.¹³

Subepithelial nerve plexus

In humans and higher mammals, the most superficial layer of the anterior stromal nerve plexus, located in a narrow strip of stroma immediately beneath Bowman's membrane, is especially dense and is referred to as the corneal subepithelial nerve plexus, its nerve density generally higher in the peripheral than in the central cornea. Two anatomically distinct types of nerve bundles are distinguished in the

subepithelial plexus. One forms a highly anastomotic mesh-work made of single axons and thin nerve fascicles located immediately beneath Bowman's membrane without penetrating it towards the corneal epithelium. The second type consists of about 400–500 medium-sized, curvilinear bundles that penetrate Bowman's membrane mainly in the peripheral and intermediate cornea, shed the Schwann cell coating, bend at a 90° angle and divide, each into 2–20 thinner nerve fascicles that continue into the corneal epithelium as the sub-basal nerve plexus. A relatively low number of stromal nerves penetrate Bowman's membrane in the central cornea, which receives most of its innervation from long sub-basal nerves that enter the peripheral cornea directly from the limbal plexus.

Sub-basal nerve plexus

The sub-basal nerve plexus in humans is formed by 5,000–7,000 nerve fascicles in an area of about 90 mm². A sub-basal nerve bundle gives several side branches, each containing 3–7 individual axons. Thus, the total number of axons in the sub-basal plexus is estimated to vary between 20,000 and 44,000.⁴

The sub-basal nerve axons may travel up to 6 mm between the basal epithelial cells and their basal lamina, roughly parallel to one another. The arrangement of a stromal nerve bundle branching into multiple, parallel daughter nerve fascicles, constitutes a unique neuroanatomical structure characteristic of the cornea and is termed an epithelial leash. Epithelial leashes are constituted by up to 40 individual unmyelinated straight and beaded nerve fibers of variable diameter (0.05–2.5 microns). Nerve fibers in adjacent leashes interconnect repeatedly such that they are no longer recognizable as individual leashes, forming finally a relatively homogeneous nerve plexus. In vivo confocal microscopy has shown that the sub-basal nerve plexus forms a whorl-like, spiral pattern of nerve fibers, the center of which is called the "vortex" (Fig. 16.2C). In humans it is located 2–3 millimeters inferior and nasal to the corneal apex. The mechanisms that govern the formation and maintenance of this spiral pattern remain unknown. However, as basal corneal epithelial cells and sub-basal nerves appear to migrate centripetally in tandem,¹⁵ it is possible that basal epithelial cells derived from limbal stem cells migrate centripetally in a whorl-like fashion towards the corneal apex in response to a chemotropic guidance, to electromagnetic cues, and/or to population pressures; and the sub-basal nerves that occupy the narrow intercellular spaces between these migrating cells would be pulled along their trajectory. An alternate possibility is that sub-basal nerves would develop their whorl-like orientation independently of epithelial cell dynamics, providing in turn a structural scaffolding that directs epithelial cell migration.^{16–19}

Despite their considerable branching, most stromal and subepithelial nerve bundles pass uninterrupted through the stroma to reach the corneal epithelium and apparently do not provide functional innervation to stromal tissue. However, a small proportion of corneal nerve fibers appear to travel downwards to terminate in the stroma as expanded structures resembling free nerve endings.

Intraepithelial nerve terminals

From the sub-basal nerves running horizontally through the basal epithelium, single fibers split off and turn 90°

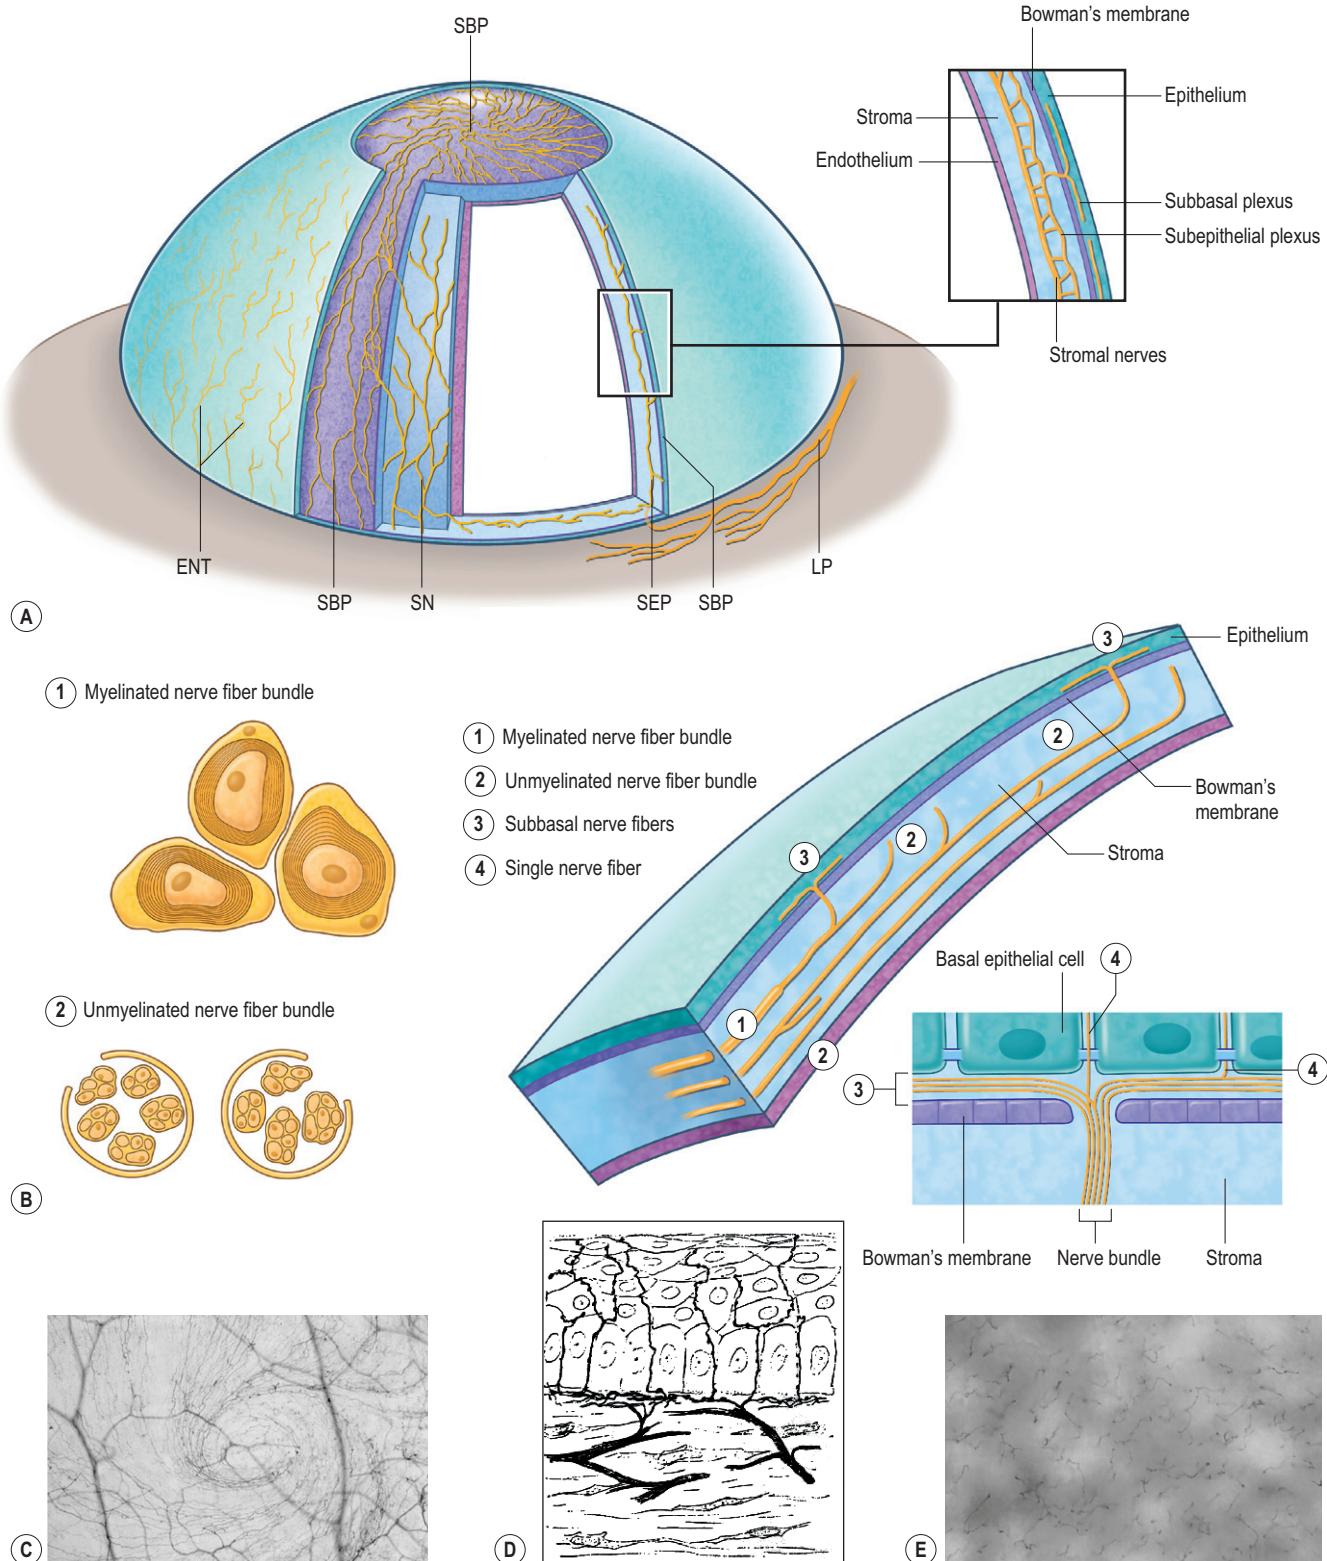

Figure 16.2 Corneal innervation. **(A)** Schematic distribution of nerves in the cornea. From the limbal plexus (LP), stromal nerve trunks (SN) penetrate the stroma radially and divide dichotomously to form the subepithelial plexus (SEP). Branches of this plexus ascend towards the epithelium, traverse Bowman's layer and form the sub-basal plexus (SBP) between the epithelium basal layer and its basal lamina, where nerve branches run horizontally as families of long parallel nerves (leashes) which in turn give rise to intraepithelial nerve terminals (ENT). **(B)** Characteristics of nerve fibers in the peripheral and central cornea. Myelinated nerve bundles (1) penetrate the stroma and immediately lose their myelin cover. Thus, only unmyelinated nerves (2) are found throughout the cornea. Subepithelial nerves ascend to form the sub-basal nerve plexus (3) from which individual axons (4) ascend vertically towards the corneal surface, with axons terminating at various levels of the corneal epithelium. **(C)** Architecture of the sub-basal nerve plexus in the infero-central region of the cornea. Whole mount of a stained mouse cornea depicting the sub-basal whorl area. **(D)** Drawing of epithelial nerve endings. Varicose intraepithelial nerve endings stained with the gold chloride impregnation method run between the epithelial elements up to the outer layers. **(E)** Single intraepithelial nerve ending. Whole mount of the mouse cornea stained with the gold chloride impregnation method, showing epithelial nerve endings at the corneal surface. (A: Modified from Müller et al 2003;⁴ B: Adapted from Müller et al 1996;¹⁴ Reproduced from Association for Research in Vision and Ophthalmology. C: From C. Belmonte and E. Raviola, unpublished results; D: From Ramon y Cajal S, Textura del sistema nervioso del hombre y de los vertebrados, Vol. I. Imprenta y Librería de Nicolás Moya, Madrid, 1899; E: From F. De Castro and C. Belmonte, unpublished results.)

vertically as a profusion of thin, short, and beaded terminal axons ascending between the epithelial cells, often with a modest amount of additional branching, up to the more superficial layers of the corneal epithelium (Fig. 16.2D,E).^{4,20} Intraepithelial fibers end as free nerve endings, appearing as prominent, bulbous terminal expansions that appear morphologically homogeneous when visualized using optical or electron microscopy, though immunocytochemical staining reveals differences in the expression of neuropeptides and other neurotransmitters, suggesting a functional heterogeneity.⁴ At the ultrastructural level, corneal nerve endings contain abundant small clear vesicles, perhaps filled with excitatory amino acids, and large, dense-cored vesicles containing neuropeptides such as calcitonin gene-related peptide (CGRP), substance P, and/or other peptides. They also contain mitochondria, glycogen particles, neurotubules, and neurofilaments.^{3,4,21} The nerve terminals are located throughout all layers of the corneal epithelium, extending up to a few microns of the corneal surface, but being especially numerous in the wing and basal cell layers. Occasionally, epithelial cell membranes facing the nerve terminals show invaginations that may eventually completely surround the nerve ending.^{4,19,20} This intimate relationship raises the possibility of bidirectional exchange of diffusible substances between both structures. The intimate contacts also allow nerve endings to detect changes in epithelial cell shape or volume, such as those produced by ocular surface desiccation or swelling.

The innervation density of the corneal epithelium is probably the highest of any surface epithelium. Although the actual number of corneal nerve endings remains a matter of speculation, considering that each sub-basal nerve fiber gives at least 10–20 intraepithelial nerve terminals, it is reasonable to speculate that the human central cornea contains approximately 3,500–7,000 nerve terminals/mm². This rich innervation provides the cornea with a highly sensitive detection system, and it has been hypothesized that injury of a single epithelial cell may be sufficient to trigger pain perception.¹⁹ Nerve terminal density, and thus, corneal sensitivity, are higher in the central cornea and decrease progressively when moving towards the periphery. Similarly, corneal sensitivity and nerve density decrease progressively as a function of age and in several ocular pathologies.

An individual stromal axon entering at the corneoscleral limbus undergoes repetitive branching and eventually travels across as much as three-quarters of the cornea before terminating.²⁰ As a result, individual receptive fields of corneal

sensory fibers range in size from less than 1 mm² to as much as 50 mm² and may cover up to 25 percent of the corneal surface. The extensive branching also explains the significant overlapping of receptive fields found in electrophysiological studies of single corneal nerve fibers.

1.4 Central sensory pathways

Sensory information from the eye is carried by trigeminal ganglion neurons to the ventral portion of the ipsilateral trigeminal brainstem nuclear complex (TBNC), to activate ocular sensory second-order neurons located mainly in the intermediate zone between interpolaris and caudalis subnuclei (Vi/Vc), in laminae I-II of the subnucleus caudalis/upper cervical spinal cord (Vc/C1), and in the adjacent bulbar lateral reticular formation (Fig. 16.3).^{22–24} Additionally, few trigeminal neurons innervating ocular and periocular tissues project to the principal nucleus of the TBNC, and a very sparse number are confined to a few locations along the ventral border of the pars oralis and interpolaris of the spinal trigeminal nucleus. Second-order ocular neurons located in the Vi/Vc area project to different places in the central nervous system including brainstem regions as the superior salivatory/facial motor nucleus and the contralateral thalamus.^{25–27} Neurons receiving corneal information have been identified in the thalamic posterior nucleus and the zona incerta. These thalamic neurons project in turn to primary (SI) and secondary (SII) somatosensory cortical areas responsible for pain sensations and reactions. Non-visual sensory input from the eye is represented in contralateral cortical SI areas 3b and 1 (Fig. 16.3), located together with those that represent nose, ear, and scalp. Projections to the insula and to the cingulate and prefrontal cortex provide the neural substrate for the affective and cognitive components of sensations evoked by eye stimulation.

2. Development and remodeling of corneal innervation

2.1 Development of corneal nerves

The cornea lacks sensory innervation until the fifth gestational month, when corneal nerve endings appear. During development, sensory axons first form the nerve ring around the cornea (the limbal nerve plexus) and subsequently axons

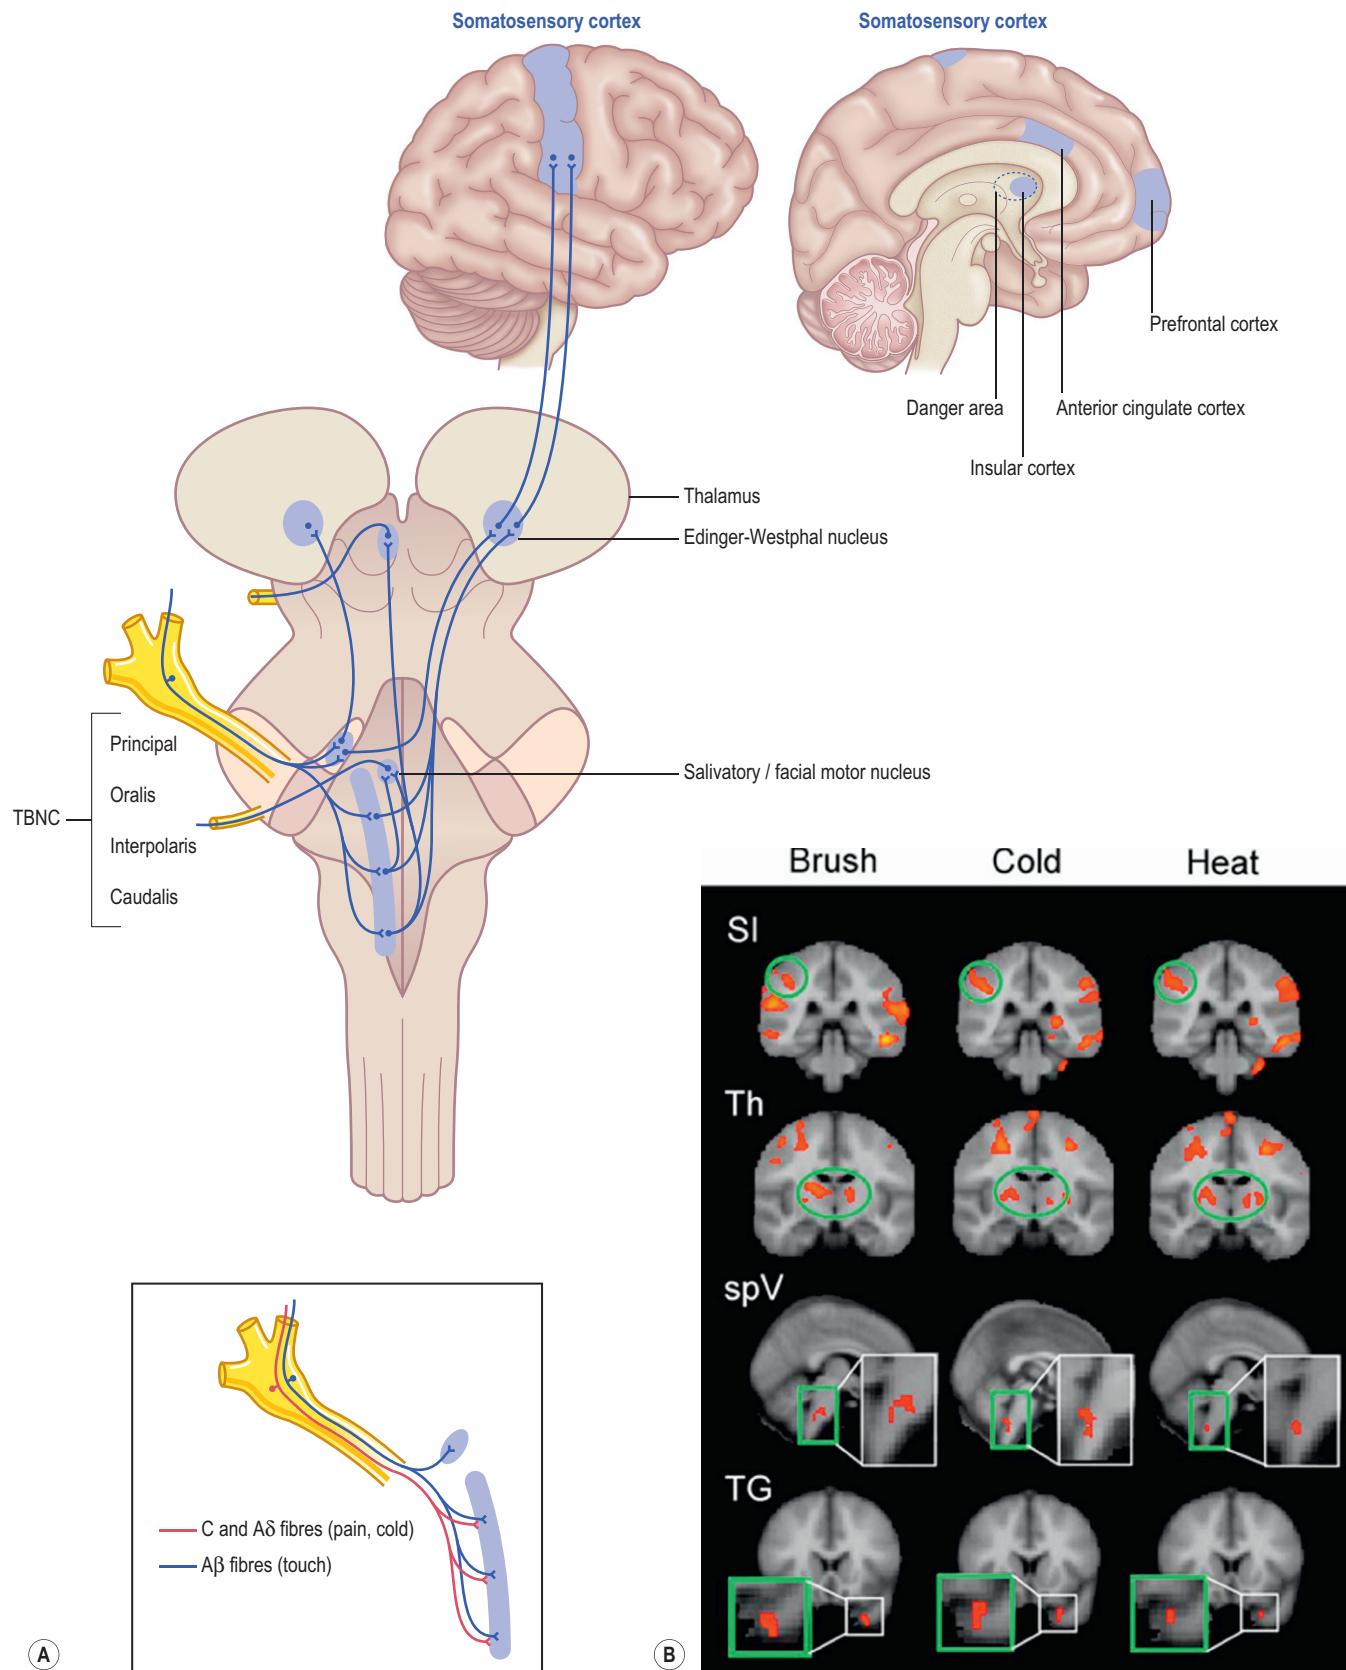

Figure 16.3 Ophthalmic trigeminal pathways. **(A)** Schematic representation of the trigeminal brainstem nuclear complex (TBNC), composed of the principal nucleus, located in the mesencephalon, and the spinal nucleus, subdivided into subnucleus oralis, interpolaris, and caudalis. TBNC projects to the contralateral thalamus, and from there to the primary somatosensory areas cortex (insular, cingulate, and prefrontal cortex). Thalamic projections also reach other areas of the cortex involved in the processing of affective and cognitive aspects of ocular pain. Trigeminal projections to the salivatory/facial motor nucleus, and to the Edinger-Westphal nucleus are also represented. Inset: Distribution of thick myelinated mechanosensory fibers and thin (thermosensitive and nociceptive) fibers within the TBNC. **(B)** MRI images showing the activation by noxious stimulation of the trigeminal sensory pathway. grow radially into the corneal tissue (Fig. 16.4A).^{20,28} The molecular signals controlling ocular nerve growth remain unknown, though several guidance molecules may regulate the process. Corneal and lens-derived semaphorins appear to mediate the initial repulsion of trigeminal sensory axons from the cornea,²⁹ thus inducing the proper formation of the pericorneal nerve ring meshwork, and also contribute to the positioning of a subset of axonal projections in the choroid fissure, that form a ventral plexus from which the iris innervation is later supplied.³⁰ Upon completion of the pericorneal nerve ring, sensory nerves enter the cornea as bundles, at uniformly spaced sites around its entire circumference and begin to extend radially inside the cornea, first innervating its periphery and then the entire stromal surface. The depth at which nerves enter the corneal stroma correlates with the area of the cornea that they will innervate, so that the deepest stromal nerves innervate almost the entire corneal surface, whereas the more superficial nerves which enter the stroma nearest to the epithelium mainly supply the periphery.¹⁷

The uniform separation between corneal nerve bundles during embryogenesis seems to be due to the release of neuro-repulsive factors from pioneering growth cones as they leave the limbal nerve ring and enter the corneal stroma, keeping nerve bundles growing relatively straight towards the center of the cornea as centripetal radii and separated one from another. The extension or radial innervation within the cornea is produced by bifurcation of nerve fascicles in successive, concentric zones, thus suggesting that the position and orientation of intracorneal nerves is determined by the intra-corneal milieu¹⁶ and the migration of epithelial cells.¹⁷ Stromal composition and neurotrophic factors released from corneal epithelium also participate in the regulation of nerve density and orientation of corneal nerves during development.^{31,32}

2.2 Dynamic remodeling of adult corneal innervation

Corneal nerves are subjected to a remodeling in the adult cornea throughout life. Deep stromal nerve fiber bundles maintain a relatively constant position and configuration within the cornea while the corneal sub-basal nerve plexus, and especially intraepithelial nerve terminals, experience an extensive rearrangement (Fig. 16.4B; Box 16.1). Time-lapse, *in vivo* confocal microscopic examination of living human eyes reveals that the human sub-basal corneal nerve plexus is a dynamic structure with a slow but continuous centripetal movement (5–15 microns/day) that changes the whorl-centered plexus in a 6-week period.³³ Intraepithelial nerve endings are subjected to faster morphofunctional changes; their continuous remodeling follows the long-term, sub-basal nerve reconfiguration. The continuous shedding of corneal epithelial cells also strongly influences the rearrangement and dynamics of epithelial nerve terminals.

Reorganization of differentiating corneal epithelial cells migrating up to the most superficial layers of the corneal epithelium induces changes in intraepithelial nerve ending architecture that occur in less than 24 hours.³⁴ The molecular mechanisms responsible for this continuous rearrangement of corneal nerves are unknown. Adult corneal sensory nerves retain the ability to respond to semaphorins,

Box 16.1 Corneal nerve remodeling and ocular pathologies

The continuous remodeling of corneal nerves may be disturbed by an altered corneal architecture or prolonged wound healing. Abnormal patterns in sub-basal nerve organization have been observed following corneal epithelial pathologies such as basement membrane dystrophy, recurrent erosions, or dry eye.

which inhibit nerve sprouting both in transected and intact nerves.³⁵ In several mammalian species, corneal nerve terminal density decreases with age,^{36,37} and this may be the basis of the decreased corneal sensitivity reported in the elderly.^{38–41}

2.3 Regeneration of injured corneal nerves

Adult corneal nerves retain the ability to regenerate following injury. Nevertheless, after damage or transection, the morphology and functional properties of corneal nerves change substantially. Nerve processes distal to the site of lesion degenerate, whereas central stumps start to regenerate, finally producing a nerve pattern rather different from the original corneal nerve architecture.^{42,43} The regenerative process takes place in several stages (Fig. 16.4C). When corneal nerves are cut, the denervated area is first invaded by sprouts of adjacent, intact nerve fibers. Later, the central stump of injured axons starts to regenerate, forming micro-neuromas from which newly formed sprouts begin to develop, while the early branches from intact fibers begin to degenerate.^{4,42} It may be that interruption in the injured nerve terminals of the uptake of signal molecules such as nerve growth factor (NGF) produced by corneal cells, which are centripetally transported along the parent axon to the neuron's soma to regulate gene expression, causes morphological and functional changes in regenerating neurons.⁴⁴

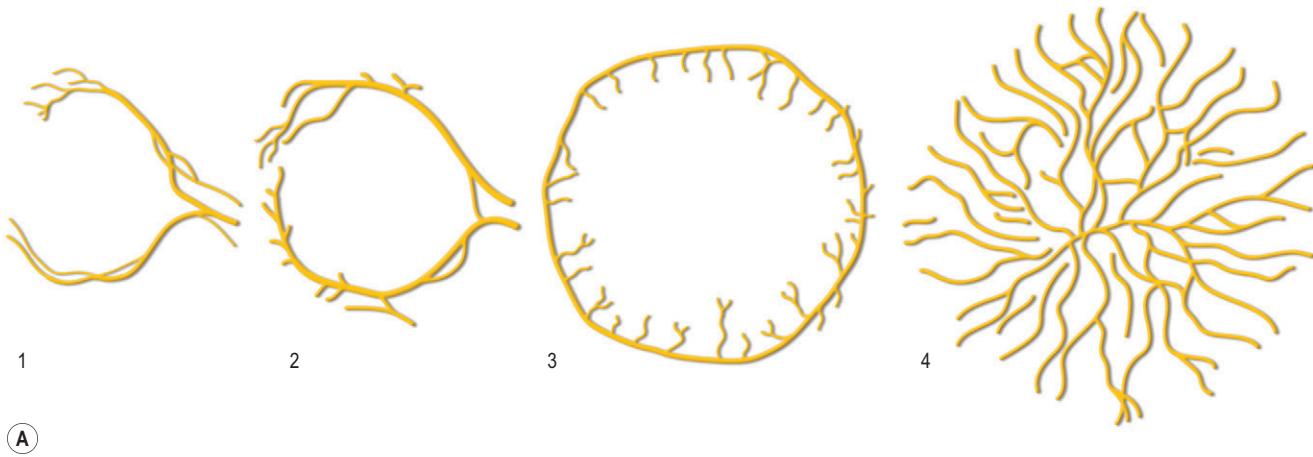

3. Functional characteristics of ocular sensory innervation

3.1 Trigeminal ganglion neurons

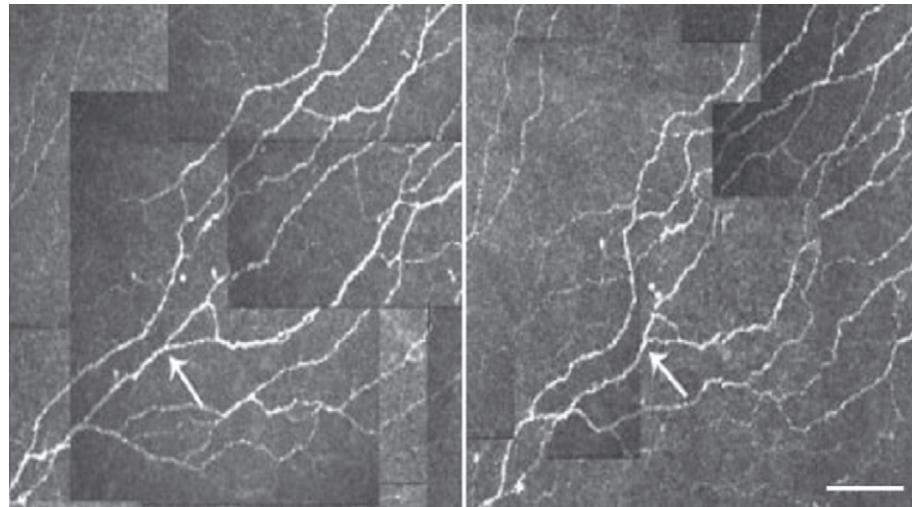

Electrophysiological studies of ocular sensory neurons have been centered mainly on extracellular recordings of the propagated impulse activity in the peripheral axons of trigeminal ganglion neurons, in most cases nerve fibers innervating the cornea and bulbar conjunctiva. Ocular sensory neurons innervating the cornea and uveal tissues possess in general thin myelinated (A δ) axons (conducting action potentials at velocities between 3–15 m/s) or unmyelinated (C) axons, which conduct at less than 2 m/s. A reduced number of neurons with thick myelinated axons (A β) provide innervation to the limbus, lids, and conjunctiva.

3.1.1 Sensory fibers of the cornea and conjunctiva

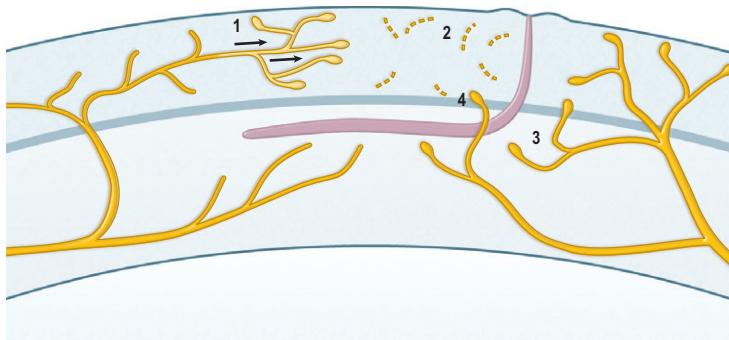

As in other parts of the body, the response levels of the peripheral endings of sensory axons to different modalities of physical and chemical stimuli have been used to

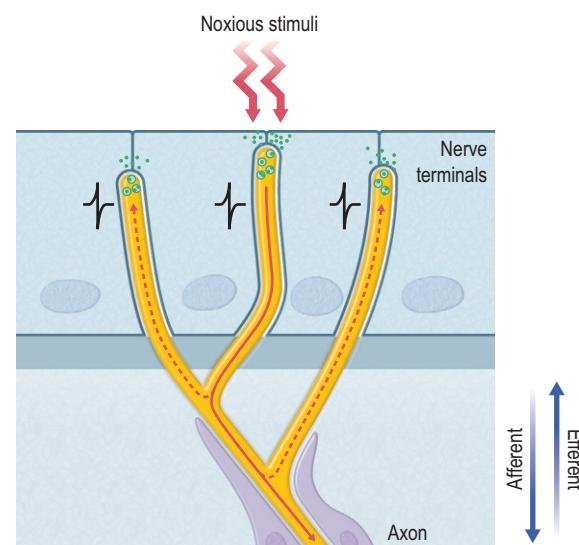

(A)

(B)

(C)

(D)

Figure 16.4 Development, remodeling and regeneration of corneal sensory nerves. (A) Schematic representation of corneal sensory nerve growth during development, in the chick cornea. Growing trigeminal sensory axons avoid the cornea and extend dorsally and ventrally (A1), forming a pericorneal nerve ring at E8 (A2). Upon completion of this ring, sensory nerves begin to enter the cornea radially, first innervating its periphery at E9–E10 (A3), and finally its entire surface at E15 (A4). (B) Continuous remodeling of nerves in the healthy cornea. In-vivo confocal microscopy images showing changes in human sub-basal nerve morphology occurring within a 2-week period. (C) Schematic representation of the changes taking place in corneal sensory axons following injury. Sprouts of intact nerves (1) invade the injured area while the distal end of axotomized fibers degenerate (2). Central stumps of lesioned nerves form neuroma endings (3) from which sprouts begin to invade the denervated area (4) initiating the recovery of corneal sensitivity. (D) Schematic representation of afferent and efferent functions of polymodal nociceptors. Stimulation of a section of the peripheral branches of a polymodal nociceptor fiber by a noxious substance directly depolarizes the nerve endings affected by the stimulus. This depolarization generates action potentials that travel centripetally (continuous arrow), and also cause the local release of neuropeptides (dots) contained in sensory nerve terminals, which contribute to local inflammation. Action potentials traveling centrally also antidromically invade (interrupted arrows) unstimulated neighboring branches. These then become depolarized and release neuropeptides in an area of the tissue that was not directly affected by the stimulus, thus extending inflammation ("neurogenic inflammation"). (B: From Patel & McGhee 2008;³³ Reproduced from Association for Research in Vision and Ophthalmology. C and D: Modified from Belmonte et al 2004b.³⁶)

distinguish various functional classes of sensory fibers innervating the various eye tissues (Fig. 16.5).

Polymodal nociceptors

About two-thirds of the sensory fibers innervating the cornea and the bulbar conjunctiva are activated by physical and chemical stimuli of intensity within the noxious or near noxious range, including mechanical forces, heat, intense cold, exogenous chemical irritants and a large variety of endogenous molecules released by tissue injury. Accordingly, they were named polymodal nociceptors (Figs 16.5 & 16.6).^{45–47} Most of them are unmyelinated while a small portion, depending on species, belongs to the group of thin myelinated (A δ) nerve fibers. Their receptive fields are round or oval, are usually large, often covering up to one-quarter or more of the cornea, and may extend several millimeters beyond the cornea onto the adjacent limbus and bulbar conjunctiva (Fig. 16.5). The large size and extensive overlapping of adjacent receptive fields of polymodal nociceptors, coupled with convergent mechanisms in the central nervous system, explain why stimuli of the corneal surface are poorly localized.

Corneal polymodal nociceptors respond to their natural stimuli with a continuous, irregular discharge of nerve impulses at a frequency roughly proportional to the magnitude of the stimulus, which persist as long as the stimulus is maintained, thus codifying its intensity and duration. Occasionally, the nerve impulse discharge overpasses the duration of the stimulus (post-discharge). All polymodal nociceptors respond to mechanical stimuli and to temperatures over 39–40°C (Fig. 16.6A:ii,iii). About half of the polymodal fibers in the cat also develop a low-frequency response with corneal temperature reductions below 29°C.^{45,47,48} Polymodal nociceptors are additionally excited by many chemical agents. Acidic solutions ($\text{pH} < 6.5$) (Fig. 16.6A:iv) or gas jets containing increasing concentrations of CO₂ (the carbonic acid formed at the corneal surface drops the local pH) evoke robust impulse discharges in corneal polymodal nociceptors.^{46–49} The sensitivity of polymodal nociceptors to acidic stimulation with CO₂ has been used for corneal esthesiometry. A large number of endogenous chemicals (inflammatory mediators) also activate polymodal nociceptors (see below). Expression of different membrane transduction molecules provides polymodal nociceptors with the ability to respond to stimuli of different quality. These include various members of the TRP ion channels superfamily: (a) TRPV1, gated by heat, protons, endogenous mediators and external chemical irritants; (b) TRPA1, that

responds to a large number of volatile irritant chemicals; (c) TRPV2 and TRPV3, which are excited by high temperatures. Additionally, polymodal neurons express ASIC channels, which respond to acid and endogenous mediators, while various types of stretch-activated, mechanosensory channels mediate the mechanical responsiveness (Fig. 16.5C).

Mechano-nociceptors

Around 15–20 percent of the nerve fibers innervating the cornea respond only to mechanical forces of near-noxious intensity. Accordingly, they were classified as mechano-nociceptors. All the axons of this class of receptor are thinly myelinated (A δ). The receptive fields are generally round and of medium size, covering about 10 percent of the corneal surface (Fig. 16.5). The force required to activate corneal mechano- and polymodal nociceptors (that is, their mechanical threshold) is around 0.6 mN – about 10 times lower than the force required to activate the equivalent fibers in the skin. This is possibly due to the proximity of corneal nerve terminals to the surface and to the absence of a keratinized surface epithelium in the cornea. Mechano-nociceptors fire only one or a few nerve impulses in response to brief or to sustained mechanical stimuli (Fig. 16.6A:i). Therefore, corneal mechano-nociceptors have a limited capacity to codify the intensity and duration of the stimulus and probably serve mainly to signal the presence of noxious mechanical stimuli (touching of the corneal surface, foreign bodies, etc.), presumably being responsible for the acute, sharp sensation of pain produced by sudden mechanical insults.

Cold thermal receptors

About 10–15 percent of corneal nerve fibers discharge spontaneously at the resting temperature of the corneal surface (around 33°C), and increase their firing rate when this temperature is decreased while they are transiently silenced upon warming.^{47,50,51} Cold receptor fibers have small receptive fields (around 1 mm diameter) located all over the corneal surface but more abundant in the peripheral areas (Fig. 16.5). Corneal cold-sensitive thermal receptors increase their firing rate as soon as the temperature of the cornea drops, which occurs, for example, during evaporation of the corneal surface tear film, application of cold solutions or blowing of cold air on the cornea. In mammals, corneal cold receptor fibers are able to detect small falls in temperature (0.1°C or less) and encode the final temperature in its static impulse frequency.⁴⁷ Small corneal temperature reductions are perceived as a sensation of innocuous cooling⁴⁸ with a variable

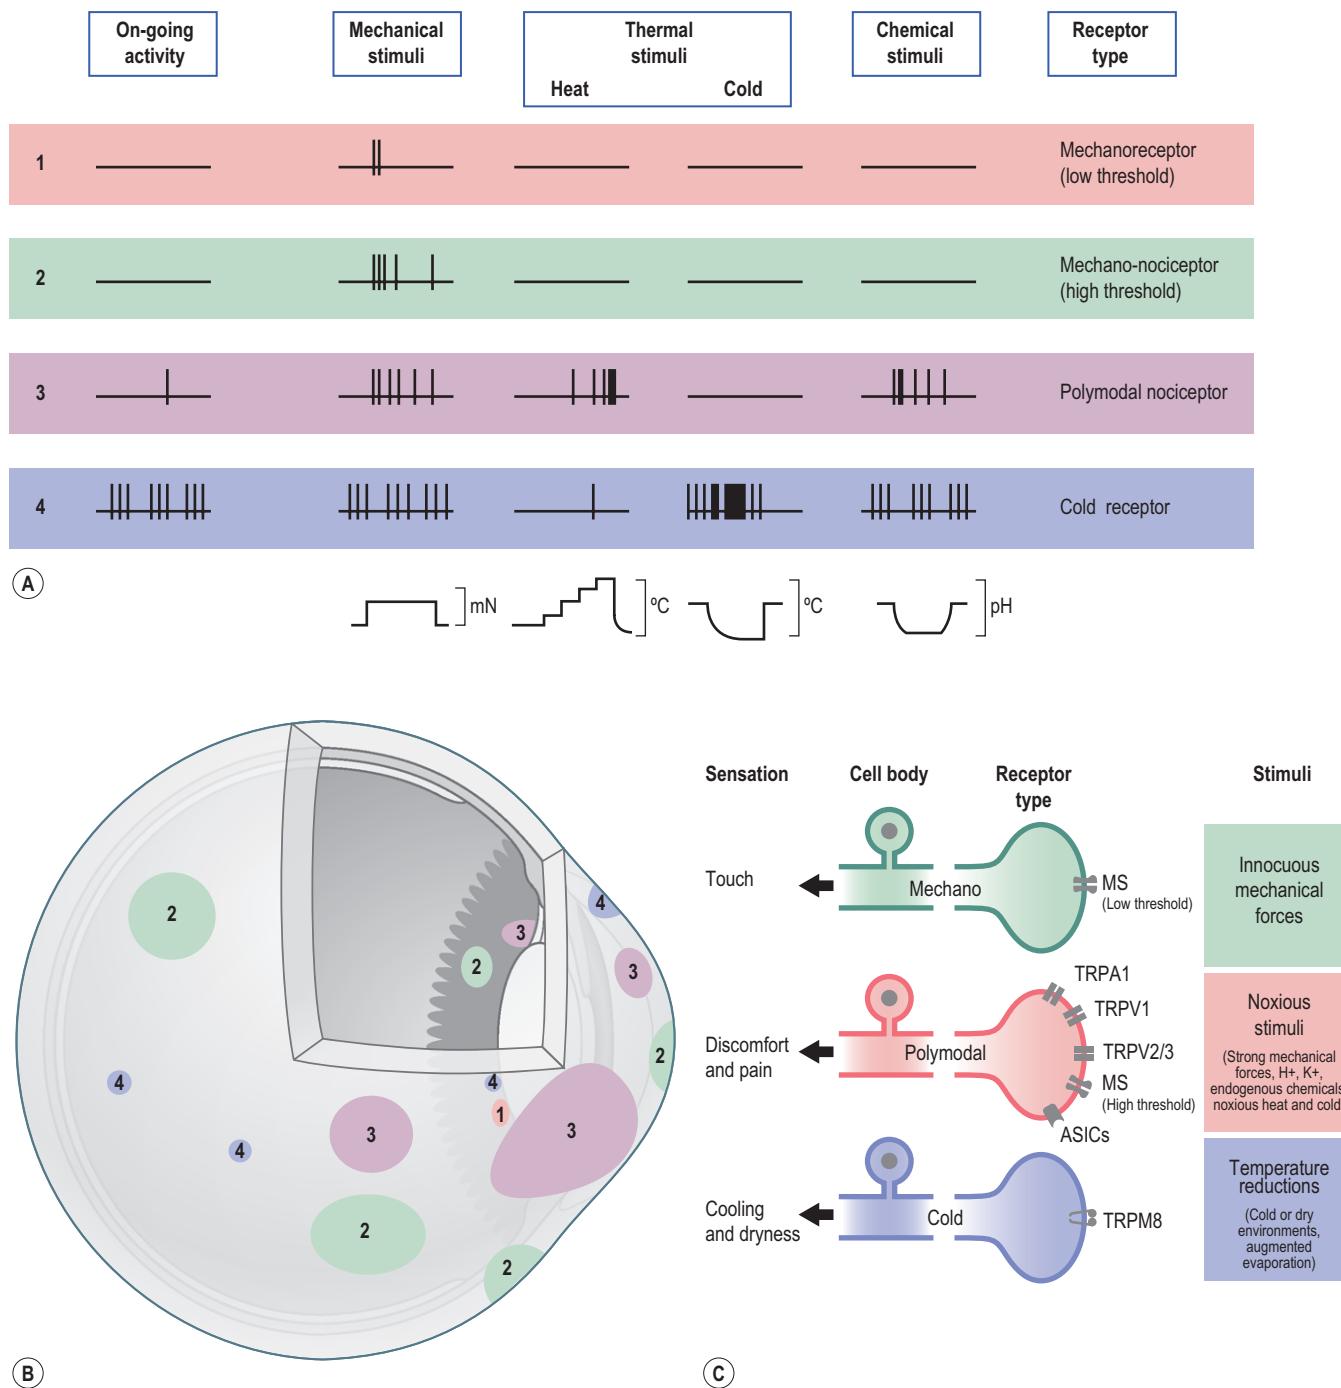

Figure 16.5 Functional characteristics of ocular sensory fibers. (A) The presence of ongoing activity at rest and impulse discharges in response to different stimuli are represented for each functional type of sensory receptor. (B) Diagram of the eyeball showing the distribution, size and location on the ocular surface, the ciliary body and the iris of the receptive field of mechanosensory, polymodal and cold sensory fibers innervating the eye. (C) Schematic representation of various modality-specific primary sensory neuron peripheral endings, and the putative membrane ion channels involved in the detection and transduction of the different stimuli. (A, B: Adapted from Belmonte et al 1997,² 2004a;⁴⁴ C: Adapted from Belmonte & Viana, 2008.¹⁴⁵)

irritative component. It is possible that corneal cold thermal receptors contribute to ocular dryness sensations when excessive evaporation reduces corneal temperature. Cold sensitivity of TG ocular neurons depends critically on the expression of TRP8 ion channels. Corneal cold receptors of TRPM8 null mice remain silent and do not respond to cooling. Basal tearing flow in these animals is reduced to half, while the tearing response to ocular surface irritation,

which is mediated by polymodal nociceptor stimulation, remains normal.⁵² This supports the interpretation that this type of fiber is involved in signaling dryness of the ocular surface and contributes to regulate basal tearing flow.

"Silent" nociceptors

The existence in the cornea of nociceptor fibers that are insensitive to all types of stimulus when the tissue is intact

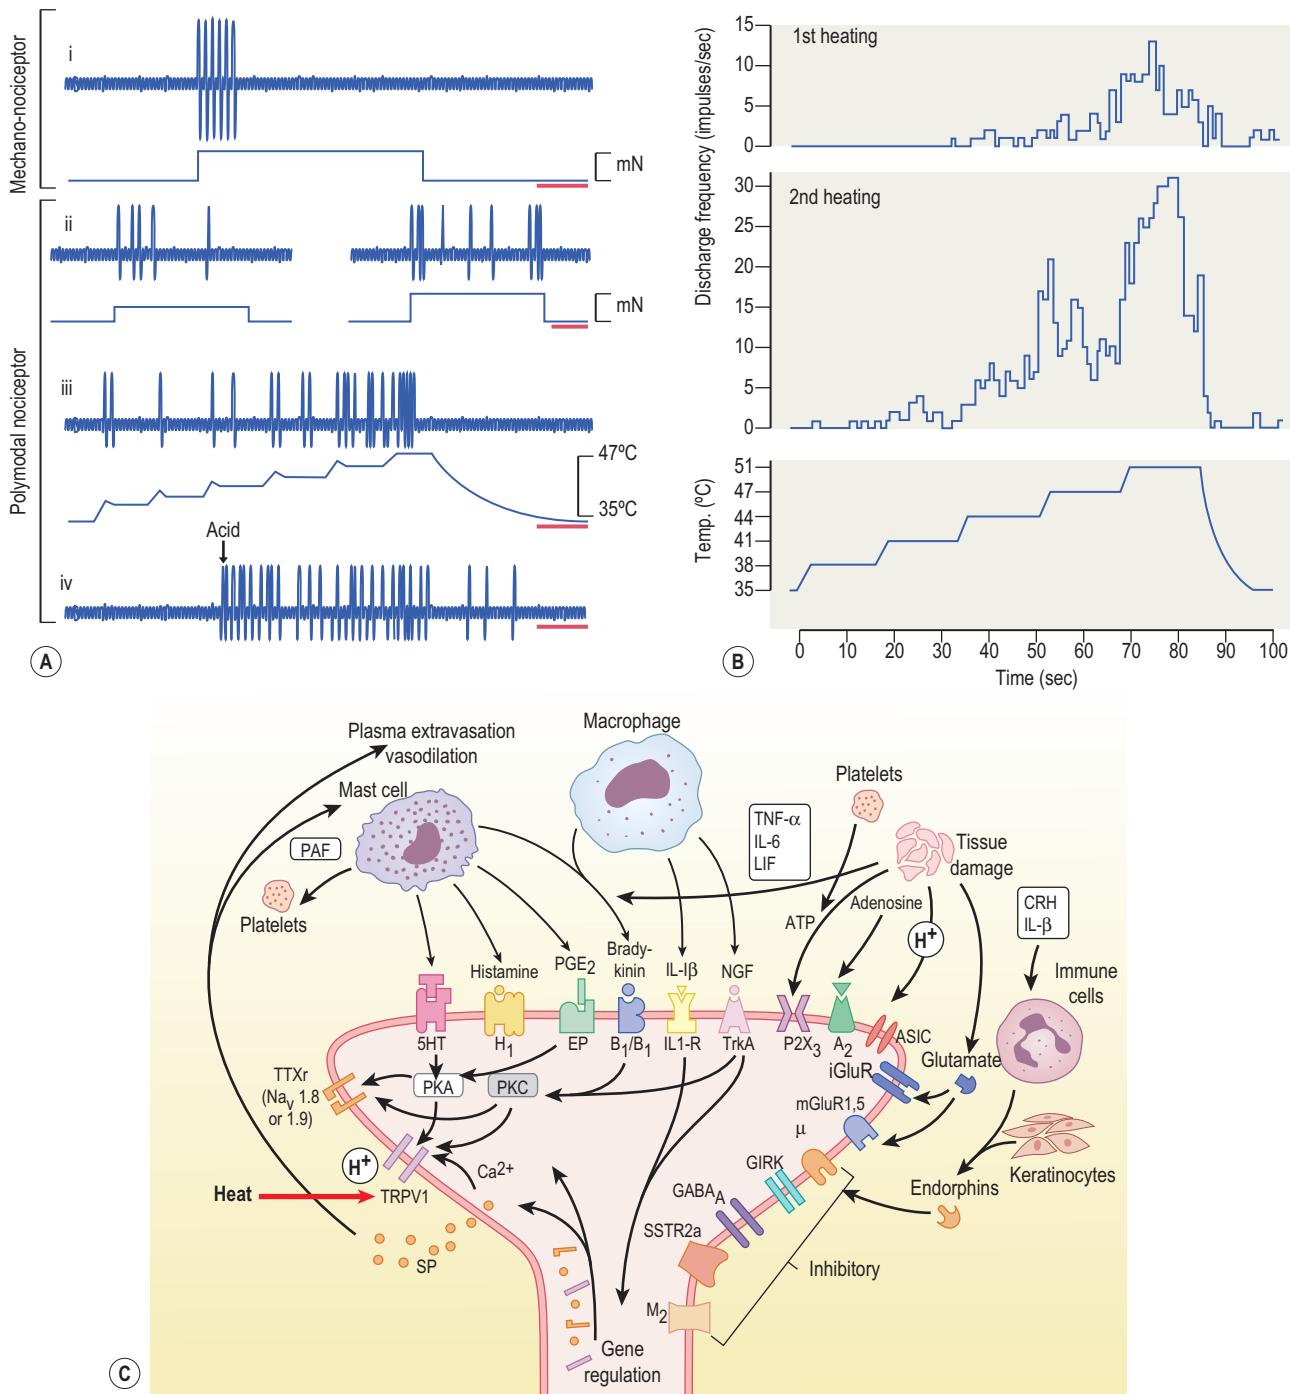

Figure 16.6 Response characteristics of corneal sensory fibers. **(A)** Effect of different types of stimuli on mechano- and polymodal nociceptors. (i) Transient (phasic) discharge evoked by a sustained mechanical indentation in a corneal mechano-nociceptor fiber. (ii) Response of a polymodal nociceptor fiber to mechanical indentations of increasing amplitude (80 and 150 µm). (iii) Activation of a polymodal nociceptor fiber by stepwise heating (from 35°C to 47°C) of the corneal surface. (iv) Response of a polymodal nociceptor fiber to application of a drop of 10 mM acetic acid (arrow) on the corneal receptive field. Upper traces depict nerve impulse recordings and lower traces the stimulus waveform. **(B)** Sensitization of corneal polymodal nociceptors. Frequency histograms of the impulse discharge evoked by two identical stepwise heating cycles of the corneal surface separated by a 3-min interval, showing the lowered threshold and enhanced impulse firing in response to the second heating cycle. **(C)** Receptor mechanisms underlying activation and sensitization of polymodal nociceptive afferents by inflammatory mediators released after tissue injury. In turn, neuropeptides released by activated nociceptors contribute to local inflammation (neurogenic inflammation). (A: From Belmonte & Gallar 2000;⁷⁸ B: Adapted from Belmonte & Giraldez 1981⁴⁵; C: Adapted from Black et al. 2004.¹⁴⁶)

but become excitable to mechanical, chemical, or thermal stimuli after a local inflammation develops ("silent" nociceptors)⁵³ was suggested by McIver & Tanelian.⁵⁴ Although experimental evidence for their presence in the cornea is indirect, silent nociceptors have been identified in many somatic tissues, particularly in humans – where they seem to play an important role in inflammatory pain. Therefore it is conceivable that they also exist in the cornea.

3.1.2 Sensory fibers of the sclera, iris, and ciliary body

Although the functional properties of sensory nerve fibers innervating the conjunctiva and the sclera have not been studied in great detail, the same main functional classes of sensory afferents as in the cornea, i.e. polymodal nociceptors, mechano-nociceptors, and cold receptors, have been identified in the sclera,^{47,55,56} iris and ciliary body,^{10,56,57} and the bulbar conjunctiva^{45,58} (Fig. 16.5). Mechanosensitive and polymodal nociceptor fibers of the sclera, uvea, and cornea are readily activated by externally applied pressure but only transiently by sudden increases of intraocular pressure up to 100 mmHg,⁵⁶ which explains the absence of pain in most forms of glaucoma. However, combination of high intraocular pressure with inflammation, as occurs in congestive glaucoma, possibly causes nociceptor sensitization and a more sustained nociceptive inflow from ocular polymodal nociceptors to the brain, producing the intense pain characteristic for this disease (see below). On the other hand, a small number of low threshold, myelinated mechanosensory nerve fibers responding to moderate changes of intraocular pressure have been identified functionally. They may correspond to axons of the encapsulated nerve endings found in the chamber angle and scleral spur and may be associated with neural regulation of the intraocular pressure.^{59,60}

Cold-sensitive nerve fibers with response properties similar to thermal receptors present in the cornea and conjunctiva are also found in the iris and in the posterior sclera. Cold receptor endings in these locations are not exposed to environmental temperature changes but are close to blood vessels and may serve to detect choroidal and retinal blood flow changes, thus contributing to reflex blood flow regulation rather than to the production of conscious thermal sensations or tearing regulation.⁵⁵

3.1.3 Ocular trigeminal ganglion neurons

The cell bodies of TG neurons innervating the eye are heterogeneous not only in their expression of different transducing channels and their conduction velocity but also in their passive and active membrane properties, thus presenting different impulse firing characteristics. When recorded intracellularly, corneal mechanosensory neurons associated to thin myelinated fibers exhibit fast and short-lasting action potentials, possibly due to the expression of tetrodotoxin-sensitive Na⁺ channels, while A_δ and C polymodal nociceptive neurons are rich in tetrodotoxin-resistant Na⁺ channels and present slower and longer action potentials. Finally, a small population of neurons with a high excitability and very high input resistance has been identified as cold-sensitive neurons.⁶¹

3.2 Central pathways

Most ocular neurons found in the trigeminal subnucleus caudalis are mechanoreceptive neurons responding only to

noxious ocular stimulation or to stimulation of the cornea and periocular skin.⁶² A modality-specific distribution of corneal neurons within the trigeminal complex has been proposed. Neurons of the interpolaris and caudalis subnuclei responded to all modalities of stimuli while those within the superficial laminae of the subnucleus caudalis and the cervical cord transition responded only to heat and chemical irritation, suggesting that the input to this region is restricted to TG polymodal nociceptor neurons.^{24,63}

Second-order ocular neurons project to the thalamus and brainstem regions as the superior salivatory or facial motor nucleus – depending on their peripheral input.^{25–27} They participate in several trigeminal-evoked blink reflexes, like the corneal blink reflex, in which corneal afferent information projects to orbicularis oculi motor neurons responsible for lid closing.⁶⁴ Likewise, a population of neurons specifically inhibited by wetting and excited by drying of the ocular surface may be involved in reflex tearing and fluid homeostasis of the ocular surface.²⁷ We can speculate that these neurons receive at least part of their input from peripheral cold fibers innervating eye surface tissues.

Ocular neurons with large receptive fields have been identified in SII areas, where a systematic representation of the face including the eye, and the rest of the body has also been described.^{65,66} Cortical processing of ocular sensory information is sustained by reciprocal interactions between cortical and thalamic areas, and also by a direct modulation of the pre-thalamic relays. So, processing of nociceptive input at the ocular neurons of the TBNC is modified by activation of descending pathways from the pontine parabrachial area and the nucleus raphe magnus mediated by GABA(A) receptors.^{24,67}

4. Inflammation and injury effects on ocular sensory neurons

4.1 Local inflammation

A key role of ocular sensory nerves is protection of the eye against injuring or potentially injuring forces acting on the eye. Accordingly, impulse firing in ocular nociceptors evoked by the direct action of such forces leads to immediate pain and aversive motor responses. As well as this immediate effect, tissue damage also produces a slower increase in the excitability of corneal, scleral, and uveal nociceptor endings. This phenomenon is called "sensitization" and is a general property of polymodal nociceptors in all superficial and deep tissues of the body, including the eye.^{68,69} It is manifested by a long-lasting, irregular, low-frequency firing that reappears seconds after the impulse discharge directly caused by the stimulus has subsided, and persist for minutes in the absence of new stimulation.⁴⁵ This ongoing discharge is accompanied by an enhanced responsiveness and a lowered threshold to new non-noxious and noxious stimuli (Fig. 16.6B).^{10,45,47}

Sensitization of ocular nociceptor fibers explains the presence of spontaneous pain after injury or inflammation of the eye (due to the development of ongoing activity) and the "tenderness" of damaged tissues to non-noxious (allodynia) and noxious stimuli (hyperalgesia). Sensitization of ocular nociceptors is the consequence of the action on nerve endings of a large variety of inflammatory mediators

(including H⁺ and K⁺ ions, adenosine and ATP, serotonin, histamine, platelet-activating factor, bradykinin, prostaglandins, leukotrienes, thromboxanes, interleukins, tumor-necrosis factor, NGF, among others) that are released locally by damaged cells and by resident and invasive cells of the immune system attracted to the injured area.⁷⁰ These mediators act on a variety of membrane receptor proteins at the ocular nociceptor nerve endings. Several ion channels present in the membrane of polymodal nociceptor endings as TRPV1 and TRPA1 are activated by many of these inflammatory mediators, thus enhancing ion flow, which causes the increased membrane excitability, augmented impulse firing frequency and reduced threshold that characterize sensitization of injured ocular nerve terminals (Fig. 16.6C).

These effects on membrane ion channel activity are exerted either directly or through different signaling pathways. Membrane receptors for prostaglandin E2, ATP, adenosine, and 5-HT ultimately activate the protein kinase A (PKA) signaling pathway, whereas receptors for other mediators such as bradykinin act on protein kinase C (PKC) to induce sensitization. Inflammatory mediators are also responsible for the local inflammatory reaction (vasodilatation, plasma extravasation, and cell migration). Drugs known to interfere with the formation and/or release of inflammatory agents, such as the non-steroidal anti-inflammatory drugs (NSAIDs) that inhibit the production of prostaglandins, not only decrease local inflammation but also reduce sensitization of ocular nociceptors.^{71,72} This explains the analgesic effect exerted by these drugs on post-surgical ocular pain.^{73,74}

Sensitization of corneal nociceptors develops within minutes of acute corneal injury and normally persists as long as the inflammation remains. During long-lasting inflammatory processes, as in chronic dry eye, more permanent changes take place in the cell bodies and peripheral terminals of nociceptor neurons, including a modified expression of membrane receptors and ion channels present in both structures, possibly induced by growth factors, in particular NGF (Box 16.2).^{75,76}

In addition to signaling damage, ocular nerves also contribute to the local vascular and cellular response to injury. Nerve impulses evoked by noxious stimuli in nociceptors not only travel centripetally through the axon to the central nervous system but also antidromically invade the non-stimulated peripheral branches of the axon^{51,77} (see Fig. 16.4D). This evokes the release of several neuropeptides contained in its peripheral endings.^{44,78} Neuropeptides CGRP

and SP are found in most trigeminal neurons and their terminals. When released by depolarized nociceptor endings, CGRP and SP contribute to the local inflammatory response inducing vasodilatation, plasma extravasation, and cytokine release, thus amplifying the inflammatory effect of the endogenous mediators. This “neurogenic inflammation” caused by sensory nerves affects both the injured and the non-injured areas innervated by branches of the affected nerves, which may explain the extension of inflammation to distant, intact tissues (conjunctiva, iris, ciliary body, etc.) following a limited corneal lesion.⁴⁴

Second-order neurons responsive to stimulation of the ocular surface at the trigeminal subnucleus interpolaris/caudalis transition and subnucleus caudalis/cervical cord junction also exhibit increased responses to chemical stimulation of the ocular surface days after development of an experimental uveitis, reflecting an alteration of the properties of second-order neurons following sustained and recurrent peripheral inflammation.⁷⁹ This “central sensitization” contributes to the hyperalgesia shown by inflamed tissues.

4.2 Nerve injury

Several circumstances – such as ocular surgery, accidental trauma and certain ocular or systemic diseases – cause damage of ocular sensory nerves at different points in their trajectory. As previously noted, lesion of the peripheral axons of ocular neurons substantially changes the morphology and functional properties of nerve fibers projecting to the eye, in particular to the cornea, where denervated areas are invaded by outgrowths of adjacent, non-injured nerve fibers and by sprouts of the injured axons, which are sometimes entrapped by scar tissue and form microneuromas.⁸⁰ Morphological alterations in peripheral axons are accompanied by functional disturbances in the cell body of primary sensory neurons. Expression of transcription factors and neuropeptides and of genes that encode ion channel and receptor proteins is altered to a variable degree depending on the location and extension of nerve damage.⁸¹ In particular, Na and K channels are overexpressed.^{82,83} As a consequence, during axonal regeneration nerve excitability of the neuroma endings formed by damaged neurons is disturbed, leading to ectopic discharges⁸⁴ and abnormal responsiveness to natural stimuli.⁸⁵ This impaired activity is the origin of peripheral neuropathic pain.^{82,86} Such functional alterations have been reported in axotomized corneal neurons at different times after lesion. Polymodal nociceptors^{87,88} and corneal cold-sensitive nerve terminals exhibit an increase in spontaneous and stimulus-evoked activity weeks after injury, presumably due to an enhanced expression of tetrodotoxin-resistant Na channels.⁸⁹

5. Trophic effects of ocular sensory nerves

As well as their role in signaling external or internal stimuli, ocular sensory nerves play an important role in the trophic maintenance of their innervated tissues. This effect is particularly prominent in the cornea.

Impairment of corneal sensory innervation causes a number of functional disturbances and development of epithelial defects and recurrent ulcers (neurotrophic keratitis).

Box 16.2 Ocular nociceptive nerve fibers

Sensitization of nociceptive nerve fibers innervating the eye is the basis of persistent pain developed after ocular injury or inflammation. It also accounts for the development of allodynia (pain sensations evoked by non-noxious stimuli) and primary hyperalgesia (enhanced pain evoked by noxious stimulation) in the inflamed eye. It explains for instance the development of sustained pain after the iris has been touched accidentally during ocular surgery or after argon laser pulse application to the posterior uvea, and is possibly also the reason for the intense sustained ocular pain experienced in congestive glaucoma, in which uveal inflammation developed during congestion probably induces sensitization of nociceptors, increasing their excitability.

Table 16.1 Causes of reduced or enhanced corneal sensitivity

Reduced sensitivity	
Genetic diseases	<ul style="list-style-type: none"> Familial corneal hypoesthesia Congenital corneal anesthesia (CCA) CCA associated with trigeminal hypoesthesia and neurological disorders (Moebius syndrome; hereditary sensory and autonomic neuropathies type III – Riley-Day syndrome, IV, or V – congenital insensitivity to pain, cerebellar ataxia, etc.) CCA associated with somatic disorders (Goldenhar–Gorlin syndrome or oculo-auriculo-vertebral dysplasia, ectodermal dysplasia, etc.) CCA associated with multiple endocrine neoplasia 2b (prominent corneal nerves) CCA associated with other genetic ocular alterations (corneal dystrophies, epithelial basement dystrophy, microsomia, etc.)

Diseases of the ocular surface	<ul style="list-style-type: none"> Dry eye with conjunctival or corneal epithelial lesions (sensitivity to air conditioning, contact lenses, cigarette smoke, etc.) or unstable tear fluid (lid function, pinguecula, stiches) Recurrent erosion or map-dot-fingerprint corneal dystrophy, exposure to toxic chemicals
Acute or chronic inflammation of the ocular surface	<ul style="list-style-type: none"> Inflammatory dry eye in Sjögren's syndrome, rheumatoid arthritis, graft-versus-host disease Conjunctivalization of the cornea, pterygium Post-refractive surgery pain (occasionally) Acute Acanthamoeba infection Corneal ulcers and inflammations (acute stage)

Adapted from Belmonte & Tervo 2006.¹²²

Corneas with reduced sensitivity resulting from ocular or systemic conditions affecting its nerves (Table 16.1) show altered healing capabilities,^{4,90–94} increased epithelial permeability,⁹⁵ punctate staining following instillation of fluorescein or Rose-Bengal, poor healing of corneal ulcers and reduced transparency. Epithelial micro-defects present in patients with decreased corneal sensitivity expressive of an altered innervation may be seen in the cornea or the conjunctiva, usually in the areas not covered by the lids and therefore continuously exposed to environmental changes.

As mentioned above, corneal sensory nerves release neuropeptides, in particular SP and CGRP, that either alone or

in combination with other growth factors present in the cornea (e.g. insulin-like growth factor, epidermal growth factor, NGF, etc.) appear to be important agents in maintaining corneal epithelial integrity and promoting wound healing in the normal cornea.^{91,96–100} On the other hand, ocular tissues produce several growth factors necessary for the development, remodeling, and regeneration of corneal nerves. Tissue-derived growth factors, such as glial cell line-derived neurotrophic factors (GDNF), brain-derived neurotrophic factor (BDNF), opioid growth factor (OGF), ciliary neurotrophic factor (CNTF), pigment epithelium-derived factor (PEDF), and neurotrophins such as nerve growth

Box 16.3 Symbiosis between ocular tissues and sensory neurons

Ocular tissues and their sensory nerves maintain a symbiotic, dynamic interdependence. Sensory neurons innervating the eye exert a well-known trophic effect on target ocular structures. Long-standing clinical observations show that accidental or surgical lesion of the trigeminal nerve leads to the appearance of severe lesions in the cornea (keratitis neuroparalytica). Conversely, ocular tissues strongly contribute to the development, remodeling, and survival of their sensory and autonomic innervations.

factor (NGF), neurotrophin-3 and -4 (NT-3, NT-4), have been found in the cornea and possibly participate in the maintenance of corneal innervation (Box 16.3).^{4,91,101–103}

6. Sensations arising from the eye

6.1 Techniques for testing ocular surface sensitivity

Traditionally, clinical exploration of corneal or conjunctival sensitivity to mechanical stimulation has been performed by gentle touching of the ocular surface with a wisp of cotton, asking the subject about the sensation experienced or observing the evoked blink reflex. A more quantitative approach was obtained using modified von Frey filaments which are employed to explore cutaneous mechanosensitivity. These are nylon threads of fixed diameter and variable length, whose tip is pressed against the skin until they start to bend. At this moment, the force per surface unit exerted by the filament is constant and proportional to its length. The Cochet–Bonnet esthesiometer, composed of a filament of adjustable length,¹⁰⁴ is the best-known instrument based on this principle and has been widely used to explore mechanical sensitivity of the cornea in normal and pathological conditions.

To prevent the risk of tissue injury associated with contact esthesiometry, particularly in hypoesthetic corneas, non-contact esthesiometers that use an air jet to apply controlled mechanical forces on the cornea have been developed.^{105,106} The Belmonte esthesiometer¹⁰⁷ is a non-contact gas esthesiometer that allows evaluation of the mechanical, and also thermal and chemical, sensitivity of the eye surface. It uses a gas jet of adjustable flow to apply a controlled pressure (over or below mechanical sensitivity threshold) on any point of the ocular surface. The temperature of the air jet can be adjusted, thus allowing cold or hot thermal stimulation. Finally, when air in the gas jet is mixed with CO₂ at variable concentrations, CO₂ combines with water at the ocular surface and forms carbonic acid, thus decreasing local pH proportionally to the CO₂ concentration and causing a chemical stimulation.^{40,107} Gas esthesiometry has been used in recent years to define normal values of corneal and conjunctival mechanical, thermal, and chemical sensitivity in relation to age, sex, pregnancy, iris color, and use of contact lenses, and also to assess sensitivity changes associated with surgery, ocular surface pathologies such as herpes virus infections, dry eye, keratitis, iritis, uveitis and glaucoma, or systemic diseases like fibromyalgia or diabetes.^{40,41,108–110}

6.2. Psychophysics of corneal and conjunctival sensations

Classical psychophysical studies applying crude mechanical and thermal stimulation to the cornea concluded that pain is the only sensory modality that can be evoked from this tissue, although some authors proposed that specific sensations of touch, heat, cold, and pain were evoked when more selective corneal stimulation was used.^{111–115} During the past decade, application of controlled stimuli of different types to the cornea with the Belmonte esthesiometer evidenced that mechanical, acidic, and thermal stimulation each evoked sensations of different quality, allowing the subject to identify the mode of stimulus applied.⁴⁸ Moreover, electrophysiological recordings of impulse activity in nerve fibers of the cornea and conjunctiva of the cat stimulated with the Belmonte esthesiometer showed that different types of stimuli evoked variable degrees of response from the different functional types of sensory receptors. Therefore, the distinct quality of the conscious sensations evoked by stimulus of the cornea or conjunctiva appears to be primarily determined by variable recruitment of the mechano-nociceptors, polymodal nociceptors, and cold receptors innervating these structures.⁴⁸ Sensations produced in healthy human subjects by corneal stimulation with mechanical forces, heat, or acid in all cases include a component of irritation, possibly because polymodal nociceptors were always evoked by these stimuli.^{48,116} In contrast, application of moderate cold stimuli evoked almost exclusively a non-noxious cooling sensation that became irritating only when more pronounced temperature reductions were applied (Fig. 16.7).^{48,114,116} In the conjunctiva, sensitivity is comparatively lower than in the cornea; also, low-intensity mechanical stimuli are felt as non-irritating.^{41,116–118}

6.3 Sensitivity of the injured cornea

In a number of pathological conditions affecting the ocular surface (Table 16.1) or after surgical procedures for retinal detachment, cataract removal and glaucoma, and particularly following corneal surgery (radial keratotomy, PRK, LASIK, keratoplasty, etc.), sensory nerves directed to the cornea become damaged at a level determined by the location and extent of wounding. Injured corneal nerves start to regenerate soon after injury, possibly stimulated by an enhanced local production of NGF, but successful recovery is only partially attained and corneal nerves remain disorganized and significantly reduced in number for months and even years after surgery (Fig. 16.8).⁹⁰ In parallel with morphological disturbances, severed nerves in healing corneas experience functional alterations evidenced by an altered threshold and an abnormal responsiveness to mechanical and chemical stimuli applied to the wounded area (Box 16.4).⁸⁹

As a result of a nerve lesion during ocular surgery, corneal sensitivity to mechanical stimulation is altered, with a remarkable increase in threshold of the denervated areas that takes months to recover and may never return to normal values.^{119–122} Transplanted corneas or implanted lenticles in epikeratophakia remain totally anesthetic for years, or recover at best a very limited mechanical sensitivity usually restricted to the periphery of the implant. After LASIK surgery, corneal sensitivity to mechanical and chemical stimulation measured

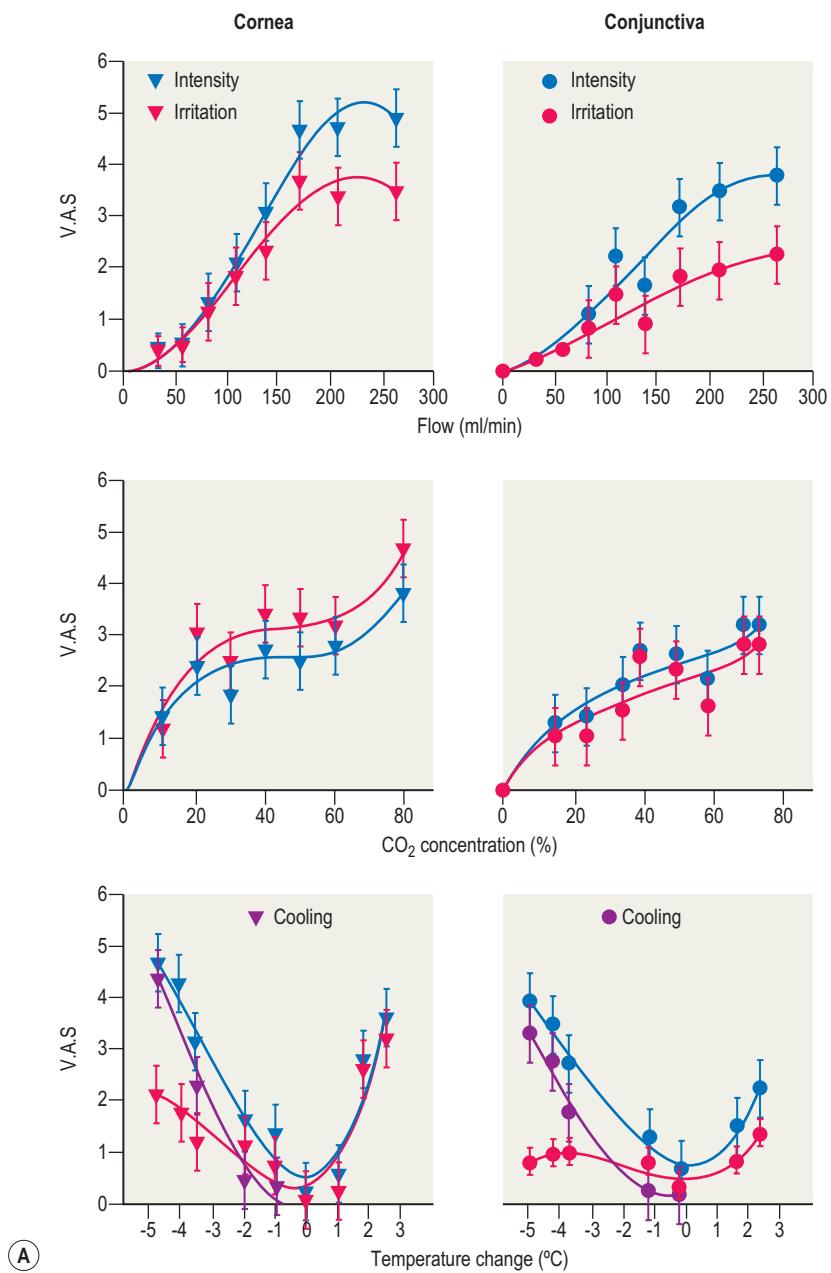

Figure 16.7 Sensations evoked by selective stimulation of the cornea and conjunctiva. **(A)** Subjective score given to the intensity and the irritation components of the sensation evoked by selective mechanical, chemical, and thermal stimuli on the cornea (triangles) and the conjunctiva (circles) with the Belmonte esthesiometer. Sensation parameters are expressed in arbitrary units marked on a visual analog scale (VAS) ranging from 0 (no sensation) to 10 (maximal value of the parameter). For thermal stimulation, VAS scores for the cooling component of the sensation have also been represented. **(B)** Thermographic images recorded during application of a gas pulse at neutral temperature for selective mechanical stimulation (left) and at 29°C (right) for cold stimulation of the cornea. (A: From Acosta et al 2001b;¹¹⁶ Reproduced from Association for Research in Vision and Ophthalmology. B: From Acosta, MC 1999, Ph.D. Dissertation, Universidad Miguel Hernández de Elche, Spain.)

(B)

with the Belmonte esthesiometer is markedly impaired and normal sensitivity is recovered only 2 years later.¹²¹ In addition to the reduced sensitivity (hypoesthesia), spontaneous pain sensations and abnormal sensations (dysesthesias), in particular dryness, appear in a significant number of patients. It has been proposed that these are the result of the activation of non-injured corneal nerve endings by the modest

reduction of tear production, stability and clearance rate reported after photorefractive surgery.^{123,124} Alternatively, abnormal firing originating from injured corneal nerve fibers may be read erroneously as ocular dryness by the brain, similar to the ectopic activity in the sensory nerve stump of amputated body extremities that is interpreted as aberrant sensations from the lost limb ("phantom limb") (Fig. 16.9).¹²⁵

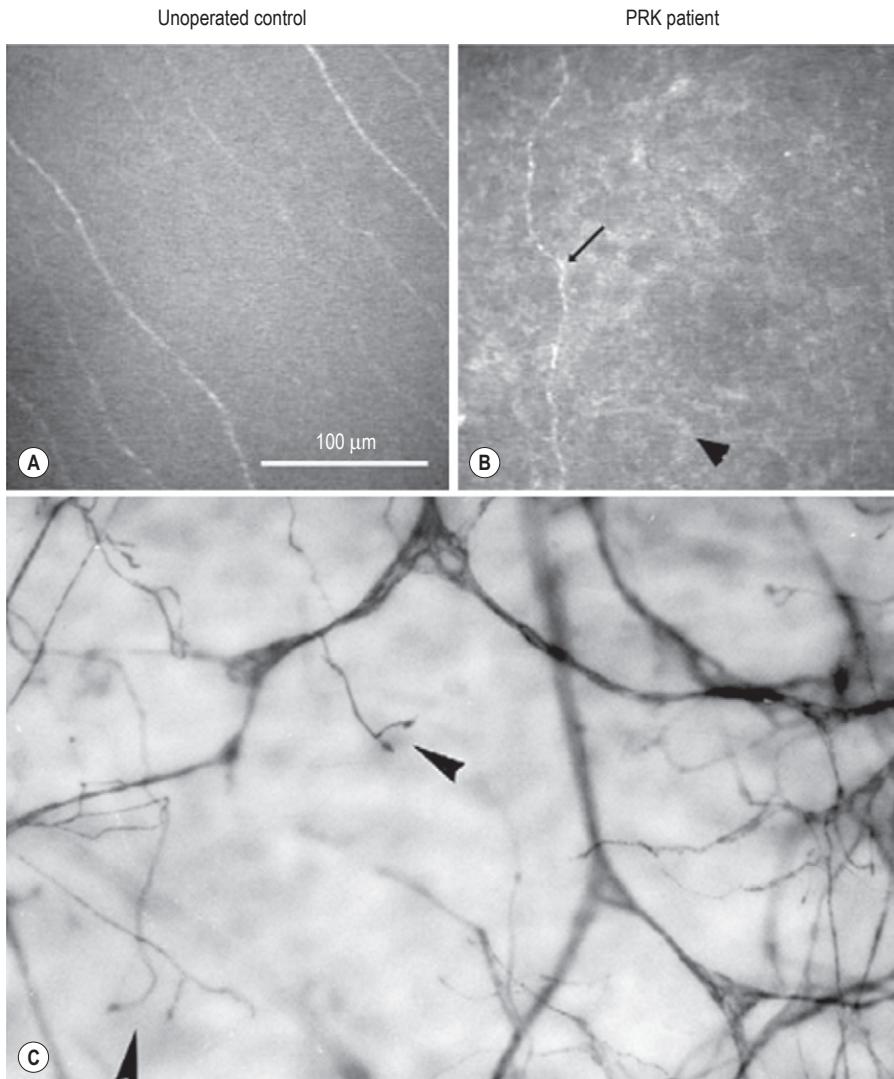

Figure 16.8 Disturbances of corneal innervation following refractive surgery. (A), (B) In-vivo confocal microscopy images of human corneal nerves. (A) Sub-basal leashes in an intact cornea (B). Appearance of a sub-basal nerve fiber (arrow) 3 years after PRK, to illustrate incomplete nerve recovery and the persistence of haze signs (arrowhead). (C) Regenerating stromal nerve fibers in the rabbit cornea after PRK. Acetylcholinesterase-stained corneal nerves 1 month after surgery, showing abundant regenerating leashes, sometimes with "growth cone-like" endings (arrowheads). (A: Adapted from Müller et al 2003;⁴ B: From Tervo & Moilanen, 2003.³⁰)

Box 16.4 Alternations of ocular sensitivity

Until recently, most alterations of ocular sensitivity were associated with ocular inflammatory processes (that cause hypersensitivity, sustained pain, itching, etc.) or were the consequence of surgical procedures directed to preserve or recover vision (such as keratoplasty, cataract removal, vitreoretinal surgery, etc., usually producing ocular hypoesthesia). Nowadays, reduced sensitivity and in particular dysesthesias (abnormal sensations) are increasingly associated with lifestyle (pollution, air conditioning, etc.) and the growing number of ocular interventions, in particular corneal refractive surgery.

7. Ocular pain

Several ocular and neurological conditions produce pain in or around the eye.¹²⁶ Based upon the source, ocular pain can be classified as: superficial pain, deep ocular or orbital pain, and pain sensed in the eye but originated at processes in other tissues (referred pain). Ocular pain is due to conditions of diverse etiology and is often an extension of head and face pain, although complete ocular examination (Table 16.2)

Table 16.2 Complete ocular examination in ocular pain

- Visual acuity (best-corrected)
- Slit lamp examination (conjunctiva, episclera, sclera and cornea: dry eye, punctate keratitis, abrasions, etc.; anterior chamber and iris)
- Assessment of dry eye (Schirmer test, lissamine green, osmolality, tear film evaluation)
- Pupil analysis (size, reactivity, reflexes)
- External exam of the lids (erythema, ptosis, lag, retraction, etc.), periorbital skin (rashes, sores, etc.) and lacrimal glands, including palpation (focal tenderness, presence of masses, etc.), checking of preauricular lymphatic ganglia, and transillumination of maxillary and frontal sinuses
- Ocular asymmetries
- Relative position of the lids, cornea, and pupil
- Exophthalmometry (proptosis, exophthalmos)
- Ocular motility examination
- Functional examination of trigeminal system, including face (response to periorbital cutaneous pinprick) and corneal sensitivity (esthesiometry)
- Intraocular pressure measurement
- Ophthalmoscopy examination
- In-vivo confocal microscopy

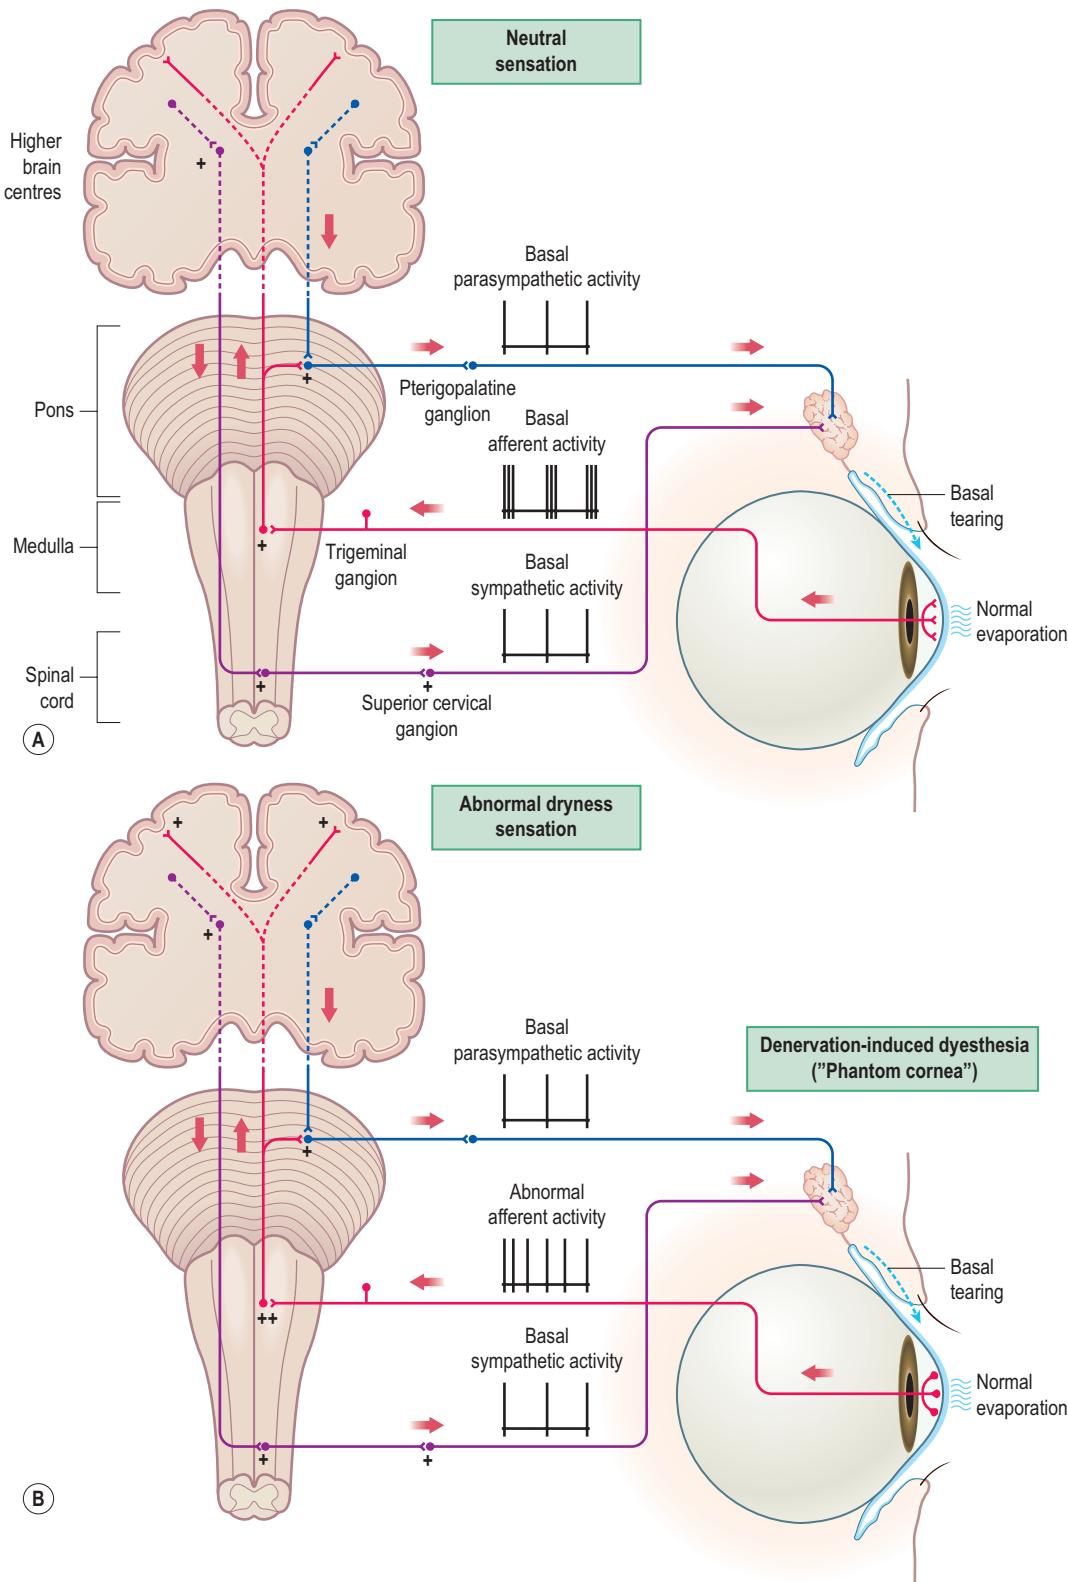

Figure 16.9 Corneal sensation and tear secretion before and after photorefractive surgery. Schematic representation of the mechanisms involved in ocular sensation and lacrimal secretion. **(A)** Basal tearing is maintained by low-frequency impulse activity of corneal sensory nerves. This activates efferent parasympathetic, and perhaps also sympathetic, pathways in the central nervous system stimulating basal tear secretion. However, basal sensory activity is too low to produce conscious sensations of ocular dryness. **(B)** When corneal nerves are surgically injured, severed axons generate ectopic impulse discharges that reach the brain and evoke abnormal dryness sensations despite the normal tear production. (Adapted from Belmonte 2007.¹²⁵)

should always be performed to define or exclude the real ocular origin of the eye pain experienced by the patient.¹²²

7.1 Superficial ocular pain

Superficial pain, i.e. pain originated at the ocular surface, is a complex sensation usually caused by infectious or inflammatory conditions such as corneal ulcers and conjunctivitis, and also to systemic diseases affecting connective tissue, such as rheumatoid arthritis, systemic lupus erythematosus (LED), Sjögren's syndrome, or sarcoidosis, and some heavy metal intoxications.^{127,128} Superficial ocular pain is often felt as foreign body sensation, and presents a prominent itching component in allergic inflammation and chronic blepharitis. This pain results presumably from the direct effect of local inflammation on peripheral endings in episclera or sclera (episcleritis or scleritis, respectively) causing an ipsilateral intense pain that can be triggered by pressing the area involved. Very intense pain is experienced during bacterial infections producing corneal ulcers (Acanthamoeba keratitis), in which corneal nerves are thickened probably due to inflammation, as well as 12–24 hours after photorefractive keratectomy (PRK).⁹⁰ As corneal nerve endings become easily stimulated at the areas not covered by an intact epithelium, the intense pain present in these conditions diminishes or stops when the epithelial defect is healed or covered with a therapeutic contact lens. Nevertheless, during some corneal stromal inflammations, such as stromal herpes virus keratitis, the eye may remain painful even in the presence of an intact epithelium, probably due to the abnormal activity in corneal sensory neurons affected by the virus infection (Box 16.5).

The section of a part of the ocular sensory nerves during orbital or ocular surgery causes hypoesthesia but spontaneous acute and chronic pain sensations may also appear. This problem has become more prominent in recent years with the extended use of surgical procedures on the cornea for correction of refractive errors (radial keratotomy, PRK, LASIK). In PRK, pain usually begins 15–60 min after surgery (when the local anesthetic drops have lost their effect) and becomes maximal within 3–6 hours. It is relieved after the first night but may persist as a moderate or low discomfort sensation for at least one week.¹²⁹ Such acute pain is presumably due to sensitization of nerves innervating the injured tissue. Pain of lower intensity may also be present for 1–3 days following LASIK.¹³⁰ It is worth noting that long-lasting symptoms after LASIK or PRK, including sharp pain, eye soreness, or dryness sensations, are found in 10–40 percent of these patients.^{130,131} This is significantly more common, severe and prolonged after PRK. However, anti-inflammatory medication with NSAIDs, steroids, and cyclosporine normally reduces these symptoms significantly in clinical

practice (see below). As mentioned above, these abnormal sensations may result from an aberrant spontaneous and stimulus-evoked nerve impulse firing of the damaged corneal nerves during their regeneration, evoking a perceptual disturbance known as "phantom cornea" (Fig. 16.9).¹²⁵

7.2 Deep ocular pain

Deep ocular pain arises from structures inside the eye globe, generally as a consequence of inflammation of uveal structures, such as iritis/uveitis, which is typically associated not only with pain but also with photophobia. Pain after inflammation of the uveal tract is attributable to enhanced activity in the abundant polymodal nociceptor fibers innervating these structures. The mechanism for the additional discomfort evoked by light exposure is uncertain but reflex contraction of ciliary and/or iris muscles triggered by light or accommodation may become painful if nociceptor sensory nerve endings in these structures were also sensitized. Consequently, besides anti-inflammatory and analgesic treatment, cycloplegic drugs and dark glasses are recommended for these patients.

Although the retina lacks sensory nerves, retinitis and endophthalmitis are usually painful, probably because of the parallel involvement of uveal tract inflammation. Intraocular tumors are normally painless, unless the tumor causes necrosis.^{125,132} Unlike chronic forms of glaucoma, acute congestive glaucoma, producing a sharp elevation of the intraocular pressure, is usually very painful, thus provoking a vegetative reaction that includes a decrease in blood pressure, headache, nausea, and vomiting.

There are many inflammatory processes and infections in the orbit that elicit pain. Most non-infectious (sterile) orbital inflammations imply accumulation of leukocytes within the orbital structures, with local release of inflammatory mediators and cytokines that are the likely cause of the signs of inflammation, including pain and edema.¹²² Some of the symptoms of these orbital inflammatory processes are related not only to the action of inflammatory mediators on sensory nerve endings but also to the pressure exerted by the inflammatory mass within the orbit and to vascular, neural or extraocular muscle involvement. Orbital tumors are usually painless unless they become infiltrated by blood vessels or cause orbital hemorrhage. Also, lachrymal gland tumors are often painful. Inflammations of the optic nerve (optic nerve neuritis) are associated with decreased vision, orbital and ocular tenderness and pain provoked by eye movements, probably due to the involvement of adjacent orbital structures. Eye movement-evoked pain can also be observed after fractures of the orbital floor or in the presence of a foreign body (e.g. after scleral buckling operations performed for retinal detachment).

Refractive errors resulting in eye strain or overaccommodation may cause ocular and eye-referred pain of variable intensity. Anisometropia may not only produce ocular discomfort and "tired eyes" but also aggravate headache and evoke migraine symptoms. Pronounced astigmatism and uncorrected presbyopia, which may go in parallel with dry eye in middle age, often causes ocular discomfort. As mentioned above, muscles responsible for accommodation contain sensory terminals that may become sensitized during continuous, ineffective accommodation,

Box 16.5 Dry eye

The most common reason for superficial eye discomfort is possibly "dry eye" also termed "ocular surface disease". This is a common multietiological condition in which impaired tear production or/and altered tear film stability compromise the ocular surface, producing dot-like micro lesions in conjunctival and corneal epithelia, suggestive of neurotrophic defects.

giving rise to pain sensations. The phantom eye syndrome develops after eye enucleation in about 26 percent of patients,¹³³ and is characterized by chronic pain referred to the eye as well as non-painful visual sensations (photopsia). Neuropathic pain may also result from lesion of intraocular sensory nerves due to compression after retinal surgery.

7.3 Pain referred to the eye

As noted above, pain referred to the eye and periorbital region is often attributable to a systemic condition. Eye-referred pain is often due to a pathological process of the trigeminal ganglion and nerves innervating the orbit and adjacent tissues that leads to an abnormal activation of second- and higher-order ocular neurons caused by neural input from other structures. Augmented nociceptive input from the damaged structures elsewhere may induce sprouting of trigeminal sensory projections to ocular neurons, inducing central sensitization and giving rise to pain referred to the eye. Sharp, short-lasting, severe, unilateral, repeated painful sensations referred to the eye are typical of trigeminal neuralgia, related to a general, abnormal activation of trigeminal pathways. Referred pain can also be observed in a variety of conditions such as orbital surgery, cluster headache,¹³⁴ or SUNCT syndrome.¹³⁵ Migraine hemicrania continua and tension headache also lead to facial and ocular pain.¹³⁶ On the other hand, certain forms of headache may be due to eye disease.¹³⁷

8. Drugs acting on ocular sensory nerves

Drugs affecting ocular sensory nerve activity are widely used in ophthalmology – in part for their therapeutic effects but mainly because common ophthalmological explorations as tonometry or goniscopy, and manipulations such as foreign body extraction, paracentesis, and most surgical ophthalmological operations such as cataract and vitreo-retinal surgery are performed under local, regional anesthesia. General anesthesia is only rarely used in elective surgery.

Topical anesthetics

Nearly all local anesthetics are highly lipid-soluble amine compounds that cross cell membranes and nerve sheaths and block propagated action potentials by blocking Na channels.¹³⁸ Instillation into the eye of a drop of a topical anesthetic solution (e.g. proparacaine, bupivacaine, oxybuprocaine, amethocaine, lidocaine) anesthetizes the cornea in about one minute due to blockade of nerve impulse propagation in corneal and conjunctival sensory nerve fibers. Thus, pain and thermal sensations arising from these structures are immediately suppressed, although some sensitivity may remain in subconjunctival structures and lids. Topical anesthetics are also used for ophthalmological explorations, including differentiation between superficial and deep ocular pain and ocular surgery (see below). Nevertheless, repeated application of local anesthetics for the management of ocular surface discomfort and pain is contraindicated because prolonged administration of topical anesthetics leads to development of corneal epithelial defects, serious corneal healing problems, and eventually corneal melting.¹³⁹

Anti-inflammatory drugs

Both steroid (e.g. fluorometholone, dexamethasone, prednisolone)¹⁴⁰ and non-steroidal anti-inflammatory drugs (NSAIDs),^{141,142} cyclosporine A or tacrolimus,^{141,142} are used as topical or systemic drugs to prevent or treat ocular discomfort and pain associated with inflammatory processes. NSAIDs are potent inhibitors of the two cyclo-oxygenases (COX-1, constitutive and COX-2, inducible) that form active prostaglandins and thromboxane from arachidonic acid released by damaged cell membranes. NSAIDs include different compounds with variable potency and speed of elimination, including for example diclofenac, flurbiprofen, ketorolac, nepafenac, indometacin, or acetyl salicylic acid. When applied topically to the cornea, some of the NSAIDs reduce pain not only through inhibition of the formation of prostaglandins and of their sensitizing effects on nociceptors but also through a direct action on membrane excitability of polymodal nociceptor endings.^{71,72} This direct analgesic action explains the usefulness of NSAIDs in treating not only ocular and orbital inflammatory processes, but pain associated with hyphema and post-surgical pain. Topical cyclosporine A is mainly used in the USA and has been reported to diminish inflammation and discomfort related to various dry eye syndromes.¹⁴¹

Cycloplegic agents

As indicated above, prevention of movement in the dilator and sphincter muscles of the iris, and in the ciliary muscle, using cycloplegic drugs (e.g. atropine, cyclopentolate, homatropine, tropicamide) often relieves pain associated with inflammatory conditions such as uveitis, and has become a standard therapeutic procedure. Furthermore, the iris usually becomes constricted during ocular inflammation and surgery due to local release of prostaglandins, which facilitates the formation of adhesions with the lens. Cycloplegic drugs also help to prevent this complication.

Analgesics

Analgesic drugs acting on the central nervous system such as non-acidic antipyretic analgesics (paracetamol) and weak (codeine) or strong (morphine) opioids are occasionally used to treat ocular pain. Pain of neuropathic origin such as phantom eye, post-refractive surgery eye pain, or posttherapeutic neuralgia and pain caused by acute congestive glaucoma often requires strong, systemic pain medication not only to abolish the acute pain sensations but also to prevent pain-related systemic symptoms such as nausea, vomiting, or even cardiac arrhythmia and shock. Drugs known generically as antidepressant analgesics, such as amitriptyline, butriptyline and some anticonvulsants such as carbamazepine or gabapentin, that antagonize neural transmission in the central nervous system and block neuronal Na channels, are being used to treat neuropathic pain.¹⁴³

Prevention of surgical pain

General anesthesia is seldom used today in eye surgery, although it is still occasionally needed in severe trauma, invasive tumor surgery, poor patient cooperation, or extensive plastic surgery.¹⁴⁴ When corneal pain must be prevented but blockade of the extraocular muscles (akinesia) is not needed, topical anesthetics applied either as drops or gels are sufficient when a small corneal incision is performed, e.g. in cataract removal through a corneal tunnel using

phacoemulsification. Surgery directed towards deeper ocular structures may require subtenon, periocular, or retrobulbar injection of the anesthetic drugs, performed alone or in combination with topical anesthesia.¹⁴⁴ For long-duration surgical procedures, compounds with a long-lasting effect such as bupivacaine are combined with compounds of shorter duration but faster onset such as lidocaine. Post-operative pain is prevented or treated with NSAIDs, alone or combined with codeine or oxycodone, in the latter case following posterior segment surgery.

Outward-Directed Transport

Pradeep K. Karla, Sai H.S. Boddu, Chanukya R. Dasari & Ashim K. Mitra

Introduction

In ocular therapeutics, the current literature describes drug delivery limitations posed by outward directed transport mechanisms of the eye. Drug delivery to ocular tissues is restricted by various factors such as limited tissue penetration, rapid clearance rate, and dose-limiting toxicity. Though diffusion plays a role, efflux transport proteins constitute a major driving force behind selective removal of therapeutic agents from ocular tissues. Therapeutic agents must penetrate the globe through the anterior or posterior route, depending on the mode of administration. The cornea forms a major barrier for anterior segment drug delivery. Presence of epithelial tight junctions, along with a wide array of efflux transporters causes poor permeation of drugs across the cornea. Apart from these, the drug molecules should possess optimum physicochemical properties to penetrate the different corneal layers.^{1,2} The blood-retinal barrier (BRB) forms a major barrier to posterior segment ocular drug delivery. The BRB is composed of retinal vascular endothelium and retinal-pigmented epithelium and is categorized as inner BRB and outer BRB.^{3,4} Inner BRB is composed of a monolayer of endothelial cells, which are non-fenestrated, and outer BRB is composed of retinal-pigmented epithelial cells.^{4,5}

Multi-drug resistance mediated by the efflux transporter (pump) is a widely explored field in the area of cancer research. Efflux pumps belong to the ATP binding cassette (ABC) transporter family.⁶ Family members such as P-glycoprotein (P-gp), multidrug resistance associated protein (MRP), breast cancer resistance protein (BCRP) and lung resistance protein (LRP) are known to play a vital role in imparting drug resistance to cancer cells. Efflux transporters are known to be protective in preventing the entry of toxic substances into cells which results in outward directed transport of toxins.⁶

The presence of efflux transporters on various physiological barriers protecting the eye was only recently discovered. Their existence in various ocular tissues such as cornea, retina, and conjunctiva has been established at molecular and functional level by various researchers. To a large extent the role of these efflux transporters in ocular drug resistance remains to be explored.

Various drug delivery strategies are employed to bypass the efflux transporters. The prodrug strategy, which involves

linking of the active drug molecule to a promoiety, is known to reduce or eliminate the substrate specificity of drugs to the efflux transporters. Our recent findings revealed that amino acid and peptide prodrugs of quinidine, val-quinidine and val-val-quinidine were able to bypass the MRP class efflux transporters on the corneal epithelial cells.⁷ Earlier it was shown that val-quinidine and val-val-quinidine can effectively bypass P-gp mediated efflux on the cornea.⁸ This chapter comprises a discussion on the presence of efflux transporters in various ocular tissues and their possible role in outward directed transport. Various strategies employed to modulate or bypass efflux transporters are presented.

Efflux transporters – brief history

Though outward directed transport mediated by efflux transporters is a new field in the area of ocular drug delivery research, it has been widely explored in the area of cancer therapeutics. The role of ABC transporters in treatment failure has been attributed to overexpression of efflux transporters.⁹

First evidence of outward directed transport resulting in drug resistance was recognized in 1973.¹⁰ Ehrlich astrocytes accumulated lower amounts of daunorubicin intracellularly primarily due to outward transport.¹⁰ Later a higher-molecular-weight glycoprotein (P-gp) was identified in multidrug-resistant cells.¹¹ It took a considerable amount of time and effort to confirm the hypothesis that a protein binds to the therapeutic agents or toxins intracellularly and transports them out of the cells utilizing energy from ATP hydrolysis. P-gp was confirmed as a primary drug efflux transporter leading to drug resistance.¹² This protein was later found to be a major efflux pump involved in resistance to various cancer drugs including paclitaxel and doxorubicin. P-gp is also demonstrated as ATP-binding cassette subfamily B member 1 (ABCB1), MDR1 and PGY1. It is also designated as cluster of differentiation 243 (CD243). It is a ~170 kDa transmembrane glycoprotein with 10–15 kDa of N-terminal glycosylation.¹³ P-gp has wide substrate specificity and is involved in the transport of lipids, steroids, bilirubin, xenobiotics, steroids, cardiac glycosides (digoxin), glucocorticoids (dexamethasone), HIV drugs (non-nucleoside reverse transcriptase inhibitors and protease inhibitors) and immunosuppressive agents.¹⁴ Apart

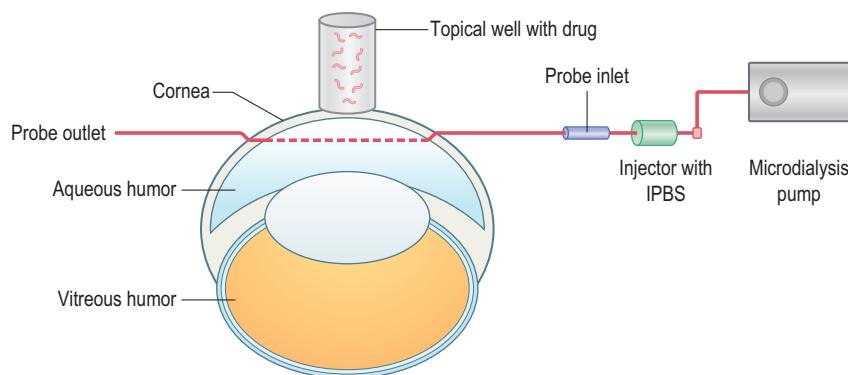

from being overexpressed in cancerous tissues, P-gp is expressed on various tissues including capillary endothelial cells of the blood-brain barrier (BBB), liver, intestine and renal proximal tubules.^{13,15}

Another drug efflux transporter resulting in outward directed transport is multidrug resistance associated protein (MRP). It was identified in 1992 in a human lung cancer cell line (H69AR) demonstrating multidrug resistance. The cell line did not express P-gp despite conferring significant resistance to the absorption of doxorubicin. Later, the efflux transporter responsible for outward directed transport was found to be MRP.¹⁶

Apart from MRP and P-gp, various other human ATP binding cassette (ABC) transporters have been identified. A new efflux protein which is currently known as breast cancer resistance protein (BCRP) has been identified at protein level and cloned by three research groups.¹⁷ It is also known as the mitoxantrone-resistance protein (MXR) or placenta-specific ABC protein (ABCP). This protein is an ~70 kDa efflux transporter belonging to the ABC family and proved to play a significant role in drug resistance.^{18–20}

Another new efflux transporter belonging to the ATP binding cassette family is lung resistance protein (LRP).²¹ It is also known as major vault protein (MVP) and can cause multidrug resistance. LRP was initially identified in P-gp negative MDR lung cancer cells^{20,22} and is composed of complex ribonucleoprotein particles.^{23,24} Vaults are present mainly in the cytoplasm and partially in the nuclear membrane. These structures are assumed to cause nucleocytoplasmic and intracellular transport.²⁵ The presence of LRP in cancer cells was found to result in resistance development to cisplatin, doxorubicin, carboplatin and melphalan.^{25,26} Other than the eye it is present in various tissues such as colon, lung, macrophages, adrenal cortex and renal proximal tubules.²⁷ However, contradictory reports have appeared in the literature questioning the role of LRP or MVP. A few studies revealed that MVP does not play a significant role in drug resistance. The primary physiological function of LRP is not completely understood and is being further evaluated.²⁸

Multidrug resistance conferred by efflux transporters is a relatively new area of interest in ocular drug delivery. Most of the transporters are ubiquitously expressed in various tissues of the body and have a protective role. The presence of efflux transporters in various ocular tissues and their role in ocular drug efflux resulting in drug resistance is discussed in the following sections.

Efflux transporters in ocular tissues

P-gp

P-gp in isolated primary culture of rabbit corneal epithelial cells was reported by Kawazu et al.²⁹ The presence of P-gp at protein level and a series of uptake experiments demonstrated that the tear-side-facing membrane (apical) of rabbit corneal epithelial cells expressed P-gp. This article further concluded that the presence of P-gp on corneal cells protects them from toxic agents.²⁹ Later the presence of P-gp in human cornea was demonstrated by Dey et al.³⁰ This report further confirmed the expression of P-gp in rabbit cornea and rabbit corneal epithelial cells. Uptake of Rho 123, a P-gp substrate, was significantly higher in the presence of P-gp inhibitors like cyclosporine A (CsA) indicating the role of P-gp in corneal drug efflux. Ocular pharmacokinetic studies involving male New Zealand Albino rabbits revealed a significant elevation in aqueous humor drug concentrations in the presence of various P-gp inhibitors, i.e. testosterone, quinidine, verapamil and CsA.³⁰ Moreover dose-dependent suppression in P-gp efflux was evident at various inhibitor concentrations. The presence of P-gp in the cornea was corroborated by a recent report on the quantitative expression of P-gp in human cornea.³¹ The relative role of P-gp in the outward directed efflux of drugs used in glaucoma, anti-bacterial and anti-viral agents has yet to be established.

An ocular microdialysis technique was applied to determine the role of efflux transporters on the cornea.³⁰ Figure 17.1 shows a schematic diagram of the surgical implantation of the microdialysis probe. A well is placed on the top of cornea filled with drug solution. The sample is collected from the anterior end of the probe which protrudes from the cornea. Drug diffuses across the dialyzing membrane placed in the aqueous humor. This technique helps to quantitatively determine the drug concentrations in the aqueous humor at different time points. This study reported that P-gp inhibitors significantly raised drug concentration in aqueous humor (both C_{max} and AUC) (Table 17.1). The results demonstrated that P-gp can play a vital role in conferring resistance to drug absorption across the cornea. This article also suggested the use of efflux pump inhibitors along with therapeutic agents – a strategy that helps to increase the overall ocular bioavailability of drugs which are substrates of efflux pumps.

Figure 17.1 Schematic representation of ocular microdialysis technique that shows surgical implantation of linear probe in rabbit eye and adhering topical well on the surface of cornea as described by Dey S et al.¹ A microdialysis pump infuses isotonic phosphate buffer (IPBS), pH 7.4 at constant rate and sample is collected at the other end. Reservoir of drug loaded in the well is also shown. The extent of outward directed transport by an efflux pump can be estimated with the use of specific inhibitors.

Along with cornea, the BRB limits the permeability of various therapeutic agents into the eye.³² Retinal pigmented epithelium (RPE), situated between the retina and its choroidal blood supply, forms a diffusional barrier controlling access to subretinal space. Transport proteins present on the RPE regulate ionic composition and hydration of the subretinal space.³³ Immunohistochemistry revealed that P-gp is localized both on the apical and basolateral sides of human RPE. Basolateral P-gp is attributed to the function of neural retina in clearing toxic and unwanted molecules from the subretinal space. Apical expression of P-gp appears to assist in the delivery of lipophilic substrates to subretinal space and engulfment by photoreceptors.³³ Three RPE cell lines, ARPE-19, D-407 and h1RPE, are usually employed for *in vitro* studies. Screening of these three cell lines for P-gp expression revealed that D-407 is suitable for functional expression and drug transport screening. ARPE-19 cells lacked both molecular and functional expression of P-gp, whereas h1RPE lacked functional expression of P-gp. D-407 demonstrated both molecular and functional expression of P-gp. Also, P-gp was found to be expressed on the choroidal

blood vessels.³⁴ Further work is in progress to understand the role of P-gp in the choroid.

P-gp is also expressed in rabbit conjunctival epithelial cells. It is present on the apical side of the conjunctiva, conferring resistance to the absorption of cyclosporine A and other lipophilic drugs.³⁴ Use of various P-gp inhibitors – such as verapamil, progesterone, cyclosporine A, rhodamine 123 and metabolic inhibitor 2,4-DNP – enhanced the uptake of the model drug propranolol in rabbit conjunctival epithelial cells.³⁴ Yang et al³⁵ concluded that P-gp can play a vital role in decreased absorption of various lipophilic drugs across the conjunctiva.

P-gp appears to play an important role in the outward transport of cytotoxic drugs and in the modulation of chloride channels which regulate and initiate osmotic cataract. Further, findings by Miyazawa et al³⁶ revealed that P-gp might be induced by aldose reductase overexpression and osmotic stress. P-gp was found to maintain lenticular osmotic balance in sugar cataract. The role of P-gp in the drug disposition of various ocular agents is being further evaluated.

Mode of action and structure of P-gp

P-gp requires ATP for its function. There are two ATP binding sites, also known as nucleotide binding domains (NBD). Apart from NBD, there are two transmembrane domains incorporating six transmembrane domains at each site (a total of 12). A pictorial representation of P-gp is provided in Figure 17.2.³⁷

MRP

Various classes of MRPs are expressed in the retina and other ocular tissues; the outer BRB expresses MRP. Functional characterization showed that the BRB is similar to the BBB. Functional studies using P-gp and MRP modulators revealed that outer BRB epithelium demonstrates similar pharmacological properties to endothelial BBB and expresses the same efflux transport systems.³⁸ Also, Wilson et al³⁹ demonstrated that retinoblastoma tumors express MRP1, 2 and 4. Immunohistochemistry revealed intense localization of these efflux pumps along with P-gp/BCRP in tumor tissue.^{33,39} The possible role of these transporters, either individually or collectively, in tumor therapy needs to be evaluated.

Table 17.1 Effect of various P-gp inhibitors on the $AUC_{0-\infty}$ and $C_{aq,max}$ of [^{14}C]erythromycin in rabbit cornea

Drug and/or Inhibitor	$AUC_{0-\infty}$	C_{max}
Erythromycin	31.67 ± 4.99	0.136 ± 0.009
Erythromycin + 100 μ M test	40.21 ± 5.29	0.151 ± 0.021
Erythromycin + 150 μ M test	43.51 ± 7.75	0.183 ± 0.033
Erythromycin + 250 μ M test	$88.58 \pm 6.34^*$	$0.489 \pm 0.095^{**}$
Erythromycin + 500 μ M test	$118.76 \pm 10.72^{**}$	$0.672 \pm 0.095^{**}$
Erythromycin + 20 μ M CsA	$65.18 \pm 7.09^*$	$0.356 \pm 0.060^*$
Erythromycin + 200 μ M Quin	$52.63 \pm 7.79^*$	$0.286 \pm 0.052^*$
Erythromycin + 500 μ M Vera	43.56 ± 6.99	0.205 ± 0.039

As evident from the data, 250 and 500 μ M testosterone inhibited P-gp-mediated efflux to a significant extent. Among the other inhibitors studied, CsA and quinidine also inhibited P-gp-mediated efflux. Each point represents mean \pm SD ($n = 4$). (Adapted with permission from Dey et al.³⁰)

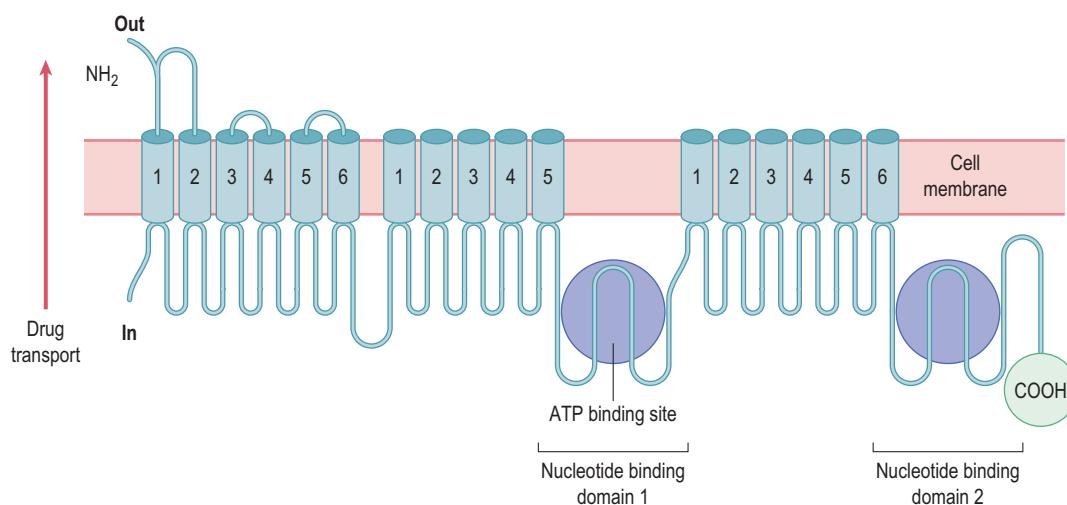

Figure 17.2 P-glycoprotein (P-gp) structure comprising 12 transmembrane domains, two nucleotide binding domains and two ATP binding sites. Drugs and toxins are effluxed out of the cell. (Drawn based on inspiration from Perez et al.³⁸ Reproduced from Association for Research in Vision and Ophthalmology.)

MRP7 (NM_033450)	GAACGGCTGCTTAACTTGC AGGTATAACACAGGCCGCATC

MRP is another major class of ABCC efflux transporter imparting drug resistance. The MRP family has nine members (MRP 1–9) and substrate specificity varies significantly among them.⁴⁰ As shown in Figure 17.3, RT-PCR performed on primary human corneal epithelial cells (based on protocol established in our laboratory¹) revealed the expression of MRP1–7. Primary culture of human corneal epithelial cells was obtained from Cascade Biologics (Portland, OR) and RT-PCR performed based on an established protocol² – primers used for the RT-PCR are presented in Table 17.2. MRP is regarded as an organic anion transporter, but some MRP (MRP 4,5) are known to transport nucleoside and nucleotide analogs.⁴¹

The presence of MRP2 at the gene and protein level, as well as its functional expression in rabbit corneal epithelial cells, was established in 2007 in our laboratory.² A possible role of MRP2 in conferring resistance to the absorption of erythromycin across rabbit corneal epithelial cells was reported. In an article by Karla et al,² MRP2 expression on rabbit corneal epithelial cells at the gene and protein level was reported. [¹⁴C]-erythromycin was selected as a model

substrate and affinity to the transporter was measured employing a specific inhibitor, MK571. This work demonstrated apically polarized localization of the transporter in rabbit corneal epithelial cells. Also, uptake and transport of [¹⁴C]-erythromycin was significantly elevated in the presence of MK571, suggesting that the transporters might act in conjunction towards outward directed transport.²

Later studies by Karla et al revealed significant expression of MRP2 conferring drug resistance in human corneal epithelial cells.⁴² (As stated in our earlier publication:²

"Significant elevation in uptake of model drugs

[¹⁴C]-erythromycin and [³H]-cyclosporine-A in the presence of MK-571 indicated the functional activity of MRP2 in human corneal epithelium. Expression of ABCC2 may play a critical role in reducing the bioavailability of topically applied drugs. Cyclosporine-A is widely used as an immunosuppressive agent in corneal transplants and it is also indicated in the treatment of various corneal opacities. Erythromycin in various topical formulations has been used a drug of choice for treating minor corneal opacities. Though these compounds are substrates for P-gp, use of MK-571 reveals contribution of only MRP. A significant elevation in uptake of [¹⁴C]-erythromycin in the presence of unlabeled cyclosporine-A was also observed. The results indicate a dose-dependent inhibition of ABCC2 in both rPCEC and SV40-HCEC cell lines. Further studies indicate similar MDR expression profiles in human and rabbit corneal epithelium, which validate rabbit as a suitable animal model for in-vivo MDR-mediated drug absorption studies. Transport studies across SV40-HCEC and rabbit cornea revealed a significant increase in drug concentration in receiver chamber in the presence of inhibitor. Enhanced permeability of [¹⁴C]-erythromycin and [³H]-cyclosporine-A from apical to basolateral side across SV40-HCEC in the presence of MK-571 reveals the important role of ABCC2 as a barrier in corneal drug influx. In human corneal epithelial cells apical to basolateral side transport of [³H]-cyclosporine-A was elevated almost ~4-fold as compared to basal to apical transport, which increased ~2-fold in the presence of an inhibitor. Similar trend is observed for the passage of [¹⁴C]-erythromycin where elevation in apical to basolateral transport was almost ~4-fold as compared to control whereas basal to apical transport was only ~1.5-fold higher than control. Acceleration in the basal to apical transport might be due to the presence of a homolog in MRP family."

These results indicate that the MRP class of transporters can confer significant resistance to the absorption of drugs across human corneal epithelium. Literature review indicates that many ocular drugs are substrates for MRP2 – these include sulfated steroids, macrolides such as azithromycin, erythromycin, antibiotics and quinolones such as ciprofloxacin and grepafloxacin.^{2,43–49} Fluoroquinolones are applied topically for treating conjunctivitis and keratitis⁵⁰ in a large number of cases.^{42,51} As demonstrated in our earlier studies, erythromycin is a substrate for the MRP class of efflux transporters. Fluoroquinolones such as sparfloxacin, levofloxacin and grepafloxacin interacted with erythromycin. The use of MRP inhibitors in ophthalmic formulations or use of combination drugs which interact with the transporters might be an efficient strategy to increase drug delivery to the anterior segment.

Preliminary results from our laboratory indicate the expression of the nucleoside and nucleotide efflux transporters MRP4 and MRP5 in human corneal epithelial cells (Fig. 17.4). However, the functional role of these efflux pumps in ocular drug resistance has yet to be established. Preliminary results from our laboratory indicate that these transporters play a vital role in the outward directed transport of adefovir and acyclovir (unpublished results). Also, additional experimentation revealed that some drugs used in the treatment of glaucoma (bimatoprost and latanoprost) are effluxed by MRP on the corneal epithelium (unpublished data). Ocular microdialysis in an in vivo rabbit animal model revealed the functional role of the MRP4/MRP5 system in conferring resistance to the absorption of acyclovir.⁵² Use of the specific inhibitor MK571 increased aqueous humor concentrations of acyclovir by ~2-fold.^{37,53} Expression of various MRPs in the cornea and their relative role resistance to various ophthalmic drugs needs to be further explored.

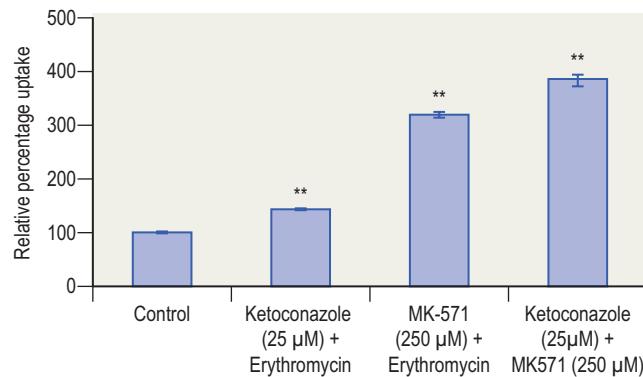

Figure 17.4 Collective role of P-gp and MRP in corneal drug efflux. Ketoconazole, a specific P-gp inhibitor (25 μ M) along with MK-571 (250 μ M) was used to demonstrate the dual efflux. Each data point represents the mean \pm SD of three determinations. Statistical significance was tested by two-factor ANOVA. * $P \leq 0.05$; ** $P \leq 0.01$. (Adapted with permission from Karla et al.²)

Mode of action and structure of MRP

It is well known that MRP utilizes ATP for its functional activity. Similar to P-gp there are two ATP binding sites, also known as NBD. Apart from NBD, the protein is made up of three transmembrane sites (two sites with six transmembrane domains and one site with five transmembrane domains – a total of 17).^{37,54} Also, the N-terminal loop is present outside the cell membrane – unlike P-gp, where it is present in the cytoplasm.⁵⁴ A pictorial representation of MRP structure is shown in Figure 17.5.

BCRP

BCRP is expressed on the retina and choroid and may be involved in outward directed transport. It is also expressed on retinal capillary endothelial cells which form the barrier at the inner BRB. Dual immunolabeling of BCRP and glucose transporter 1 in mouse retina by Asashima et al⁵⁵ revealed that BCRP is localized on the luminal side of retinal capillary endothelial cells. Using a BCRP inhibitor, Ko143, Asashima et al also established that BCRP acts as an efflux transporter of photosensitive toxins such as protoporphyrin IX and pheophorbide. BCRP is also expressed on the retinoblastoma cells. Its role in drug resistance still needs to be elucidated.

BCRP is another efflux transporter expressed on human corneal epithelial cells.^{56,57} Studies in our laboratory have demonstrated that BCRP plays a significant role in conferring resistance to the absorption of drugs (mitoxantrone; MTX) across transfected human corneal epithelial cells (SV40-HCEC). We also reported the functional expression of BCRP in human corneal epithelial cells and proved it can play a role in drug efflux.⁵⁷ Significant efflux of [³H]-MTX in the presence of FTC and GF120918 (inhibitors of BCRP) established the functional activity of BCRP in SV40-HCEC and its possible role in limiting the ocular bioavailability of topically applied drugs. Dose-dependent inhibition of efflux was noticed with both fumtrexamic-C (FTC) and GF120918 in MDCKII-BCRP (+ve control) and SV40-HCEC. FTC and GF120918 are well-known inhibitors of BCRP and their use

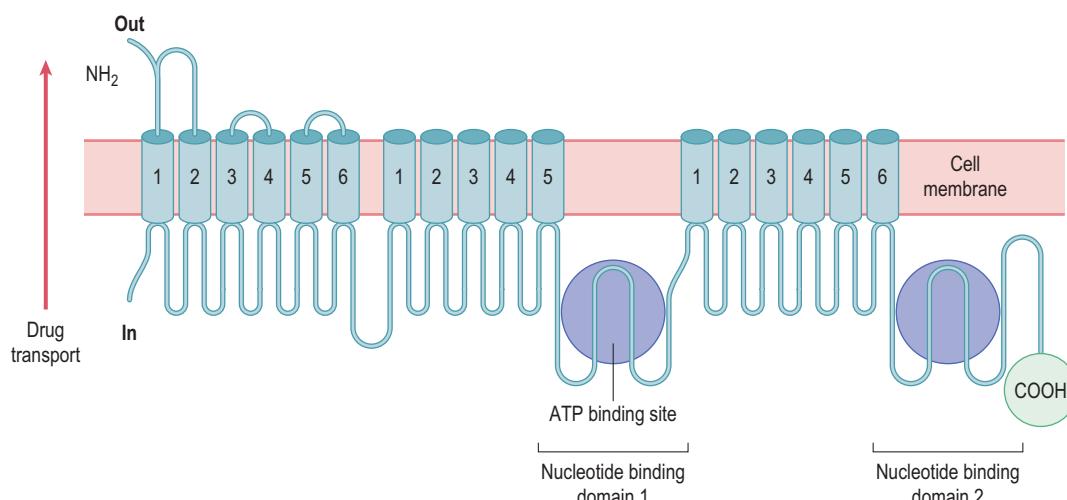

Figure 17.5 Multidrug resistance associated protein (MRP) structure comprising 17 transmembrane domains, two nucleotide binding domains and two ATP binding sites. Drugs and toxins are effluxed out of the cell. (Drawn based on inspiration from Perez et al³⁸ and Gottesman et al.⁵⁵)

in SV40-HCEC resulted in diminished efflux and increased uptake.⁵⁷

An interesting study by Umemoto et al⁵⁸ revealed that basal limbal epithelial cells of the rat eye express BCRP significantly. Also, side population stem cells which help in the regeneration of corneal epithelium express BCRP – but at a relatively very low level compared to limbal side population cells. BCRP is expressed at a relatively low level in stem cells which help in regenerating corneal epithelium. Hence, it is regarded as a putative stem cell marker used to identify the corneal stem cells responsible for regeneration of epithelial cells. This is of high clinical significance as constructs generated from limbal epithelial cells were successfully used in clinical transplantation.^{57,58} The fact that BCRP is expressed on the stem cells and on human corneal epithelial cells provides a new insight into the mechanism of ocular drug resistance development.⁵⁷ Relative expression of BCRP in stem cells and epithelial cells should be investigated.

Mode of action and structure of BCRP

BCRP requires ATP for its function. Unlike P-gp and MRP there is one ATP binding site, also known as the nucleotide binding domain (NBD). There is also a single transmembrane site incorporating six domains – hence it is regarded as half transporter.⁵⁴ A pictorial representation of BCRP is shown in Figure 17.6.

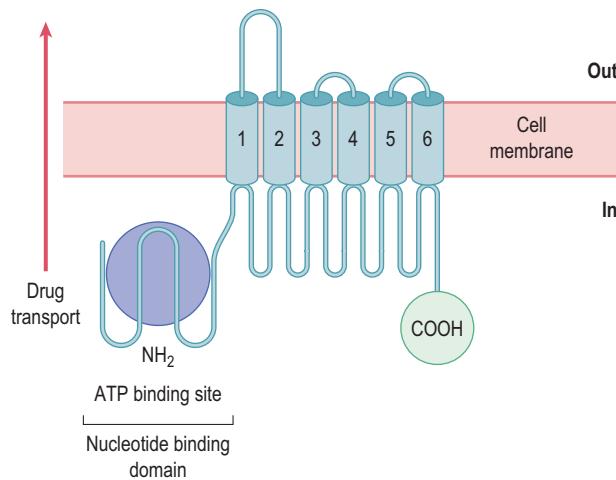

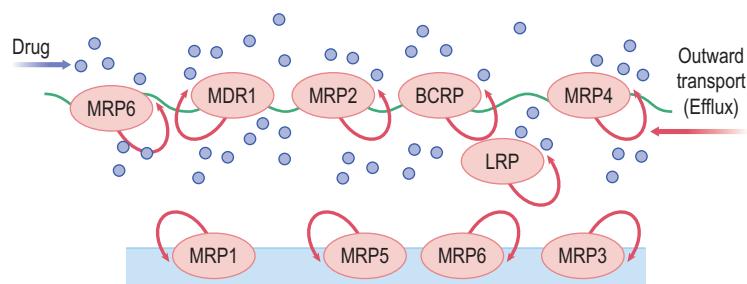

Figure 17.6 Breast cancer resistance protein (BCRP) structure comprising six transmembrane domains and one nucleotide binding domain. Drugs and toxins are effluxed out of the cell. (Drawn based on inspiration from Perez et al³⁸ and Gottesman et al.⁵⁵)

LRP

The presence of LRP in human corneal tissue was first indicated by Becker et al.⁵⁶ As described earlier there are contradicting reports with respect to the role of LRP in drug resistance. It is located inside the cell (intracellular) and is regarded as a major vault protein which aids in the outward directed transport of toxins.^{21,59} Figure 17.7 demonstrates the intracellular localization of LRP.

Localization of transporters

Efflux transporters are localized on either apical/basal sides or are present intracellularly. Localization of transporters in biological membranes is represented in Figure 17.7. However, the localization may vary in some tissues. The BBB shows differential localization of transporters. MRP1, MRP3 and MRP5 are expressed on both apical and basal sides of the BBB.⁶⁰ Preliminary results from our laboratory indicated that MRP5 is localized on both apical and basolateral sides of the cornea. However, expression is predominantly on the basal side (unpublished data). Based on the localization and distribution in various tissues the transporters appear to confer a concerted protective role. The exact nature and function of most of the transporters still need to be explored.

Discussion

Clinical correlates from literature

Depending on the route of drug delivery, different structural barriers must be overcome to improve ocular bioavailability. Traditionally drug delivery mechanisms are divided into two categories: anterior segment and posterior segment. A topically administrated dose is cleared rapidly by tear turnover and blinking reflex before encountering the conjunctiva, which absorbs a substantial portion. Often the cornea is the target tissue, but it is composed of a low permeability cell structure with efflux pumps which effectively inhibit therapeutic agents. Even drugs delivered directly into aqueous humor either by intracameral injection or ocular inserts, are prone to removal by Schlemm's canal. Drug delivery to the posterior segment is similarly hindered. Delivery to the retina can be achieved via intravitreal, periorbital, or systemic routes. Intravitreal injection must allow for a long residence time in the vitreous humor, in order for the drug to traverse multiple neuronal layers before reaching the intended segment of the retina. Periorbital applications intended for the retina must traverse the thick sclera, choroid

Figure 17.7 Schematic representation of apical and basal distribution of efflux transporters on cells. In general, apical transporters comprise of MDR1, MRP2, 4, 6 and BCRP. MRP1, 3, 5 and 6 are present basolaterally. LRP is present in the cytoplasm. This scheme represents the common insight on localization of transporters, but various sites like blood-brain barrier and cornea were found to show differential localization.

Box 17.1 ABCA and Macular Degeneration

ABCA mutations have been directly related to the pathogenesis of Stargardt and age-related macular degeneration, retinitis pigmentosa, and recessive cone rod dystrophy. In normal retinal pigment epithelial cells, ABCA-4 transports photobleached rhodopsin out of cells to prevent damage caused by toxic end products. A deficiency in the efflux protein leads to accumulations of N-retinylidene-PE, all-trans retinal, and A2E in disc membranes, eventually leading to photoreceptor death by accumulation of photo-oxidation products.⁵⁹

Box 17.2 ABCC and Ocular Bleeding in PXE

Ocular bleeding observed in pseudoxanthoma elasticum (PXE) syndrome is caused by a recessive mutation in ABCC6 (MRP6) on chr 16p, next to the ABCC1 gene. ABCC6 is highly present in the liver and kidney, and is responsible for the efflux of glutathione conjugates such as LTC₄, and perhaps even triglycerides and HDL. Transport may be inhibited by organic anions or mis-sense mutations in pseudoxanthoma elasticum, which presents with dermal connective tissue calcification and cardiovascular disease.⁵⁹

Box 17.3 ABCD1 and Adrenoleukodystrophy

ABCD1 is a peroxisome transporter that mediates the efflux of very-long-chain, unbranched, saturated fatty acids from cells and cholesterol esters of the brain and adrenal cortex. Several hundred mutations in the ABCD1 gene have been identified and implicated in adrenoleukodystrophy – a variable onset, X-linked, recessive disease characterized by adrenal deficiency and neuronal deficits. Ocular manifestations include progressive vision loss, optic nerve hypoplasia, exotropia, esotropia, retinal ganglionic atrophy; cataracts; and altered macular pigment.⁷⁰

VLCFA levels in the blood can be normalized by conventional treatments; however cerebral fatty acid levels remain elevated leading to disease progression over time. Experimental studies have been conducted using fibrates, a class of cholesterol-lowering drugs, to induce ABCD2, a transport protein closely related to ABCD1 and found principally in the brain and adrenals. The hope is to upregulate fatty acid efflux from peroxisomes in neuronal and ocular tissue.⁵⁹

and RPE, which also contain efflux pumps. Systemic drug delivery to the retina must bypass the BRB to reach target tissue. Given the unique characteristics of multistep barriers and target tissues in ophthalmic drug delivery, the characterization of specific tissue types has been a recent focus. Each of the various ocular tissues, such as the conjunctiva, sclera, cornea, and retina, has a different milieu of membrane proteins which confer unique functional characteristics with respect to drug clearance (Boxes 17.1–17.3).

Table 17.3 summarizes various classes of transporters that can result in outward directed transport in ocular tissues and their function based on literature review. Highly specific ABCB1 inhibitors demonstrate the ability to decrease the extent of drug resistance, and perpetuate the therapeutic attributes of existing pharmacological regimens. Current

Table 17.3 Tabulation of various classes of transporters that can result in outward directed transport in ocular tissues and their function based on literature review

Family	Members identified in ocular tissue	Function
ABC-A	ABCA-4	Transports lipids and cholesterol
ABC-B	P-gp	Some are located in the blood-brain barrier, liver, mitochondria and transports peptides and bile, for example
ABC-C	MRP, ABCC6	Significant role in ion transport, and toxin efflux
ABC-D		Transporter on peroxisome membrane
ABC-E / ABC-F		These proteins are not thought to have a role in transmembrane transport
ABC-G	BCRP	Transports bile, lipids, cholesterol, and steroids

research is focusing on the development of additional inhibitors which will lead to more effective chemotherapy.

Outward directed transport mediated by various transporters is a relatively new and exciting field of research. A better understanding of these transporters might result in the development of efficient drug delivery strategies to improve therapy for both anterior and posterior segment diseases.

Strategies to evade efflux transporters

Expression of efflux transporters on the protective barriers of the eye prevents the entry of many drug molecules. Drug delivery strategies which can aid in the evasion of efflux transporters would be ideal for enhancing drug delivery to the eye. Various options are discussed in the literature on modulating or bypassing efflux at various sites. One promising approach is a prodrug strategy where active drug molecules are modified by chemical synthesis to attach a peptide, amino acid, vitamin or other substrate to target a specific transporter/receptor. Targeting the active drug molecules to various influx transporters present on the cornea and blood-ocular barrier (BOB) can be an efficient strategy to bypass the efflux transporters.⁸ Peptide transporters are the major influx transporters and are widely selected as a target. The oligopeptide transport system is also expressed on the BOB.^{7,67}

The BOB is the major barrier that protects the eye from toxins in internal blood circulation. Atluri et al⁶⁷ proposed that this transport system can be employed to bypass the efflux transporters present on the BOB. The presence of the oligopeptide transporter on the cornea, which is a major barrier to anterior segment drug delivery, was proposed by Anand et al in 2002.⁷ Val-acyclovir, an amino acid prodrug of acyclovir, is currently available on the market under the trade name Valtrex. It is employed in the treatment of

Box 17.4 ABCG and Sitosterolemia

Xanthelasma and corneal arcus are occasionally seen in sitosterolemia, a rare autosomal recessive lipid metabolism disorder caused by mutation in ABCG5 (Asian sitosterolemia) or ABCG8 (Caucasian). Unique to this class of efflux proteins is the mechanism of forming heterodimers to transport non-cholesterol plant and shellfish sterols which accumulate to form xanthomas.⁵⁹ Coincidentally the presence of a related protein ABCG2 (BRCP), has been demonstrated in retinal blood vessels but its function is not apparent.⁵⁶ Current treatment for this sitosterolemia involves predominantly dietary management and lipid-lowering therapy.

Box 17.5 Transporters and Multidrug Resistance to Cancer Chemotherapy

Normal cells which are exposed to toxic and xenobiotic compounds overexpress efflux pathways that ultimately lead to drug resistance. In cancer cells the process of drug resistance is accelerated by rapid growth processes. The predominant mode by which some cancers develop resistance is through overexpression of efflux proteins.⁶⁰ With regards to ocular neoplasms, P-gp, MRP and LRP exist on primary and metastatic melanomas and confer resistance to chemotherapy for these neoplasms.⁶¹ LRP has a larger influence in choroidal melanomas, but in uveal melanomas demonstrating drug resistance P-gp expression is higher.⁶² Also in enucleated retinoblastomas which failed to respond to chemotherapy, high P-gp, MRP-1, and MRP-2 expression has been histologically demonstrated.⁶³

Box 17.6 Prodrug Strategy for Increased Ocular Bioavailability and Evasion of Efflux Transporter

A prodrug of acyclovir, Valtrex is currently in the market and is administered as an oral dose.⁷⁰ The presence of an oligopeptide transporter system on the blood–ocular barrier is a recent finding.⁶⁶ Valtrex was shown to permeate the tissues using the oligopeptide transporter, hence this might be the reason for increased permeability of Valtrex across the blood–ocular barrier. Preliminary results from our laboratory suggest that acyclovir is a substrate for the MRP4/MRP5 class of transporters present on the cornea (unpublished data). Targeting of acyclovir, using a valine pro-moietry might be aiding efficient bypass of the efflux transporters present on the blood–ocular barrier.

keratitis of the cornea caused by the herpes simplex virus. As stated earlier, prodrug derivatization can aid in bypassing various efflux transporters present on the cornea. Both the amino acid prodrug (val-acyclovir) and the peptide prodrug (val-val-acyclovir) are transported across the cornea by the oligopeptide transporter, leading to increased ocular penetration.^{7,68} The peptide prodrug of acyclovir showed significantly improved anti-viral properties (Boxes 17.4–17.6).⁶⁸

Administering specific inhibitors of efflux transporters might be another strategy to improve drug delivery across the cornea. Dey et al³⁰ demonstrated increased absorption of erythromycin across the cornea in an in vivo rabbit animal model in the presence of various inhibitors. Also, modulation of the MRP class of efflux transporters with the use of

specific inhibitors elevated the absorption of erythromycin significantly across the cornea.

Outward directed transport mediated by efflux transporters at various ocular tissues is a relatively new field of research. Recent work has revealed the presence of various efflux transporters on the cornea and other protective barriers of the eye. However, extensive research work is needed to delineate their role in ocular drug delivery.

Biochemical Cascade of Phototransduction

Alecia K. Gross & Theodore G. Wensel

Overview

Phototransduction is the series of biochemical events that lead from photon capture by a photoreceptor cell to its hyperpolarization and slowing of neurotransmitter release at the synapse.^{1–10} This overall process includes an activation phase and a recovery phase. While the fundamental mechanisms of phototransduction seem to be constant over a wide range of light intensities and very similar in rods and cones, the quantitative features differ strikingly depending on the level of ambient light (see Chapter 20) and the cell type. While we know more about the biochemistry of phototransduction than we do about any other neuronal signaling pathway, there are numerous remaining mysteries.

Location and compartmentalization of rods and cones

Rod and cone photoreceptors are densely packed in the outermost layer of the neural retina, stretching from their synapses in the outer plexiform layer to their most distal tips, which are embedded in the membrane processes of the retinal pigmented epithelium (RPE) (Fig. 18.1). They are long, thin cells with their long axes aligned along the radii of the eye to maximize light collection. Efficient phototransduction depends upon the organization of photoreceptors into distinct membrane compartments (Figs 18.1–18.3). The biochemical cascade of phototransduction are restricted to the outer segment, an elongated membrane compartment separated from the rest of the cell, by a thin connecting cilium or ciliary transition zone, consisting of a 9 + 0 bundle of microtubules surrounded by a very thin layer of cytoplasm and a plasma membrane. Immediately adjacent is the inner segment, the site of active biosynthesis and oxidative metabolism. Although small molecules and proteins can diffuse along the connecting cilium between the inner and outer segments, this process occurs in general on a slower time scale than that of a light response.¹¹ This inter-compartment transport plays an important role in producing the molecules necessary for phototransduction and modulating their levels, but it does not contribute directly to the

phototransduction cascade. While cytoplasmic diffusion is limited by the constriction at the connecting cilium, this constriction does not pose a major barrier to the propagation of electrical changes along the plasma membrane. Therefore, changes in membrane potential can be passively communicated from the outer segment to the synaptic terminal at the other end of the cell, where they control neurotransmitter release and transmit the signal to higher order neurons.

The phototransduction cascade takes place in the outer segments. There are two membrane systems in rods (Figs 18.3, 18.4). The disk membranes, which can be thought of as flattened sealed vesicles, are stacked up along the long axis of the outer segment and make up the vast majority of membrane surface in the cells. The plasma membrane surrounds the disks and the cytoplasm (Fig. 18.4), and forms the interface between the cell and the extracellular space. Although there are proteins linking these two membranes, there does not appear to be any flow of lipid or trans-membrane proteins between them in the outer segment. In contrast, cones have a single membrane which forms multiple invaginations that resemble disks but are not sealed and are continuous with the plasma membrane. A cone-like relationship between plasma membrane and nascent disks appears to be present at the base of rod outer segments (ROS),¹² although there is some controversy as to whether even those nascent disks may be distinct from, and surrounded by, plasma membrane.

The components of phototransduction, discussed in detail below, are primarily localized in the outer segments, and are mostly peripheral or integral membrane proteins. The disk and plasma membranes have distinct protein compositions.

Dark-adapted rods

The most information at the molecular level is available for the dim light responses of dark-adapted rods (see Chapter 19). These cells in this state can respond with amazingly high efficiency to single photon capture events.¹³ It is useful conceptually to begin with the resting dark state and then consider the chain of events set in motion when a photon is absorbed.

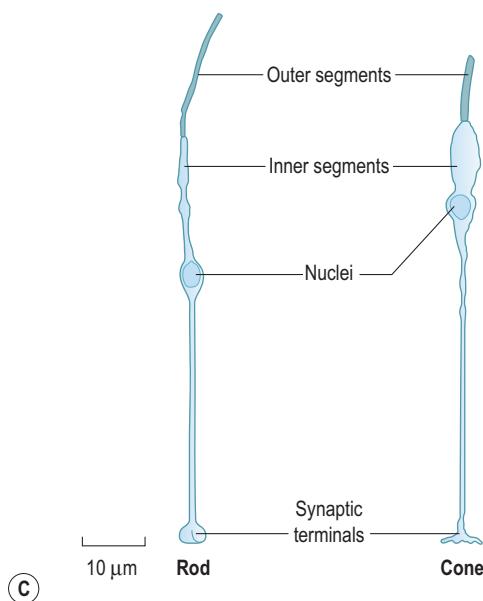

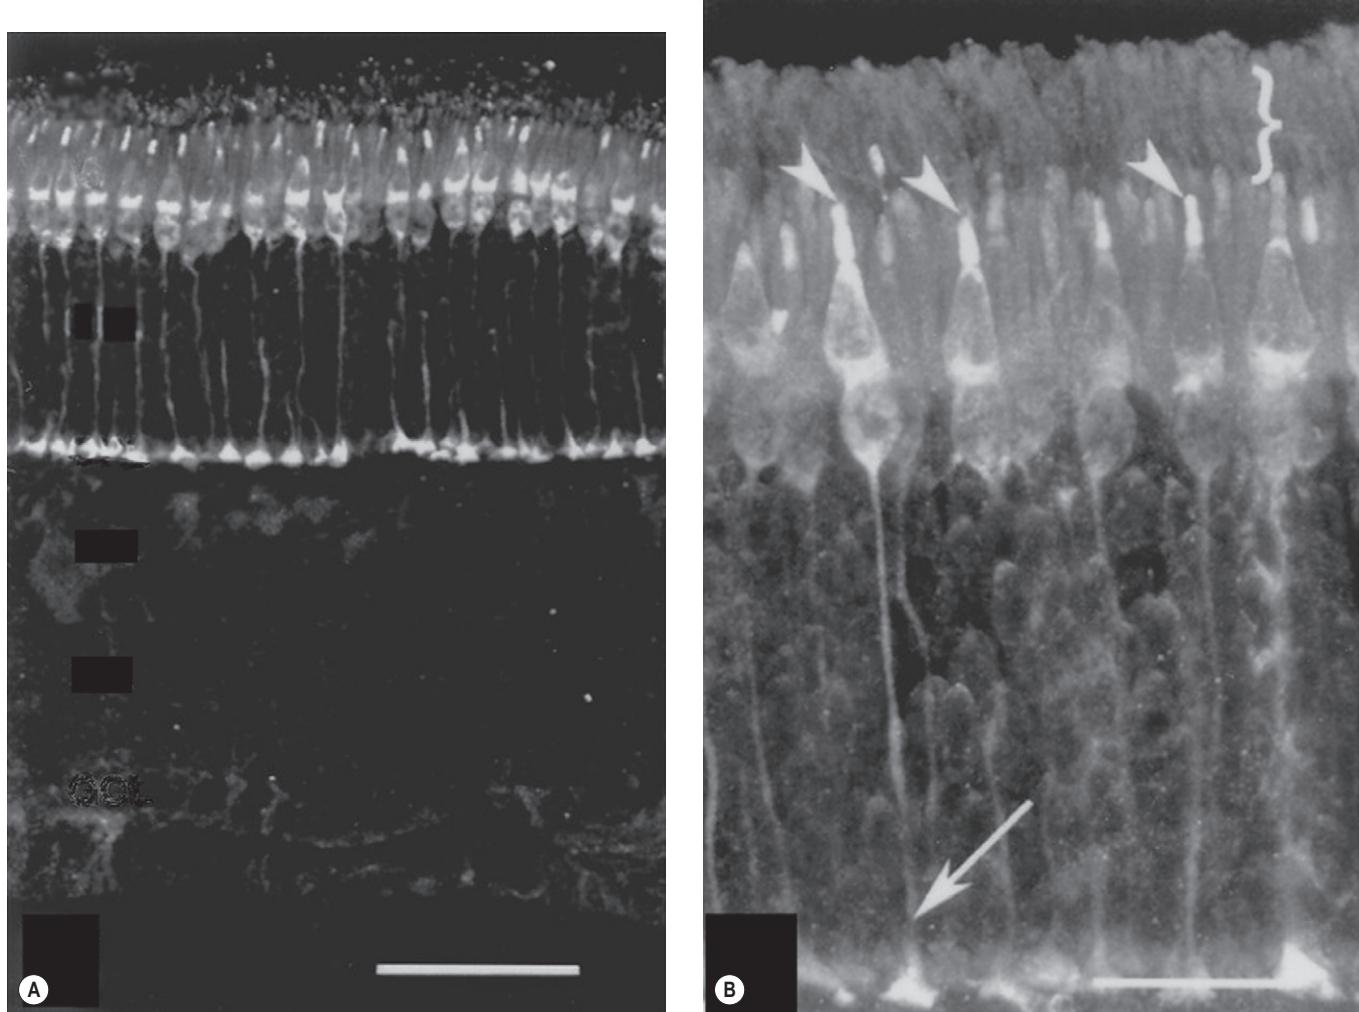

Figure 18.1 Immunofluorescence image of mammalian rods and cones. **(A)** Low magnification (scale bar, 50 μm), showing photoreceptor positions with respect to other retinal layers: OS, photoreceptor outer segments; IS, photoreceptor inner segments; ONL, outer nuclear layer (photoreceptor nuclei); OPL, outer plexiform layer (photoreceptor synapses and processes of bipolar and horizontal cells); INL, inner nuclear layer (nuclei of inner retinal neurons); IPL, inner plexiform layer (inner retinal synapses and processes); GCL, ganglion cell layers (cell bodies of retinal ganglion cells). **(B)** Higher magnification showing photoreceptors. Arrow, cone axon; arrowheads, cone outer segments; bracket, rod outer segments. The antibody used for immunofluorescence staining is specific for RGS9-1, whose concentration is 10-fold higher in cones than in rods. (Reproduced from Cowan et al 1998.⁹¹) **(C)** Schematic diagram of rods and cones and their compartments, with sizes and shapes based on a fluorescence micrograph of human retina.

(E) Magnified region of rod outer segment from transmission electron micrograph, showing the tightly packed disk membranes, and their relationship to the plasma membrane.

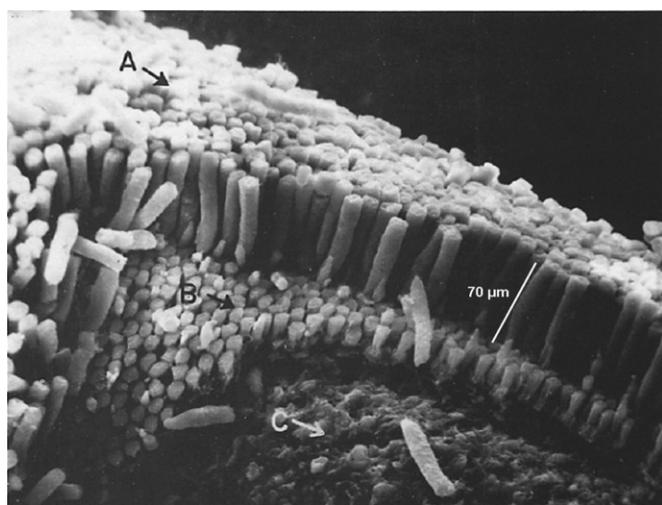

Figure 18.2 Scanning electron micrograph of bull frog outer segments. (Reproduced with permission from Bownds & Brodie 1975.¹¹³)

The resting dark-adapted state

The membrane potential

In the dark, rods have a resting membrane potential of about -40 mV.¹⁴ The negative value means that there is more positive charge on the outside of the plasma membrane than on the inside. In most resting neurons, the potential is closer to -70 mV, so rods are considered to be relatively depolarized as compared to other cells or, as we shall see, as compared to fully light-activated rods. In rods, as in other neurons, the source of membrane potential is the inequality of ion

concentrations on either side of the plasma membrane generated by the Na^+/K^+ -ATPase. This protein uses the energy released upon ATP hydrolysis to pump sodium ions out of the cell and potassium ions into the cell, and in rods it is found in the plasma membrane of the inner segment (see Chapter 19). In most neurons, potassium channels are the predominant conductance at resting potentials, and these allow potassium ions to flow out of the cell down their concentration gradient. Because these channels pass a specific cation, but no anions, a net positive charge accumulates on the outside of the membrane and a net negative charge accumulates on the inside of the membrane. This occurs until the electrical energy stored in the charge separation equals the energy stored in the potassium gradient, the relationship described by the Nernst equation, described in detail in many textbooks. Strictly speaking, this equation only works when the membrane in question contains a single type of channel permeable to only a single type of ion. In reality there are always additional minor conductances (other channels and transporters) so that the resting potential is modified by these to give the typical resting value of about -70 mV to -90 mV for excitable cells.

The dark current and the cGMP-gated channel

Rods also have a negative resting membrane potential, but its magnitude is less than in many other neurons because the effects of potassium channels in the inner segment are balanced by a major additional channel current in the outer segment. The less negative resting potential, or partially depolarized state, of rods is due to the cyclic-GMP-gated cation channel (see Chapter 19), also known as CNG channel (for cyclic nucleotide-gated) or light-sensitive channel or

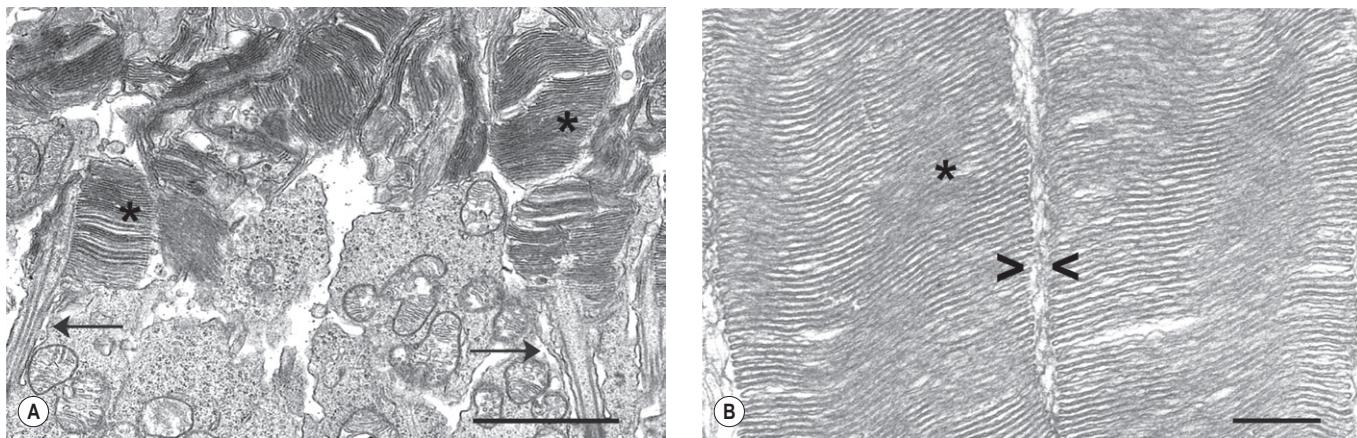

Figure 18.3 Electron micrographs showing postnatal development of outer retina in mouse. **(A)** postnatal day 10; **(B)** 5 weeks postnatal. *, rod outer segment disks; arrows, connecting cilia; arrowheads, plasma membrane separating individual rods.

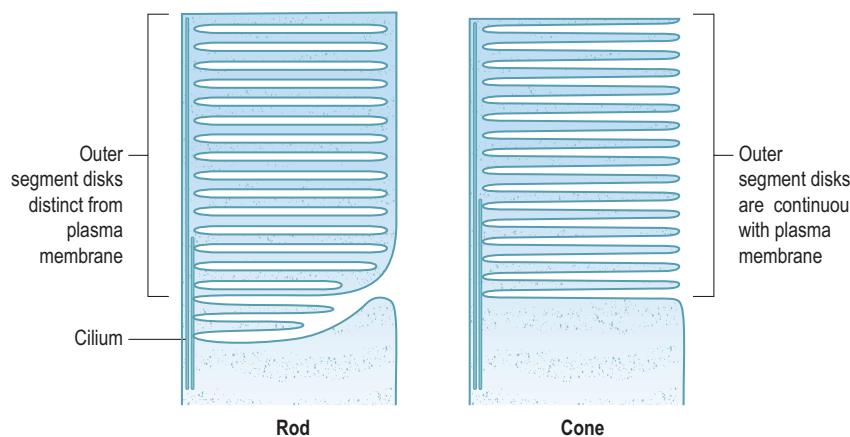

Figure 18.4 Schematic representation of base of outer segments. Both rod and cone outer segments are connected to the inner segments via the connecting cilium, or ciliary transition zone. Membrane topologies of rods and cones are similar near the base, with both rods and cones showing disk-like membranes as invaginations of the plasma membrane. Along the outer segment axis moving from the inner segment toward the distal tips, the rod disks become sealed compartments, completely surrounded by, but distinct from, the plasma membrane, whereas the cone disk and plasma membranes are continuous with the plasma membranes, and their interior is continuous with the extracellular space.

phototransduction channel (see Chapter 19). This multi-subunit channel only passes cations, but does not discriminate strictly among different cations, allowing Na^+ , K^+ , and Ca^{2+} to pass. Among physiologically important cations it has the highest permeability to Ca^{2+} , but because of its much higher concentration outside the cell (over 140 mM, as compared to ~ 1.5 mM for Ca^{2+}), Na^+ is the primary carrier of the current through the CNG channel in the dark. Because it tends to dissipate the gradient of charge, by allowing positive charge to enter the cell, the open CNG channel causes the cells to be partially depolarized. Put another way, because there are substantial inward sodium currents in the outer segment to balance outward potassium currents in the inner segment, the resting potential is moved away from the potassium "equilibrium" or Nernst potential of ~ -90 mV, and toward the sodium "equilibrium" or Nernst potential of $\sim +60$ mV. Because there is net flux of cations out of the inner segment plasma membrane, and a net flux of cations into the outer segment plasma membrane, as well as electrical conductance between the inner and outer segments, a complete circuit is made which is known as the circulating current or dark current.

Ca^{2+} and the exchanger

The CNG channel also has an influence on the concentration of Ca^{2+} , which in rods and cones, as in other cells, plays an

important role in signaling and regulation. A $\text{Na}^+/\text{Ca}^{2+}$, K^+ exchanger protein, NCKX2,¹⁵ uses the energy stored in the Na^+ gradient across the plasma membrane to push Ca^{2+} ions outside the cell, against their concentration gradient (see Chapter 19). In the absence of any inward flux of Ca^{2+} , this mechanism would lower the Ca^{2+} concentration in the outer segment cytoplasm to about 10 nM. In the dark, there is an inward leak of Ca^{2+} through the CNG channel, so the resting level of Ca^{2+} is a few hundred nanomolar.

Even though in the dark more channels are open than at any other time, because cGMP levels are at their highest, the percentage of total channels that are open is fairly small; most of the channels are closed even in the dark (see Chapter 19). One reason for this situation is that binding of more than one cGMP is necessary to give each channel a high probability of opening, i.e. the response of the channel to cGMP is non-linear and shows positive cooperativity. The other reason is that the dark concentration of cGMP is well below the concentration of cGMP at which channel opening probability is 50 percent, a number that reflects the affinity of cGMP for the channel subunits as well as the positive cooperativity. Because the dark cGMP concentration is at the low end of the dose response curve for the channel (therefore very far from saturation), even a small change in cytoplasmic concentration of cGMP can be immediately sensed as a change in

the number of open channels and therefore of the dark current.

Control of [cGMP] by guanylate cyclase and PDE6

The resting, or dark, level of cGMP is determined by the balance between the activity of the enzyme that synthesizes it, guanylate cyclase (GC),^{16–18} and the enzyme that degrades it, the cGMP phosphodiesterase, PDE6.^{19–21} Both of these have much lower activities in the dark than they do in the light. When fully activated PDE6 is one of the most efficient enzymes known, and the most active of any of the PDE superfamily of cyclic nucleotide phosphodiesterases. The maximal turnover at saturating cGMP concentrations, k_{cat} , has been reported to be between 1000 s^{-1} and 7000 s^{-1} , and the Michaelis constant, the cGMP concentration at which activity is half-maximal is about $40\text{ }\mu\text{M}$. Thus the enzymatic efficiency, k_{cat}/K_m , is thus in the range of $2.5 \times 10^7\text{ M}^{-1}\text{s}^{-1}$ to $1.75 \times 10^8\text{ M}^{-1}\text{s}^{-1}$, implying that it operates near the diffusion limit. PDE6 requires two kinds of metal ions for activity. Mg^{2+} binds reversibly along with cGMP, and Zn^{2+} is permanently bound to high affinity sites essential for catalysis.²² The other key players in photoactivation are also in quiescent states under dark conditions. The mechanisms for regulation of these enzymes by light are discussed below.

Guanylate cyclase uses GTP as a substrate, and produces cGMP and inorganic pyrophosphate as products. Inorganic pyrophosphate is rapidly broken down by the enzyme inorganic pyrophosphatase,²³ which is found at higher levels in rod outer segments than in any other cell type in which it has been measured. Guanylate cyclase is a transmembrane protein that is thought to exist in photoreceptor membranes as a dimer, with each dimer bound to the calcium binding protein, GCAP (guanylate cyclase activating protein).^{24–26} PDE6 is a heterotetrameric peripheral membrane protein consisting of two large catalytic subunits, PDE6 α and PDE6 β , as well as two smaller identical inhibitory PDE6 γ subunits. The catalytic subunits are each subject to the set of post-translational modifications associated with isoprenylation, as described below, so the enzyme is bound in a peripheral way to disk membranes. The PDE6 α and PDE6 β subunits bound in rods are similar in structure to one another, whereas in cones, two identical PDE6 α subunits are bound. PDE6 catalytic subunits are related in sequence to a large family of cyclic nucleotide phosphodiesterases, the PDE superfamily.²⁷ These share sequence similarity in their catalytic domains, where the PDE6 isoforms most closely resemble in structure the PDE5 isoforms, which are the targets of sildenafil citrate (Viagra) and other drugs used to treat erectile dysfunction. In addition to the catalytic domains, PDE6 catalytic subunits each contain two GAF domains, one of which contains a non-catalytic binding site for cGMP. Because the total concentration of cGMP-binding GAF domains in the outer segments is about $50\text{ }\mu\text{M}$, most of the cGMP in the cell is

bound to PDE6. The physiological function of these non-catalytic sites is unclear, but their occupancy is coupled to binding of the catalytic subunits by the inhibitory PDE6 γ subunit.^{28–30} It is the PDE6 γ subunit which interacts most extensively with the activated form of the G-protein, as described below.

Rhodopsin

In the dark, the photon receptor rhodopsin^{31–33} is in its inactive state^{34–36} with an inverse agonist, 11-cis retinal, covalently attached to its active site (Figs 18.5–18.7). Ligands that

activate receptors are called agonists, those that block the action of agonists are called antagonists, and those that actually reduce receptor activity below the level it has in the absence of any ligand are called inverse agonists. Rhodopsin has seven membrane-spanning helices and is a part of the G protein-coupled receptor (GPCR) super-family of signal transducing receptors. Like other GPCRs, its activity consists of its ability to catalyze the activation of a heterotrimeric G-protein. This is the activity of rhodopsin which is inhibited by the chromophore and inverse agonist 11-cis-retinal. The apo-form of rhodopsin without a ligand, known as opsin, has much higher G protein-activating activity than rhodopsin does, a fact that becomes important at high light levels but is relatively unimportant in the dark-adapted state. Rhodopsin is present at very high concentrations in the disk membrane (and somewhat lower concentrations in the plasma membrane), so that about one-third the surface area of the disks is occupied by rhodopsin, and the other two-thirds is occupied by phospholipids, cholesterol, and other minor lipids.

Rhodopsin is subject to post-translational modifications that are important for its function. N-linked carbohydrates are found on the domain of rhodopsin that faces the inside of the disks and the extracellular solution, and they appear to be important for proper transport of rhodopsin

from its site of synthesis in the inner segment to the outer segment membranes. Two palmitoyl groups are attached via thio-ester linkages to two adjacent cysteine residues near its carboxyl terminus, which tether the polypeptide chain to the cytoplasmic surface of the disk membrane forming a fourth cytoplasmic loop. In addition, the aldehyde moiety of 11-cis retinal and all-trans retinal is not bound to rhodopsin as a free aldehyde, but rather a covalent Schiff's base linkage is formed between 11-cis retinal and lysine residue 296 in the transmembrane domain of rhodopsin (Fig. 18.7).

There are 348 amino acids that comprise rhodopsin. Whereas mutations at only four different positions are found in patients with the disease congenital stationary night blindness (CSNB; Box 18.1), there are over 100 amino acid positions that are found mutated in patients with the blinding disease autosomal dominant retinitis pigmentosa (ADRP; Box 18.2). Therefore, the molecule is not only sensitive in that it can become activated with only one photon of light, it is also remarkably sensitive to its amino acid composition.

G-protein, G_t

Like rhodopsin, the G-protein, known as transducin^{37–41} or G_t (Fig. 18.9), is also found in an inactive state in the dark.

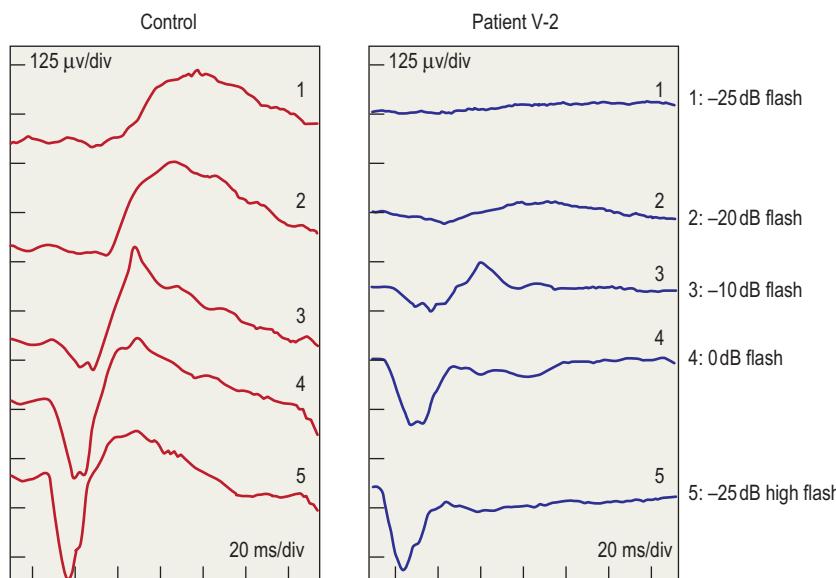

Figure 18.8 Electoretinograms (ERGs) of a patient with CNSB due to rhodopsin A295V show altered signaling. The ERG represents the massed potential changes across the retina in response to light. The early negative deflection is the a-wave, derived from hyperpolarization of the photoreceptors. The later positive deflection is the b-wave, largely derived from depolarization of ON bipolar cells, which receive inputs from the photoreceptors. Scotopic ERGs of a representative control subject (left) and a patient (right). Intensities represented are 1, 0.01; 2, 0.03; 3, 0.03; 4, 1.0; 5, 3.0 cds s m⁻². The rod response is severely diminished in the patient. (Reproduced from Zeitz et al 2008.¹¹⁷ Reproduced with permission from the Association for Research in Vision and Ophthalmology.)

Box 18.1 Congenital stationary night blindness

Congenital stationary night blindness (CSNB) comprises a group of genetically and clinically heterogeneous non-progressive retinal disorders, mainly due to defects in rod photoreceptor signal transduction and transmission. Mutations in genes coding for proteins of the phototransduction cascade (*RHO*, *GNAT1*, *PDE6B*, *RHOK*, *SAG* and *RDH5*) or genes associated with the transmission of the signals from the photoreceptors to bipolar cells (*NYX*, *GRM6*, *CANCA1F* and *CABP4*) can lead to this disease.

Night blindness, reduced or absent dark adaptation, is a typical and early sign of various forms of retinal dystrophies. Forms differ in inheritance pattern (autosomal dominant, autosomal recessive or X-linked), electroretinograms (presence or absence of a-wave), refractive error (presence or absence of myopia) and fundus appearance (Fig. 18.8). All patients with stationary night blindness have severely reduced rod ERG amplitudes and many have modestly reduced cone ERG amplitudes. Rod sensitivity in patients is decreased by 100× to 1000× compared with normals. Almost all have cone responses with a normal peak implicit time (time interval between the light flash and subsequent peak of b-wave).

For a G-protein, this means that it has GDP, rather than GTP, bound to its α subunit, $G_{\alpha\omega}$, and exists in a heterotrimeric form, $G_{\alpha\beta\gamma}$. The G-protein associates with the disk membranes by virtue of its covalently attached lipids.^{42,43} A heterogeneous mixture of saturated and unsaturated 12- and 14-carbon fatty acids are found attached to the amino terminal glycine residue of $G_{\alpha\omega}$ ^{44–46} linked through an amide bond. This reaction occurs during translation and is important for G-protein localization in the outer segment.⁴⁷ There is a 15-carbon isoprenyl group, farnesyl, attached to the carboxyl terminus of the γ subunit^{48,49} through a thioether linkage. This sort of isoprenylation is found in other phototransduction proteins; in each case it occurs at a cysteine residue four residues from the carboxyl terminus of the initial translation product. The final three residues are cleaved by the action of a protease,⁵⁰ and the hydrophobicity conferred by the isoprenyl group is enhanced by the methyl

Box 18.2 Stargardt's disease

Stargardt's disease is an autosomal recessive form of juvenile macular degeneration with variable progression and severity. It is caused by mutations in the *ABCR* (*ABCA4*) gene on chromosome 1 which encodes a retina-specific ATP-binding cassette transporter protein, in the rims of rod and cone outer segment disks, proposed to serve as a flippase protein for phospholipids conjugated to all-trans retinal. Mutations in this gene have also been attributed to some cases of cone-rod dystrophy, retinitis pigmentosa, and age-related macular degeneration. Pathologic features of Stargardt's include accumulation of fluorescent lipofuscin pigments in the retinal pigmented epithelium (RPE) cells and retinal degeneration.

An important fluorophore in lipofuscin is the bis-retinoid pyridinium salt N-retinylidene-N-retinylethanolamine (A2E) formed by the condensation of all-trans retinaldehyde with phosphatidylethanolamine. Significant accumulation of A2E is seen in the RPE of patients with Stargardt's disease.^{80,94} A2E has several potential cytotoxic effects on RPE cells, including destabilization of membranes, release of apoptotic proteins from mitochondria, sensitization of cells to blue light damage, impaired degradation of phospholipids from phagocytosed outer segments.

esterification of the carboxyl group on what has been converted into a C-terminal cysteine residue.

Importance of lipid milieu

The lipids of the disk membrane play an important role in assembling the phototransduction machinery⁵¹ and providing the proteins a stage on which to act. Rhodopsin and guanylate cyclase are transmembrane proteins, and G_t and PDE6 are peripheral membrane proteins, attached to the membrane by covalently attached lipids (Figs 18.9, 18.10). GCAPs are also covalently lipidated by fatty acids on their amino termini, and another phototransduction protein, rhodopsin kinase, is isoprenylated (discussed below). The transmembrane CNG channel is found only in the plasma

membrane, not in the disks. Experiments with purified proteins have shown that the proper assembly of these proteins on the disk membrane is essential for efficient interactions among them. Rhodopsin diffuses rather rapidly within the lipids of the disk membrane,^{52–56} so that many encounters between it and the G-protein occur every second even in the dark. ROS membranes have an unusual lipid composition, with a high content of polyunsaturated fatty acids. Close to 40 percent of the fatty acyl groups of ROS phospholipids are

the ω -3 fatty acid, docosahexaenoic acid (DHA or 22:6), which has 22 carbons and 6 double bonds.⁵⁷ DHA can only be synthesized in the body if essential ω -3 fatty acids are consumed in the diet. Cholesterol, while making up only 10–15 percent of total outer segment lipids, plays an important role in establishing the lipid environment in which phototransduction reactions occur.⁵⁶

The activation phase of a light response

Photoisomerization of rhodopsin

Phototransduction begins with absorption of light by rhodopsin (Figs 18.9, 18.11). Rhodopsin has a broad absorption spectrum with a wavelength of peak absorbance close to 500 nm in the green portion of the visible spectrum (see Fig. 18.14 below). The probability of capture by rhodopsin of a photon of green light passing through the retina is fairly

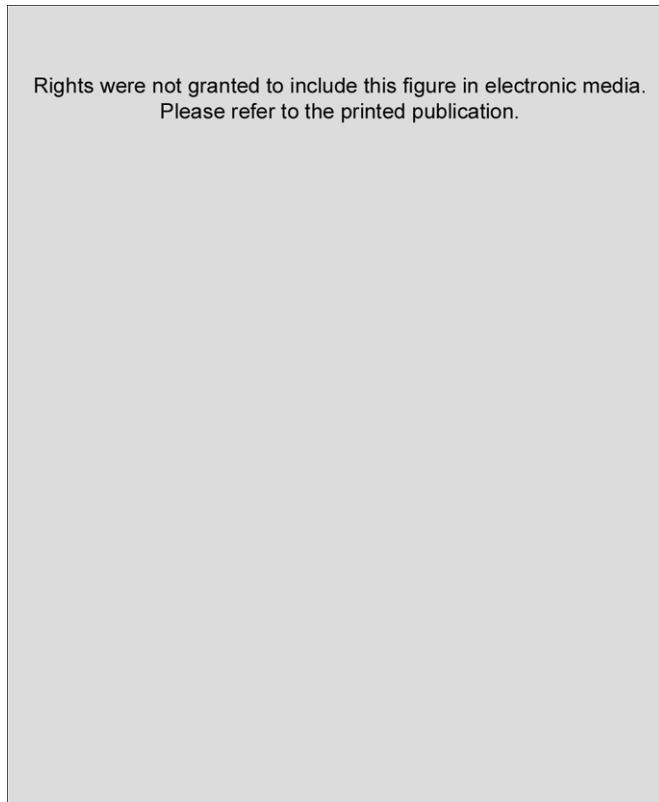

Figure 18.9 Structural models for interactions among transducin subunits, metarhodopsin II, and the disk membrane during light activation. (Modified from Wang et al 2008⁵⁶)

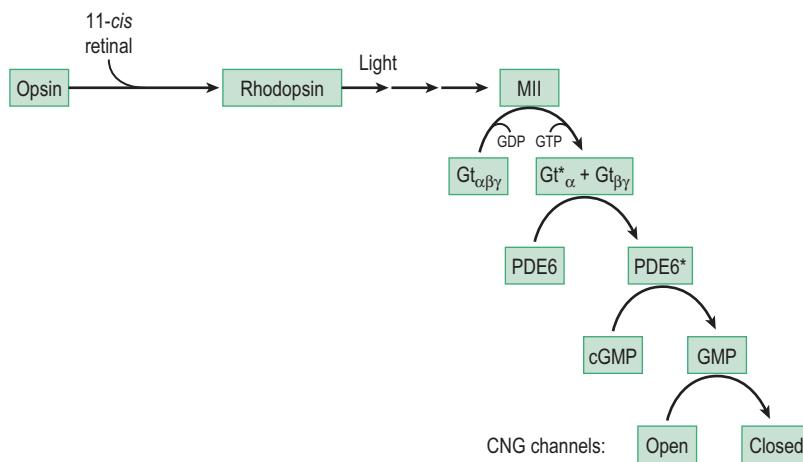

Figure 18.10 A multi-subunit complex essential for normal photoresponse recovery kinetics. PDE6 γ C-terminal fragment is shown in red space-filling representation. (Modified from Wensel 2008.⁵¹)

Figure 18.11 Schematic representation of phototransduction activation cascade.

high (~50 percent for 20 μm long human rods, and ~89 percent for 60 μm long toad rods), due to the large number of disks (~1000) through which it must pass, and the high concentration of rhodopsin in each one. When rhodopsin absorbs light, the probability that it will undergo a structural transition, or photoisomerization, is extraordinarily high: 65 percent.⁵⁸ This is one of the most efficient photochemical reactions known, and this efficiency helps explain the exquisite sensitivity of rod cells to a single photon of light. The bound 11-*cis* retinal chromophore is responsible for the light absorption (polypeptides do not absorb visible light unless they are bound to some chromophoric ligand), and in its excited state induced by the light absorption, 11-*cis* retinal undergoes a photoisomerization at the bond between carbon 11 and carbon 12 in its structure from 11-*cis* to all-*trans* retinal (Fig. 18.7). The rearrangement of bonds causes a dramatic change in the structure of retinal, with the new all-*trans* form representing a straightening out of a kinked molecule. This molecule no longer acts as an inverse agonist, but now as an agonist, or activator.

The retinal chromophore, covalently attached via a Schiff's base linkage to a lysine residue at amino acid position 296 on rhodopsin (see above), induces structural changes in the protein upon photoisomerization. After photoisomerization of the chromophore, the protein undergoes a series of conformational changes in the arrangement of its helices to accommodate this event. In other words, when retinal stretches out into the all-*trans* shape, it pushes part of the protein out of the way. These conformational changes ultimately lead to formation of Metarhodopsin II, a significantly different structure to dark rhodopsin. The intermediate conformations of photolyzed rhodopsin can be monitored by high speed and/or low temperature spectroscopy, including UV-visible absorbance, infrared, Raman, and fluorescence spectroscopies.^{59–61} These and other studies have shown that upon light activation, rhodopsin first changes to bathorhodopsin, lumirhodopsin, metarhodopsin I (MI) and metarhodopsin II (MII or R*, the form that activates transducin), and ultimately metarhodopsin III (MIII) before the all-*trans* chromophore becomes hydrolyzed, leaving the apoprotein opsin. At physiological temperatures, almost immediately upon photoactivation, MI and MII establish a dynamic equilibrium which can be monitored by the differences in their absorbance spectra. It is MII rather than MI that preferentially binds to and activates the G protein.

G-protein activation

The key functional difference between rhodopsin and metarhodopsin II is in their interactions with the G-protein transducin (G_t). MII binds to the G-protein much more tightly than does rhodopsin and serves as an efficient catalyst for the activation of G_t . G-protein activation occurs about 10 million times faster at high MII concentrations than it does in the dark.⁶² The G-protein binds to MII with GDP bound, but rapidly releases the bound GDP (Fig. 18.9). This GDP release is the slow step (~once per 10,000 s) for G-protein activation in the dark, but occurs very rapidly when G_t is bound to MII. Once GDP is released, the millimolar concentrations of GTP in the cell ensure rapid binding of GTP. Once GTP is bound to the $G_{t\alpha}$ subunit, the G-protein is in its active state. The activated $G_{t\alpha}$ -GTP complex has much lower affinity for both the $G_{t\beta}$ subunits and for MII than do either the

nucleotide-free state or the GDP-bound state of $G_{t\alpha}$. One MII molecule can activate many G-proteins in a catalytic fashion, at a rate exceeding 150 per second in mammalian rods.

PDE6 activation

When $G_{t\alpha}$ loses its affinity for MII and $G_{t\beta}$ upon binding GTP, it also gains greatly enhanced affinity for the cGMP phosphodiesterase, PDE6.^{21,63} When $G_{t\alpha}$ -GTP is bound, the catalytic activity of PDE6 goes up about one-thousand fold. This dramatic increase in enzymatic activity means that cytoplasmic levels of cGMP begin to fall rapidly in the vicinity of activated PDE6. Fully activated PDE6 is one of the most efficient enzymes known, with a catalytic efficiency, k_{cat}/K_m , of about $4 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$. This high catalytic efficiency means that nearly every time a cGMP molecule collides by diffusion with an activated PDE6 molecule, it will be hydrolyzed to form 5'-GMP. If 350 PDE6 molecules are fully activated in a single primate rod cell, they can hydrolyze most of its cGMP in one-tenth of a second.

Channel closing

Individual cGMP molecules are constantly dissociating from and binding to their sites on the CNG channel, even in the dark (see Chapter 19). Thus each CNG channel samples the cGMP concentration in the adjacent cytoplasm once every few milliseconds. For practical purposes, the channels respond immediately to the decline in cGMP in the cytoplasm, and they do this with a very steep concentration dependence, because of the cooperativity noted above. Closing of channels reduces the flow of Na^+ ions into the cell, reducing the dark current and making the membrane potential more negative (i.e. hyperpolarized). Simultaneously, the flux of Ca^{2+} into the cell is reduced as well⁶⁴ by the action of the $\text{Na}^+/\text{Ca}^{2+}$ exchanger discussed above.

Slowing of neurotransmitter release

Communication of rods with downstream bipolar cells is by the release of the neurotransmitter, glutamate. High levels of glutamate release by rods signal total darkness to bipolar cells, and reductions in the levels of glutamate release signal absorption of light. This change results from the hyperpolarization of the cell membrane, which is passively propagated along the plasma membrane from outer segment to synaptic terminal. Because rod cells are relatively short as compared to neurons with long axons, active propagation of the signal by action potentials is not needed to communicate potential changes at the outer segment to the synapse.

The recovery phase

The biochemical changes that occur during activation contain within them the seeds of destruction for the activated state; they set the stage for the recovery phase. It is simplest to consider this process, which is rather more complex than activation, in terms of recovery from activation by a single dim flash of light after which no more MII formation occurs.

Rhodopsin phosphorylation, retinoid recycling and regeneration

Because of the catalytic activity of MII, as long as MII survives intact downstream signaling will continue, and cGMP will

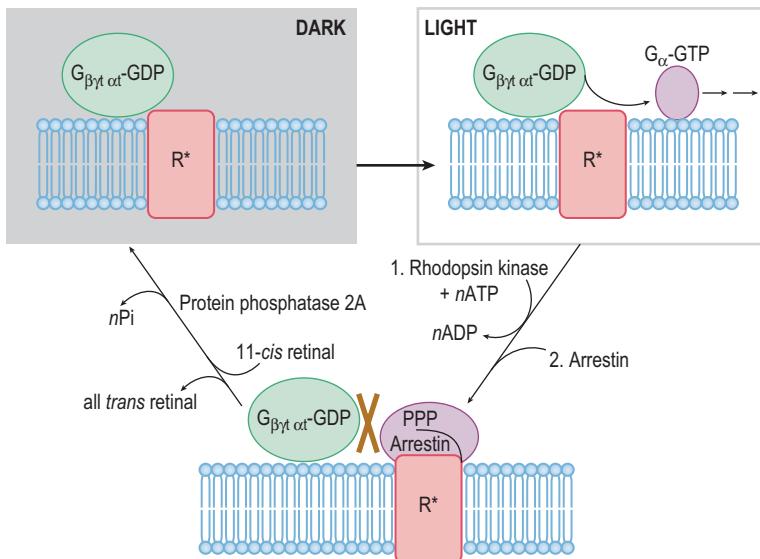

Figure 18.12 The role of phosphorylation by rhodopsin kinase in the inactivation of photoexcited rhodopsin, MII or R*. In the dark-adapted rod, rhodopsin is not the preferred substrate for rhodopsin kinase (RK), so on photoactivation and conversion to R* it catalyzes rapid guanosine diphosphate-guanosine triphosphate (GDP-GTP) exchange on G_α. Activated G_α-GTP activates cyclic guanosine monophosphate (cGMP) phosphodiesterase (PDE), leading to a closure of cGMP-gated cation channels and plasma membrane hyperpolarization. R* binds to and activates rhodopsin kinase, which uses adenosine triphosphate (ATP) to add multiple phosphates to the carboxyl-terminal region of R*, inducing a state that binds with high affinity to arrestin. Arrestin binding to phosphorylated rhodopsin effectively quenches the activity of R* until decay of metarhodopsin II and regeneration of rhodopsin lead to dephosphorylation by protein phosphatase 2A (PP2A). (Modified from Gross et al 2008.¹¹⁸)

be subject to rapid degradation. There are multiple mechanisms for inactivating MII, but the fastest-acting and most important one appears to be phosphorylation by rhodopsin kinase,⁶⁵ RK or RK1 (Fig. 18.12). Like the G-protein, RK preferentially recognizes the activated form of rhodopsin, MII. RK uses ATP to attach phosphate groups to serine residues in the carboxyl-terminal tail of rhodopsin. Up to eight phosphates may be added, and if any of the key residues are missing, MII inactivation kinetics are slowed.^{66,67} Phosphorylation of MII reduces its affinity for the G-protein, and slows the activation of the G-protein. Rhodopsin kinase is a member of a family of kinases specific for activated forms of G-protein-coupled receptors, which includes a kinase found only in cones (but not found in all species with cones), RK7.^{68,69} RK-1 associates with the disk membranes via a covalently attached farnesyl group,^{70,71} and RK7 via a geranylgeranyl group. The greater hydrophobicity of the 20 carbon geranylgeranyl group as compared to 15 carbon farnesyl moiety may enhance the efficiency of interactions between RK7 and photoexcited cone pigments.

On a slower time scale than that of phosphorylation, photo-excited rhodopsin also undergoes loss of covalently attached all-*trans* retinal. The conformational change accompanying *cis*-*trans* isomerizations and light activation renders the Schiff's base between lysine 296 and retinal accessible to water, so that unlike the dark form of rhodopsin, MII is subject to Schiff's base hydrolysis and release of all-*trans* retinal from its binding pocket. All *trans*-retinal, like other aldehydes, is a chemically reactive species that can associate with proteins in the disk membrane, including rhodopsin, and form new Schiff's base linkages to amino groups from protein lysine residues or from phosphatidylethanolamine in the lipid phase into which it segregates. The conjugate between phosphatidylethanolamine and all-*trans* retinal, sometimes referred to as APE, is the precursor of a compound known as A2E (Fig. 18.13) which accumulates in animals and human patients deficient in the product of the Stargardt disease gene ABCA4 (or ABCR, see Box 18.2). ABCA4^{72,73} belongs to a family of ATP-binding cassette transmembrane transporters which includes multidrug resistance proteins and lipid flippases. A proposed function for ABCA4

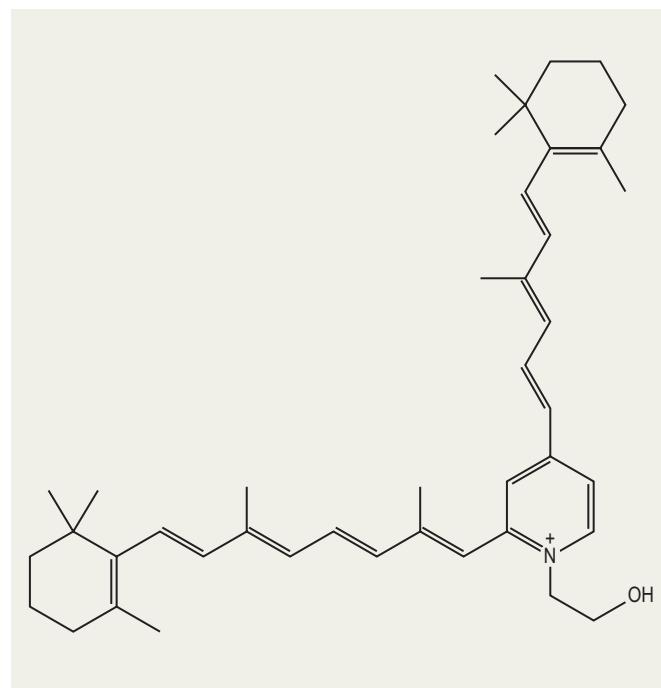

Figure 18.13 Chemical structure of N-retinylidene-N-retinylethanolamine (A2E).

is the trans-bilayer transport of APE. The aldehyde all *trans*-retinal must be converted to its alcohol form before being transported to the retinal pigmented epithelium (RPE) for recycling into 11-*cis*-retinal (see Chapter 13). This reduction reaction is catalyzed by one or more dehydrogenase enzymes, known as retinol dehydrogenases, all of which use NADPH as the reducing agent.

Opsin, whether phosphorylated or not, can bind 11-*cis*-retinal, supplied by the retinoid cycle in the RPE, to regenerate rhodopsin in its dark state. Phosphorylated rhodopsin does not bind arrestin (see below) with high affinity, and can be de-phosphorylated by the action of protein

phosphatase 2A (PP2A). Because rhodopsin with 11-*cis*-retinal bound does not activate RK, rhodopsin in the dark is predominantly in a non-phosphorylated state.

Arrestin binding

Phosphorylation of rhodopsin by RK is not, in itself, sufficient for shutting off the activity of MII completely. A key additional step is binding of the capping protein, arrestin.^{74,75} When MII is multiply phosphorylated, arrestin binds very tightly and blocks further binding and activation of G_t (Fig. 18.12). This MII is unable to propagate phototransduction due to steric hindrance of the G_t binding site. Eventually, all-*trans*-retinal will be removed by hydrolysis of the Schiff's base linkage and dissociation from the protein, yielding opsin, from which arrestin will dissociate and phosphates will be removed by a phosphoprotein phosphatase. This latter series of reactions occurs on a much longer time scale than the recovery from a dim flash excitation, as does regeneration of rhodopsin by binding of 11-*cis*-retinal to opsin (see discussion of dark adaptation below). Arrestin is a 48 kDa protein also known as 48 K or S-antigen, the latter a reference to its involvement in experimentally induced autoimmune uveitis.

cGMP restoration by guanylate cyclase activation

On an even faster time-scale than MII activation,^{76,77} changes in guanylate cyclase activity occur via a calcium-feedback mechanism that serve to halt the lowering of cytoplasmic [cGMP] and eventually restore it to dark levels. The calcium feedback consists of a lowering of cytoplasmic [Ca²⁺] that in turn activates guanylate cyclase.⁷⁸ The mechanism by which [Ca²⁺] is lowered is simply that the Na⁺/Ca²⁺ exchanger continues to pump Ca²⁺ out of the cell while the leak of Ca²⁺ into the cell through the CNG channels is reduced or blocked when the channels close (see Chapter 19). Changes in [Ca²⁺] work through calcium binding proteins⁷⁹ known as GCAPs (guanylate cyclase binding proteins), members of the calmodulin superfamily of calcium-binding proteins. They bind to GC and keep its activity low when they have calcium bound, but dramatically enhance its activity when [Ca²⁺] becomes low. Ca²⁺ inhibition of the GCAP-GC complex is also co-operative, so that the dependence of GC activity is very steeply dependent on Ca²⁺ concentration. This cooperativity allows very rapid changes in GC activity in response to changes in CNG channel current. GC activation through Ca²⁺ feedback begins to balance the activation of PDE6 in less than 100 ms after a dim flash (in mice), and eventually restores [cGMP] to the resting, dark, level.

The retinal photoreceptor guanylate cyclase (GC) isoforms^{26,80–83} are members of a family of transmembrane or particulate guanylate cyclases, some of which, unlike the photoreceptor isoforms are receptors for peptides or other extracellular ligands. Transmembrane GC enzymes are found in membranes as dimers. Each GC polypeptide has a glycosylated extracellular domain, which participates in dimer formation, a single transmembrane alpha-helix, and intracellular domains. The intracellular domains include a kinase homology domain, a dimerization domain, the catalytic domain, which is responsible for the production of cGMP, and a C-terminal domain which may mediate interactions with proteins at the cytoplasmic surface of the membrane. The GCAP proteins, which have fatty acids attached to their

amino termini, remain bound to GC even at low concentrations of intracellular Ca²⁺. Binding of Ca²⁺ changes their conformation in such a way as to allow dramatic stimulation of the activity of GC.

There are two isoforms each of GC and GCAPs in human photoreceptors and most mammals. The importance of GC1 (also known as GCE or retGC1 or ROS-GC1) in human phototransduction is underscored by mutations in the gene (GUCY2D) encoding this protein which causes Leber's congenital amaurosis (LCA) in human patients.^{84,85} The importance of GCAP1 is underscored by the association of mutations in GCAP1 with autosomal dominant cone dystrophy.⁸⁶ In mice, a double-knockout of the GCAP1 and GCAP2 genes, which are in close proximity on the chromosome, leads to dark-adapted rod flash responses that are much slower and larger in amplitude than those in wildtype rods. Transgenic expression of GCAP2 only partially rescues this phenotype, whereas GCAP1 expression appears to provide complete rescue if expression levels are sufficient.⁸⁷

G-protein and PDE6 inactivation by RGS9-1

Even after MII has been quenched by phosphorylation and arrestin binding, signaling continues as long as GTP remains bound to the G-protein so that PDE6 remains in an activated state. The dark GDP state of G_{ta} is restored through hydrolysis of the bound GTP. Once phosphate is released, causing a conformational transformation in G_{ta} that restores its affinity for G_{bγ} and dramatically lowers its affinity for PDE6, PDE6 returns to its dark inactive state. This GTP hydrolysis step is the slowest step^{88,89} in rod vision (time constant of about 200 ms in mammals and about 2 s in amphibians), and is regulated by a complex of proteins that act as GTPase accelerating proteins (GAPs). The core of this complex is RGS9-1,^{90,91} a member of the regulator of G-protein signaling (RGS) family of GAPs found only in photoreceptor cells (Box 18.3). It is always bound to two obligate subunits G_{β5L}, and a trans-membrane anchor protein R9AP. G_{β5L}^{92,93} is a member of the G-protein β subunit family, but its function is distinct from the other four members which bind very tightly to G-protein γ subunits and help G-protein α subunits couple to receptors. Rather, G_{β5L} binds tightly to a G-γ-like domain,⁹⁴ or GGL domain, found in the R7 family of RGS proteins. G_{β5L} binding is important for stability and specificity of RGS9-1 and other R7 RGS proteins, which tethers the complex to the disk membrane. This complex binds to the G_{ta}-GTP-PDE6 complex and stimulates rapid hydrolysis of GTP by G_{ta} (Fig. 18.10), with the result that PDE6 activity falls to its dark levels and cGMP levels recover to what they were before the flash. As the slowest step in the recovery phase concludes, CNG channels are once again open to the same extent as before the flash, and both the membrane potential and [Ca²⁺] have recovered as well (see Chapter 19).

Amplification

One of the most remarkable features of rod vision is that all the events described above can be triggered in a robust way by an individual photon activating a single molecule of MII within a rod cell. Rod cells thus achieve the quantum limit of sensitivity, the ability to sense and communicate the presence of a single photon of light. One reason for this ability

Box 18.3 Bradyopsia

Patients with bradyopsia, or slow vision, show a prolonged response suppression in electroretinogram recordings. Bradyopsia is a recently discovered rare genetic disorder of the retina characterized by an inability to rapidly shut off the phototransduction cascade following the stimulation of the photoreceptors by a photon of light. Patients present with symptoms of photophobia, problems adjusting to bright light, and difficulties seeing moving objects; they often complain that they cannot play ball sports such as soccer, as they cannot see the ball in motion.¹¹⁹ The mutation in these patients is in the *RGS9* (regulator of G-protein signaling 9) gene, the product of which is involved in the deactivation of photoreceptor responses (Fig. 18.12), or in the gene encoding R9AP, the RGS9-1 anchor protein, whose presence is essential to prevent degradation of RGS9-1. The discovery of bradyopsia and its molecular basis provides a fascinating insight into the ever-expanding role of medical genetics and animal models of human disease.

When the *RGS9* gene was first discovered as one encoding a key player in phototransduction, it was recognized as a candidate gene for human retinal disease. However, sequencing of DNA from numerous patients with hereditary retinal degenerations uncovered polymorphisms in the *RGS9* gene, but none with any disease association.^{120,121} Results from mice engineered to have a genetic defect in their *RGS9* gene revealed that homozygotes suffered not from retinal degeneration, but from slowed recovery from light responses in rod and cone photoreceptors. R9AP knockout mice had retinal phenotypes almost identical to those of *RGS9* knockouts. These findings led researchers at the Massachusetts Eye and Ear Infirmary to search through patient records and the ophthalmological literature for patients whose ERG results resembled those of the knockout mice. This work, combined with DNA sequencing led to the discovery of this previously uncharacterized disease.¹²²

is the multiple stages of amplification achieved by the catalytic activity of phototransduction components. A single MII molecule can produce many activated G_{α} -GTP molecules. Each of these, when bound to PDE6, can destroy thousands of cGMP molecules per second. Each cGMP molecule removed from the cytoplasm by hydrolysis decreases the number of open channels, each one of which passes nearly 2000 positively charged ions per second. Moreover, the cooperativity of the channel means that a 10 percent change in [cGMP] yields a nearly 30 percent change in the number of open channels. Depending on the species and their rod geometry, the overall gain in terms of numbers of ions blocked per rhodopsin photoisomerized is between 5×10^5 and 10^7 .⁹⁵ These staggering numbers would seem to make it obvious why a single photon can be detected, but there is one problem that always accompanies amplification: noise is amplified along with the signal. Ultimately, reliable detection depends not just on a strong signal, but on a high signal-to-noise ratio. There are many sources of noise in the phototransduction cascade, and detailed studies suggest that many of the features of the phototransduction cascade and the molecules that mediate it have evolved to minimize noise. Individual rods produce false single-photon-like signals with a frequency of about once every 160 seconds, making it difficult for us to discriminate real light from darkness at intensity levels below that needed to induce single photon responses with this frequency.

Responses to saturating light levels

When light levels exceed that needed to photoisomerize one rhodopsin in every 10,000 (0.01 percent), nearly all the cGMP in the cell is hydrolyzed, pushing the concentration near zero, and all the channels close, completely shutting off the dark current. Beyond this intensity, increasing the light intensity only accelerates the kinetics of the rising phase, and prolongs the time in saturation. As described in Chapter 19, following a flash of saturating intensity, further rod responses cannot be elicited until several seconds later when the cell has recovered from the initial response. Over a fairly wide range of intensities, the time from the flash to recovery of the dark current to a criterion level (e.g. 90 percent or 50 percent) is linear with the logarithm of the flash intensity,⁹⁶ indicating a single exponential process, characterized by a "dominant time constant,"⁹⁷ which represents the slowest step in the transduction cascade over that intensity range. Results from transgenic mice with increased levels of the RGS9-1 GAP complex⁸⁸ have revealed that the levels of this complex, and therefore, the kinetics of GTP hydrolysis by G_{α} determine the timing of the slow step in photoresponse recovery, and therefore the time resolution of rod vision.

Adaptation to changing levels of ambient lighting (see Chapter 20)

In the presence of even a fairly dim background light, the responses of rods to increments in intensity are attenuated and accelerated relative to those obtained in completely dark-adapted conditions. This desensitizing effect becomes more pronounced as the intensity of the background light increases. These changes are referred to as light adaptation. The changes are reversible upon return to darkness, with the return of sensitivity occurring over a time scale of minutes, proceeding through both fast and slow phases. This restoration of sensitivity is referred to as dark adaptation. The slow phase of dark adaptation is usually attributed to the regeneration of rhodopsin from opsin that has been formed by prolonged exposure to bright light, i.e. the rebinding of 11-cis-retinal to the pool of apoprotein formed in bright background light. Light adaptation can be observed on a time scale of seconds, and while it is not completely understood, appears to result from changes at several steps in the phototransduction cascade. The most important of these is simply an acceleration of cGMP hydrolysis and synthesis caused by PDE6 activation and low-[Ca²⁺]-induced guanylate cyclase activation. Because these reactions are already proceeding at a fast clip due to the background light, further increases in light elicit lower amplitude responses, but these occur more rapidly. In addition, the low [Ca²⁺] present under these conditions may modulate the activity of rhodopsin kinase, the CNG channel, and the RGS9-1 GAP complex.

Turnover of guanine nucleotides

While light greatly accelerates the turnover of guanine nucleotides in photoreceptors, even in the dark there is a very high rate of flux through cycles of synthesis and hydrolysis.⁹⁸ Although each PDE6 molecule may have only 0.1 percent or so of its maximal enzymatic activity in the dark, the high concentration of PDE6 (on the order of 20 μM) and its high enzymatic efficiency means that the entire cellular pool of

cGMP in a mammalian rod is hydrolyzed at a rate of about once every 2.5 seconds. This hydrolytic flux is balanced by continual cGMP synthesis catalyzed by guanylate cyclase to achieve a constant steady-state level of cGMP in the dark. This dark cycling through cGMP consumes high amounts of GTP, which must be continually replenished by energy metabolism. To that end photoreceptors can use both aerobic respiration by dense concentrations of mitochondria in the region of the inner segment proximal to the outer segment, and glycolysis, whose enzymes are found in both the outer and inner segments. GTP is produced from GDP and inorganic phosphate, Pi, in the citric acid cycle by the action of succinate dehydrogenase, from GDP and ATP by the action nucleoside diphosphate kinase, and from two molecules of GDP by the action of a GDP phosphotransferase.⁹⁹ This apparent futile cycling and squandering of cellular energy sources may seem wasteful. However, it likely contributes to the speed of phototransduction, and its cost in terms of ATP use is dwarfed by the needs of the Na⁺/K⁺ ATPase pump in the inner segment.

Comparison of cones and rods

Similarities and differences of phototransduction molecules

Many of the phototransduction molecules of rods have homologs that perform similar functions in cones. The cone pigments, which are very similar in structure to rhodopsin have different absorption spectra, and different photophysical properties (Fig. 18.14). The thermal isomerizations rates of cone pigments are higher than those for rhodopsin,¹⁰⁰ as are the rates of spontaneous dissociation of 11-cis-retinal.¹⁰¹ The evolution of different absorption spectra, known as spectral tuning, for the color pigments and rhodopsin arises due to varying amino acid side chains in and near the chromophore binding pocket. Pioneering work by George Wald¹⁰² (for which he shared the Nobel Prize in Physiology or Medicine in 1967;¹⁰³), Ruth Hubbard³⁵ and others showed that rod cells are most sensitive to green light (absorbance

maximum around 498 nm), and are not sensitive in the red (wavelengths longer than 640 nm). Many studies have addressed the molecular mechanism of spectral tuning, and it has been determined that the protonation state of the Schiff's base, as well as the polarity of the amino acids adjacent to it, dictate whether the absorption spectrum of the photoreceptor will shift to the blue (short wavelengths) or to the red (long wavelengths) (Fig. 18.14).^{104–109}

The G-protein subunits of rods and cones are distinct but closely related. Cone G_{αt} is known as G_{αt2} or cone transducin, and is 81 percent identical to rod transducin. Rod transducin's beta subunit is G_{β1}, whereas cone transducin uses G_{β3} which has 83 percent sequence identity. The rod G_γ and cone G_{γ8} subunits are less than 40 percent identical; both undergo proteolytic cleavage of three residues, farnesylation, and methyl esterification at their C-termini.

Unlike rods, in which there are two related but distinct PDE6 catalytic subunits, PDE6_β and PDE6_α, cones contain a single PDE6_α subunit, which forms a homodimer that together with two copies of cone-specific PDE6_{γC} forms the holoenzyme heterotetramer. The CNG channel has cone-specific α and β subunits. Both rod rhodopsin kinase, GRK-1 and a cone-specific rhodopsin kinase, GRK-7 are found in cones, and there is a cone-specific form of arrestin. The RGS9-1-G_{β5}-R9AP complex is identical in composition in cones (except that some of the G_{β5} is a shorter splice variant not found in rods), but is present at ten-fold higher levels in cones than in rods,^{91,110} to allow the fast kinetics described below.

Physiological differences

Cones are much less sensitive than rods, they have much faster kinetics, and they are nearly impossible to saturate even in bright sunlight. The reasons for these differences are currently the subject of research in numerous laboratories and remain controversial. However, most current data point away from the reactions of the activation phase. The quantum sensitivity of the cone pigments is very similar to that of rhodopsin, as is their efficiency at activating the G-protein. The cone PDE6 has similar kinetic properties to those of the rod isoform, and the CNG channels have similar responsiveness to cGMP. Rather, most research points toward faster mechanisms for shutting off the response as the major sources for differences in kinetics and sensitivity between rods and cones. These include, possibly, faster phosphorylation of the activated cone pigments as compared to MII phosphorylation,^{111,112} faster dissociation of all-trans-retinal, and faster G-protein GTP hydrolysis, driven by ten-fold higher concentrations of the RGS9-1/G_{β5}-R9AP GAP complex in cones than in rods. Low activity (poor G-protein activation) of bleached pigment (opsin-like apo-protein or phosphorylated and arrestin-capped forms) may also play a role in preventing saturation of cones.

Phototransduction and disease

The major classes of disease resulting from defects in phototransduction include retinal degeneration, night blindness, color blindness, and achromatopsia (Box 18.5). Of these, each of the heritable diseases, except for X-linked color

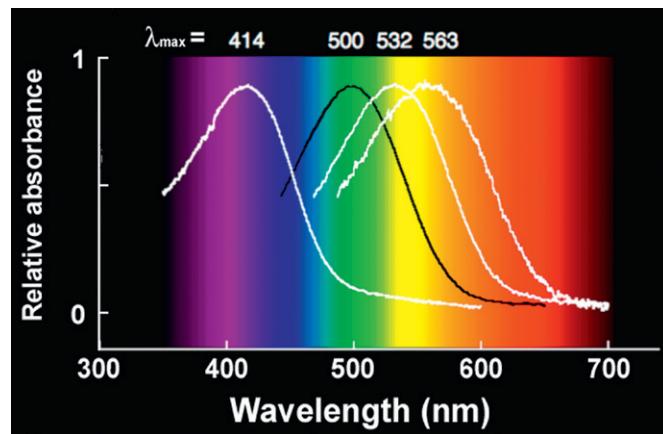

Figure 18.14 Absorption spectra of rhodopsin and the red-sensitive (L), green-sensitive (M) and blue-sensitive (S) cone pigments. (Courtesy of Dr. Masahiro Kono.)

blindness, is quite rare, but in total these conditions affect many thousands of patients who suffer various degrees of visual impairment.

Retinal degeneration and night blindness

Retinal degeneration is a progressive loss of visual function, usually accompanied by death of both rod and cone photoreceptor cells, which can lead to severe visual impairment and complete blindness. Such conditions are classified under a variety of names according to the appearance of the retina and pathology of the disease. Hereditary degenerative disorders, including retinitis pigmentosa (Fig 18.15), can arise from mutations in genes encoding photoreceptor proteins, as well as from mutations in many other non-phototransduction genes (see Box 18.4). Many such mutations have been identified in humans and animals, and lists of these can be accessed on the web site for the Retinal Information Network: <http://www.sph.uth.tmc.edu/Retnet/> or the site for the Ocular Molecular Genetics Institute: <http://eyegene.meei.harvard.edu/>. Among the phototransduction proteins discussed above, retinal degeneration has been linked to defects in the genes encoding rhodopsin, PDE6, guanylate cyclase, CNG channel, guanylate cyclase, and guanylate cyclase activating proteins (GCAPs). Congenital stationary night blindness, an absence or severe deficiency in rod vision (referred to as "stationary" because it does not progress) has been linked to genes encoding rhodopsin, the transducin (G-protein) alpha subunit, rhodopsin kinase and arrestin.

What we don't know

Although the basic biochemistry of the major events in phototransduction is fairly well understood, most of the structural and mechanistic details remain to be determined. Although some hints are available, we do not know exactly how MII activates the G-protein or how the G-protein activates PDE6. Many of the biochemical events are mediated

Box 18.4 Retinitis pigmentosa

Retinitis pigmentosa (RP) is a progressive rod-cone dystrophy that presents with progressive field loss and eventual visual activity decline. The worldwide prevalence of RP is 1 in 4000 individuals.¹²³

Typical symptoms include night blindness followed by decreasing visual fields, leading to tunnel vision and eventually blindness. Clinical hallmarks include gradually increasing bone-spiculed pigmentation, attenuation of retinal vasculature, waxy disc pallor, as well as diminished, abnormal or absent electroretinograph responses. Typically, symptoms start in the early teenage years, and severe visual impairment occurs by the ages of 40 to 50. There are early-onset forms of RP, with the underlying genetic cause proving to be a useful predictor of the severity of the disease.

The earliest of symptoms, measurable before visible onset of the disease, are abnormal light-evoked ERGs.¹²⁴ The ADRP form is less prevalent and less severe than the recessive form and has been linked to a variety of genes involved in phototransduction or rod cell function. The most prevalent mutation in human ADRP patients, in which Pro23 is replaced by His (P34H) in the rhodopsin gene, has been identified in ~15 percent of ADRP families in the United States. A comprehensive list of genes causing RP and other retinopathies can be found at the RetNet website (<http://www.sph.uth.tmc.edu/Retnet/>). In addition to simple forms of RP, there are syndromes involving pleiotropic effects (FIX). The most frequent form of syndromic RP is Usher syndrome. This disease presents as early-onset hearing loss followed by development of RP in the teenage years.¹²⁵

by large membrane-attached multi-protein complexes, but we do not know how these are organized. For example, during the rate limiting step of vision, G-protein GTP hydrolysis, a minimum of eight different polypeptides ($G_{\alpha}\beta$, PDE α , PDE β , 2 PDE γ , RGS9-1, G β 5, R9AP) are present, and we have no idea how they are arranged on the surface of the disk membrane. The multisubunit CNG channel, and Na/Ca exchanger are associated with one another in the plasma membrane, and tightly attached to proteins in the disk rims, but the structures of these complexes are also unknown. Rhodopsin can form ordered rows of dimers in isolated disk membranes, but the physiological roles of these arrays and of the dimers themselves remain controversial. These structural questions remain an active area of current research.

There are also many remaining questions about the inactivation phase of the light response and about the events of light and dark adaptation. For example, the active lifetime of MII molecules seems to be under much more stringent control than would be expected for an excited species whose inactivation occurs by way of a randomly timed event such as phosphorylation or any other chemical reaction. Modeling studies suggest that multiple sequential chemical changes are needed to explain what is known as the reproducibility of the single photon responses. Studies of the kinetics of rhodopsin phosphorylation have mostly been carried out at very high levels of MII formation, under conditions very far from single photon responses; so how MII phosphorylation proceeds at very low light intensities and how it is influenced by $[Ca^{2+}]$ remain controversial topics for further research. Certain features of long-term light adaptation are still without a molecular explanation.

Box 18.5 Cone-specific disease

Whereas retinitis pigmentosa and CSNB are thought of as diseases that primarily or initially affect the rods, there are additional hereditary visual disorders that primarily target cones. These include color-blindness (see Chapter 19), achromatopsia (see Chapter 19), cone- or cone/rod dystrophies, and inherited forms of macular dystrophy. Numerous genes have been implicated in these diseases, and these include some cone-specific phototransduction genes, including cone pigment genes, cyclic nucleotide gated channel subunit genes, a gene encoding cone-specific G protein, GCAP genes, and genes encoding potassium and calcium channels. In addition to *ABCA4*, discussed above, a gene encoding a fatty acid elongase, *ELOV4*, has been implicated in Stargardt-like macular dystrophy.

There is only a partial understanding of how the levels of the phototransduction proteins are regulated, even though it has been known for years that the levels of many of them are remarkably constant under a given set of conditions, but can vary in response to genetic defects or metabolic stress. Our understanding of how the phototransduction proteins are selectively transported to the outer segments from their sites of synthesis in the inner segment, and how they are kept there, is still at a rudimentary stage. In recent years there has been much interest in the migration during prolonged bright illumination of the G-protein transducin from the outer to the inner segment, and the movement of arrestin, under the same conditions, from the inner to the outer segment. The mechanisms by which these dramatic changes are achieved and their physiological significance are still under study.

One of the most important remaining areas of inquiry has to do with the connection between phototransduction and disease. Although defects in phototransduction components are known to lead to retinal degeneration, the molecular mechanisms by which cell death occurs are very poorly understood. It will be very important to understand these mechanisms in order to develop new therapeutic interventions, and to discover common pathways that might some day lead to therapies that could be applied to a number of different degenerative disorders.

Where the field is headed

The study of phototransduction is quite satisfying, because each new piece of information can be fitted into an overall scheme that is very comprehensive. It is like working on a jigsaw puzzle that is one-third to one-half finished. Each new piece of the puzzle can often be fit into the emerging picture and immediately reveals something new about the scene. The field at present is shifting: from the activation phase, whose mechanisms are fairly well understood, to the recovery phase, which holds more mysteries; from rods, whose properties make them easier to study, to cones, which present greater challenges; from the functions of proteins in the outer segments to understanding how they are transported and maintained there and how they are organized; from functioning of normal photoreceptors to how their malfunctioning leads to disease. There will be many exciting

opportunities for discovery in these areas in the coming years.

Photoreponses of Rods and Cones

Peter R. MacLeish & Clint L. Makino

Retinal rods and cones are highly specialized neurons that respond to light with an electrical signal (see Chapter 18) and provide the sensory input for vision. In contrast to most other neurons, rods and cones maintain a relatively depolarized membrane potential at rest (in darkness) and when stimulated (by light) decrease Na^+ entry by closing ion channels. In turn, the resultant hyperpolarization closes Ca^{2+} channels at the synapse and the ensuing fall in intracellular Ca^{2+} reduces an ongoing vesicular release of neurotransmitter onto second-order neurons (see review¹). This chapter describes the signaling properties of rods and cones, which subserve vision in dim and bright light, respectively. An overview of the voltage changes induced by light will be followed by a description of the properties of the photocurrent from which the voltage response originates and then an explanation of how voltage-dependent, inner segment conductances shape the final voltage response. For readers interested in the underlying molecular designs and mechanisms, summaries on ion channels and exchangers are included. Even though the retinal photoreceptors of all vertebrates operate similarly, there are some qualitative as well as quantitative differences. So wherever possible, we will focus on primate photoreceptors.

Photovoltage response to flashes

In darkness, rods and cones maintain a membrane potential near -40 mV .² When stimulated by flashes, rods and cones do not "fire" action potentials but instead respond with graded hyperpolarizations (Fig. 19.1)³ that in some cells, exceed 25 mV .⁴ The hyperpolarization then spreads passively to the synapse. In comparing rod and cone responses, the latter are considerably faster and require many more photons. Photoisomerization of 75 rhodopsins gives rise to a half maximal response in rods whereas in cones, it takes close to a thousand photoisomerizations (estimated from^{2,5}).

The amplitude of the single photon response in rods is about a millivolt, a few percent of the maximal response.^{2,4,6} Its time to peak of 200 ms or more is relatively slow considering that Olympic sprinter Usain Bolt covered more than two meters in that span of time. The response recovers even more slowly and may take over a second to disappear. The slow

time course of the single-photon response provided compelling evidence for an internal, second messenger(s) and for amplification steps in the signaling pathway. The duration can be specified as an integration time, calculated by dividing the response integral by the peak amplitude. For rods, the integration time of the quantal response is several hundred ms. Although cones are less sensitive than rods, they too "respond" to single photons, but the amplitude of their quantal response is much smaller and does not emerge from the baseline noise.² The cone response is faster, with a time to peak of 30 ms and an integration time of only 25 ms .^{5,7} Response kinetics and sensitivity are intimately linked and the relationship will be discussed below (see also Chapter 18). The waveforms of rod and cone flash responses change with flash strength. Responses peak sooner and the initial recovery is faster as the flash strength increases but with responses greater than half maximal, recovery stalls to a plateau before the final recovery. In cones, the recovery overshoots the baseline before the final recovery, while in rods, the plateau slowly returns to baseline without an overshoot.

Background light attenuates the response to a flash as the cells adapt (for discussions of the underlying mechanisms, see Chapters 18 and 20). The dim flash response reduces in size by two-fold with a background producing ~ 150 photoisomerizations per second in rods and ~ 8700 photoisomerizations per second in cones.⁷ The latter value obtains for an isolated cone. In reality, light has a greater effect on the cone response because of electrical coupling between rods and cones in the retina (see Chapter 22). Background light quickens flash responses in rods, but has little effect on response kinetics in cones (ignoring the rod component of the response in cones communicated electrotonically).

Photocurrent response to flashes

The photon response derives from a decrease in the number of open cyclic nucleotide gated (CNG) channels that perturbs the flow of ions across the plasma membrane and shifts the transmembrane potential to more negative voltages. CNG channels are located exclusively in the outer segments of rods and cones. In darkness, a small fraction of the

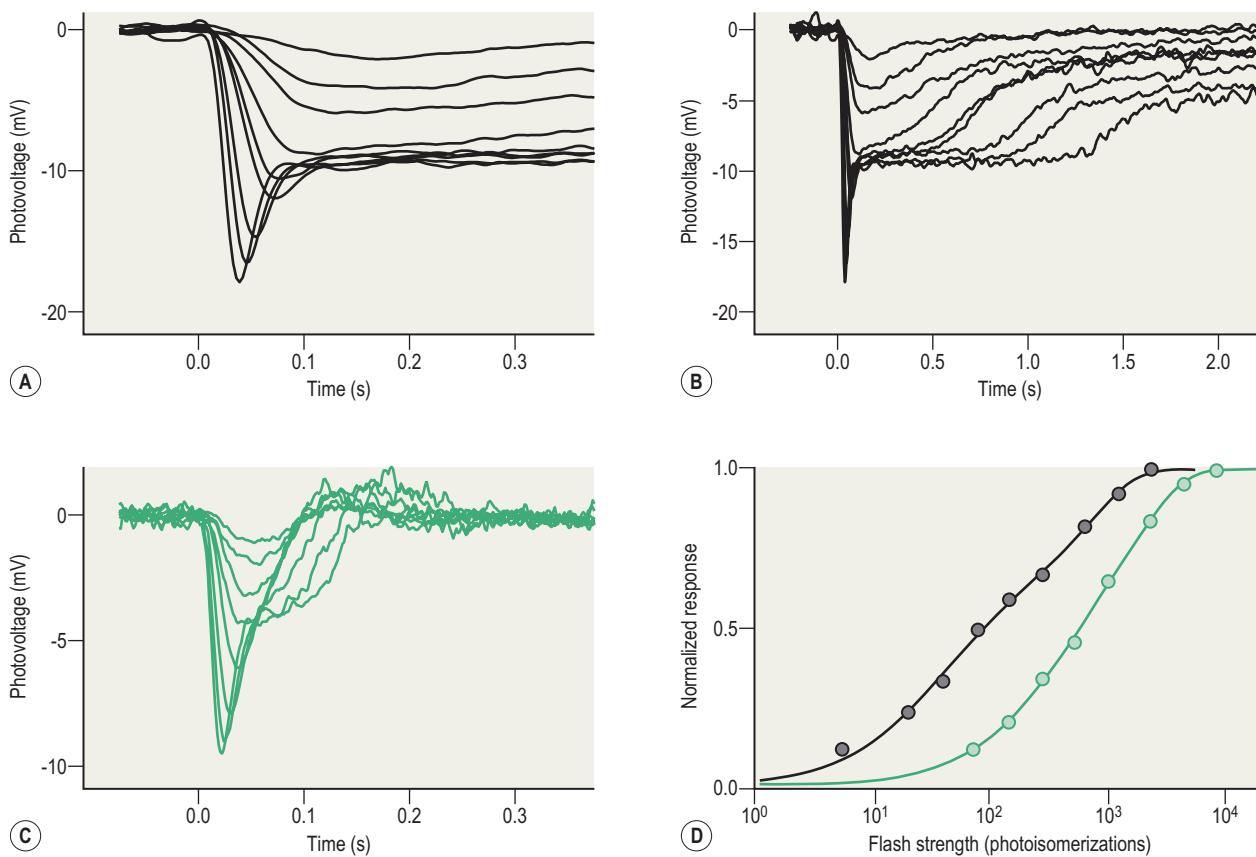

Figure 19.1 Faster voltage responses in a rod (**A**, **B** on two different time scales) than in a cone (**C**) to flashes. Photovoltage is the change in membrane potential induced by a flash, given at time zero. (**D**) The stimulus-response relation of the cone (green circles) is to the right of that of the rod (black circles), reflecting the lower sensitivity of the cone. Each response has been divided by the maximal, saturating response for that cell. (Panels A and B from Schneeweis DM and Schnapf JL: Photovoltage of rods and cones in the macaque retina, *Science* 268: 1053–1056, 1995. Reprinted with permission from AAAS;² reprinted with permission from AAAS. Panels C and D courtesy of D. Schneeweis, University of Illinois at Chicago and J. Schnapf, University of California at San Francisco, unpublished results.)

channels are in the open state, allowing an influx of cations. The intracellular concentration of Na^+ is low while that of K^+ is high relative to the extracellular space due to the action of Na^+/K^+ -ATPases in the inner segment. Thus Na^+ and also some Ca^{2+} ions flow in through the outer segment channels. K^+ ions flow out through leak and voltage-gated ion channels in the inner segment to complete the electrical circuit, which is referred to as the “dark” or circulating current (Fig. 19.2). Light absorbed by a visual pigment molecule in the outer segment closes CNG channels in an annulus of plasma membrane surrounding the site of photon absorption on the disk membrane.^{8–10}

When two photons are absorbed, it is unlikely for both absorptions to occur in close proximity. The response to each photon is generated independently and the overall response is twice as big. In other words, dim flashes lie within a linear operating range wherein the response simply scales with the flash strength. However, with increasing numbers of photon absorptions, local effects begin to overlap so fewer channels are closed per photon absorbed. With enough photons, all of the channels are closed and the rod response is maximal (Fig. 19.3). Hence the normalized response grows with flash strength according to a saturating exponential function:⁹

$$\frac{r}{r_{\max}} = 1 - \exp(-k_f i) \quad (1)$$

where r is the photocurrent response amplitude, r_{\max} is the amplitude of the maximal saturating response, i is flash strength, k_f is a constant equal to $\ln(2)/i_{0.5}$ and $i_{0.5}$ is the flash strength giving rise to a half maximal response. The $i_{0.5}$ for rods produces 30–70 photoisomerizations on average,^{11–13} while that for cones produces ~10 times as many photoisomerizations.¹⁴

As is the case with photovoltage, photocurrent responses speed up with flash strength though the effect is less pronounced in cones.^{11,14} Responses are faster in cones than in rods (note the difference in time scales in Fig. 19.3A and C) and have a marked undershoot (although cf. refs^{15,16}). Responses of different cone types are indistinguishable in waveform. However, the photovoltage and photocurrent responses of rods and cones are not mirror images of each other; photocurrent responses lack the “nose” in the photovoltage response to brighter flashes.

Once the flash is bright enough to close all of the CNG channels, more light cannot produce a larger response, so instead, the duration of the photocurrent response increments with the natural logarithm of the flash strength (Fig. 19.3D). The basis for this behavior is that a single molecular process, namely the shutoff of transducin¹⁷ (see also Chapter 18), that has a stochastic, exponential time course^{18,19} dominates the recovery from phototransduction activation in

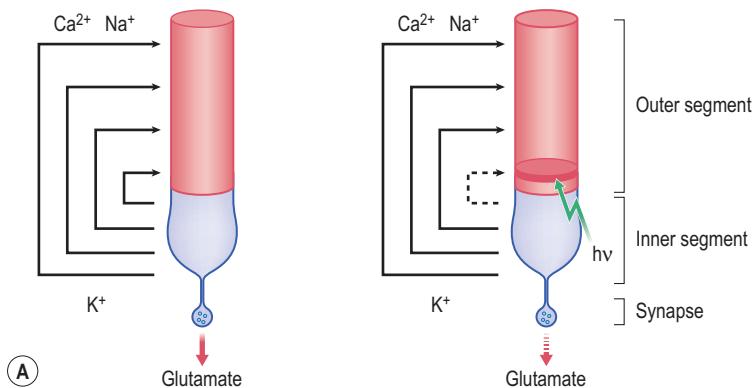

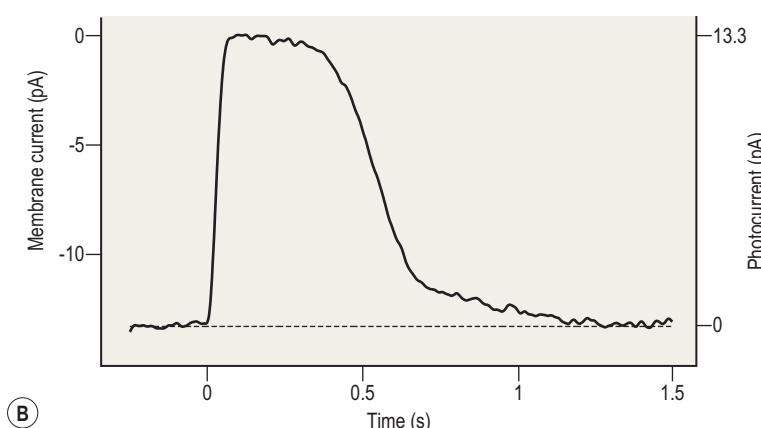

Figure 19.2 The dark current. (A) Light suppresses the entry of Na^+ and to a lesser extent Ca^{2+} into the outer segment in a ring of plasma membrane around the photoexcited rhodopsin (darkened red band). The rod hyperpolarizes, which closes Ca^{2+} channels at the synapse and attenuates the release of neurotransmitter. (B) The inward Na^+ current in this rod, plotted downward by convention, was -13.3 pA . A saturating flash, given at time zero, closes all the CNG channels and completely shuts down the inward Na^+ current. After a while, channels reopen and the membrane current is restored. For simplicity, the change in membrane current is often measured as photocurrent, shown on the right.

rods. The slope of the saturation function or “Pepperberg Plot” yields the dominant time constant of about $\sim 0.2 \text{ s}^{20}$ (a similar value has been reported by many others for murine rods). The identity of the rate-limiting step in the recovery of the cone response has not been firmly established but its time constant is an order of magnitude faster (T. Kraft, personal communication).^{15,16,21}

Detecting single photons

Rods count single photons.²² In order to do so, they must satisfy several conditions: noise must be minimal and quantal responses must be reproducible and highly amplified. Amplification is achieved by cascading several enzymatic reactions (see Chapter 18). Each chemical reaction takes time, hence the decrement in the circulating current after photon absorption is delayed by a few ms. Then the response rises to a peak amplitude of 0.1 to 0.7 pA approximately 200 ms later reflecting the suppression of the circulating current by a few per cent.^{11–13,23} With the cascade working as fast as it can, the size of the response is determined by when shutoff and recovery processes kick in. In rods, hundreds of CNG channels are closed during the single photon response. Na^+ ions traverse the channel at a rate of $\sim 10^4 \text{ s}^{-1}$ (see review²⁵), so one photon blocks the entry of a million Na^+ ions. Responses to brighter flashes in rods and in cones appear with a shorter delay and rise more steeply because many more photoexcited rhodopsins are activating the phototransduction machinery. But if the single photon

response in cones is considered, its early rise is actually pretty similar to that in rods.²⁴ However, the cone response starts to shut off in 50 ms or less at a time when it has only reached an amplitude of a few tens of fA.^{14,16,21}

It is imperative that single photon responses do not vary in size or duration because if they did, the rod would be unable to distinguish one large, slow quantal response from two or more small, brief quantal responses occurring close together in time. The coefficient of variation of the rod response, defined as the quotient of the standard deviation divided by the mean amplitude, has a low value of 0.2.^{22,26–28} When stimulated by dim flashes, the rod does not respond the same way every time, but the unpredictability arises from the Poisson distribution of photon absorptions, rather than from single photon response variability. Whenever the rod does respond, the amplitude is quantized (Fig. 19.4A).

In darkness, there are two physiological kinds of electrical fluctuations in the current baseline: discrete noise and continuous noise (Fig. 19.4B)^{11,29} Discrete noise arises from thermal isomerizations of rhodopsin. Even though rhodopsin has a half life of ~ 300 years at body temperature, a rod contains so many copies (around a hundred million) that one spontaneously activates every minute or two. Cone visual pigments are far less stable than rod pigments,^{14,30,31} making single photon detection impossible. Continuous noise springs from the spontaneous activity of PDE³² and is much more prevalent than discrete events in rods but typically has a lower amplitude. The continuous noise amplitude distribution is approximately Gaussian so, occasionally, there is a single-photon-response-like event. However, such events

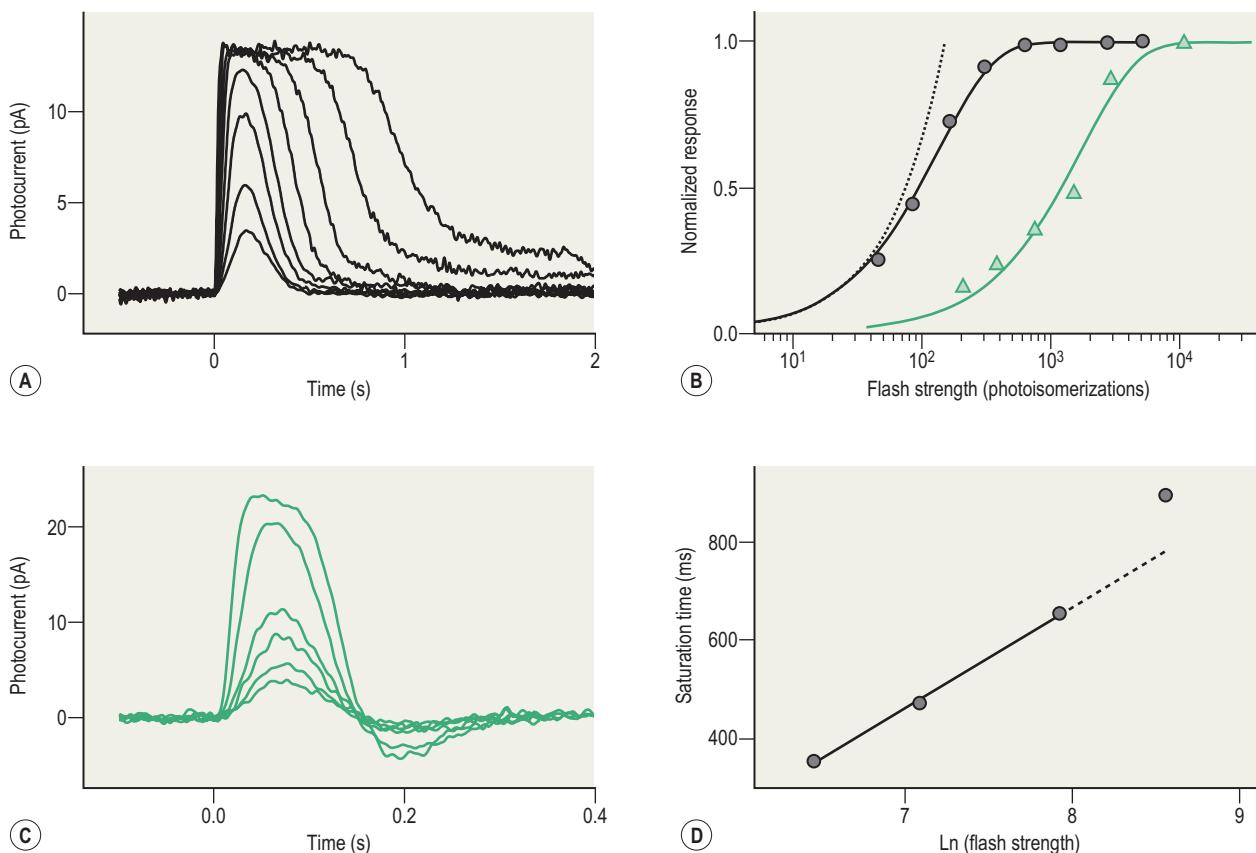

Figure 19.3 Current responses of a human rod (**A**) and cone (**C**) to flashes. (**B**) The stimulus–response relations of the rod (black circles) and cone (green triangles) follow eqn (1) (black and green lines). The dotted line shows a linear relation on semilogarithmic coordinates for comparison. (**D**) Saturation times for the rod in A, measured from midflash to 25 percent recovery. The line passing through the initial points has a slope of 205 ms and has been extended with a dashed line. (Panel A from T.W. Kraft, D.M. Schneeweis and J.L. Schnapf, 1993: Visual transduction in human rod photoreceptors, *Journal of Physiology* 464: 747–765.¹² reproduced with permission from Blackwell Publishing. Panel B contains results from Kraft TW, Schneeweis DM, Schnapf JL. Visual transduction in human rod photoreceptors. *J Physiol*. 1993; 464: 747–65¹² and unpublished results from T. Kraft, University of Alabama. Panel C from Kraft TW, Neitz J, Neitz M. Schneeweis, University of Illinois at Chicago; and J. Schnapf, University of California at San Francisco.)

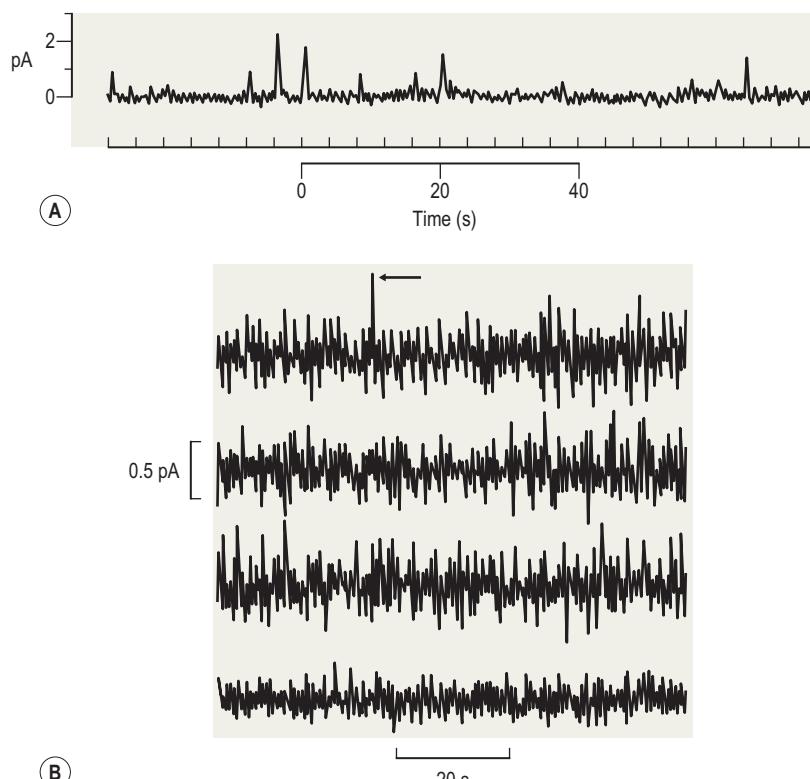

Figure 19.4 Responses of a primate rod to single, rhodopsin isomerizations. (**A**) For flashes that photoisomerize one rhodopsin on average, many trials fail to elicit a response because no photons were absorbed. Other trials produce responses whose amplitudes are multiples of the unitary response, dependent upon the number of photons absorbed. (**B**) Discrete noise events (e.g. arrow in top trace), resembling single photon responses, appear sporadically in darkness after spontaneous activations of individual rhodopsins. In addition, a continuous, lower amplitude noise component arises from basal PDE activity (top three traces). Both noise components disappear in bright light after closure of all of the CNG channels (bottom trace), leaving only the instrumental noise in the recording. (From D.A. Baylor, B.J. Nunn and J.L. Schnapf, 1984: The photocurrent, noise and spectral sensitivity of rods of the monkey *Macaca fascicularis*, *Journal of Physiology* 357: 575–607. Reproduced by permission of Blackwell Publishing.)

are inconsequential because they take place ten times less frequently than the thermal isomerizations of rhodopsin.

Thermal isomerizations of rhodopsin limit the detection of very dim light, because real photons cannot be distinguished from virtual ones. To guard against false alarms, the visual system relies on coincidence detection. A single photon response in one rod does not suffice for vision; a few rods in a small cluster of the retina must each generate a single photon response within a certain period of time before a flash is "seen".³³ The temporal requirement is specified by the integration time of the response. Thus shortening the integration time detracts from sensitivity of the system. This consideration also applies below, when rods and cones respond to steps of light. The integration time for rods is ~300 ms,^{11,12,23} while for cones, it is ~20 ms (segment preceding undershoot¹⁴).

Thus rods are well suited for single photon detection. Oddly though, rods sometimes generate single photon responses that are truly aberrant.^{11,34} For reasons unknown, one photoexcited rhodopsin out of several hundred fails to shut off properly^{35,36} and gives rise to a two-fold larger than average response that can last for a very, very long time (Fig. 19.5). Aberrant response durations are exponentially distributed with a mean value of about 4 s, but some last for tens of seconds. Aberrant responses have little impact on photon counting due to their rarity, yet they prolong the recovery after exposure to bright light (flashes and steps), leaving rods vulnerable to saturation (Box 19.1).

Photocurrent response to steady light

The rod response to dim, steady light summates individual single photon responses.¹¹ But with brighter light, adaptation within the outer segment causes the step responses to fall short of the amplitude expected from a simple saturation behavior^{23,37,38} (see Chapter 20). Midrange responses droop as additional adaptational mechanisms with a slower time course reduce the cascade gain and cause the stimulus-response relation to rise even more gently (Fig. 19.6). Light producing 300–600 photoisomerizations per second decreases the circulating current in darkness by 50 percent.^{23,39} In contrast, the peak of the cone response to steps nearly does obey simple saturation.¹⁴ A hundred ms in the light later, however, cone responses begin to droop as they too adapt. For dim steps, the droop reduces the amplitude to less than half that at the peak. The initial droop is typically larger and faster in cones than in rods.

In steady light, incremental flashes give rise to responses in rods that are smaller (Fig. 19.7) and recover more rapidly than in darkness, another manifestation of light adaptation^{11–13,23,37,38} (see Chapter 20). Flash response kinetics change very little with background light in primate cones, differing in this respect from cones of cold-blooded vertebrates.¹⁴ Light producing one to a few hundred photoisomerizations per second reduces flash sensitivity to half its value in darkness in rods,^{11,12,23,39} where the value may increase slowly over tens of seconds in the light.^{40,41} Adaptation is more powerful in cones, for which 10,000 or more photoisomerizations per second reduce sensitivity two-fold.^{7,14} Mammalian rods adapt over several log units of background light intensity before saturating.^{23,37,38} Amphibian rods adapt

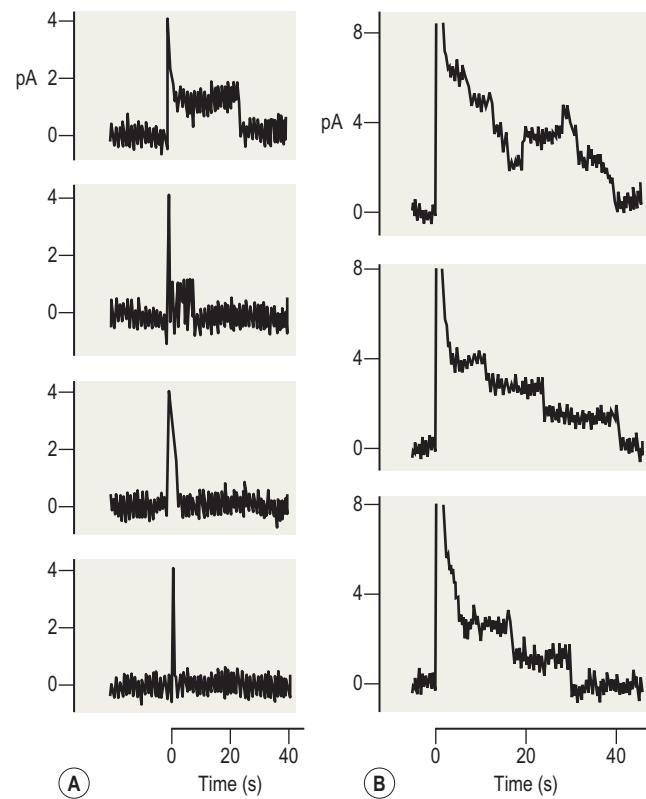

Figure 19.5 Aberrant responses in rods. The peaks of the responses are not shown. (A) In these four responses to a flash eliciting about 250 photoisomerizations, an aberrant response component can be seen at late times in the top three traces. The appearance of an aberrant response after a flash, as well as its duration is random. The aberrant response in the top trace persists for more than 20 s. The second trace does not initially contain an aberrant response. Then one appears and recovers only to reappear before shutting off for good. (B) In these three responses to a flash over ten times brighter than that in A, multiple individual aberrant responses add together to create protracted, stair-cased recoveries. (From D.A. Baylor, B.J. Nunn and J.L. Schnapf, 1984: The photocurrent, noise and spectral sensitivity of rods of the monkey *Macaca fascicularis*, *Journal of Physiology* 357: 575–607. Modified with permission from Blackwell Publishing.)

over an even greater range of intensities at least in part because they lack aberrant responses.

Light that is bright enough to bleach a significant fraction of visual pigment causes rods to behave for a period as if they were being exposed to a virtual, "equivalent light" that lingers after the light is removed (see review⁴²). Rods adapt to the equivalent light with a reduction in circulating current and accelerated flash response kinetics as well as a profound loss of flash sensitivity exceeding that expected from the decrease in photon capture.⁴³ It turns out that bleached rhodopsin constitutively activates the phototransduction cascade. Although the activity of a single bleached rhodopsin is minuscule, the summated activity over hundreds of millions of bleached rhodopsin molecules is substantial. The equivalent light fades as visual pigment regenerates (see Chapter 13). Circulating current after full bleach recovers halfway in 15 min and is fully restored in ~25 min.³⁹ Cones are not impaired in this way by bleaching;^{14,44} their bleached pigment seems to be inactive (although the situation is not yet clear for bleached blue cone pigment⁴⁵). That means that when a very bright light is turned on, cones may saturate, but they

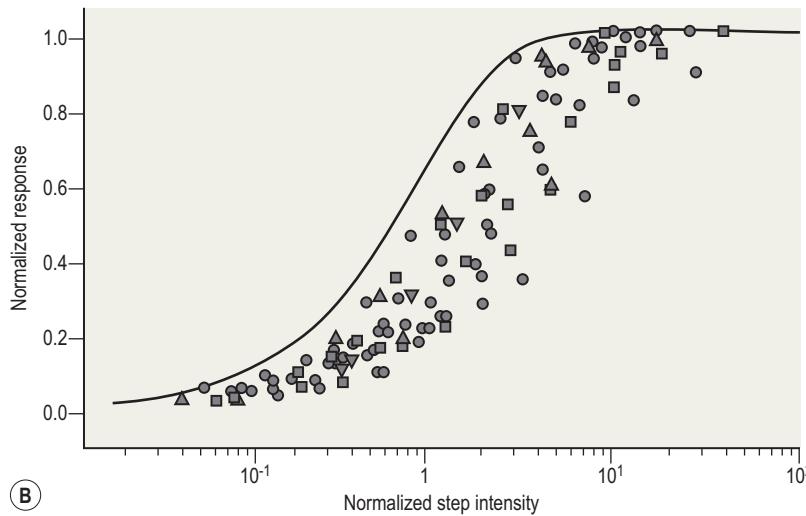

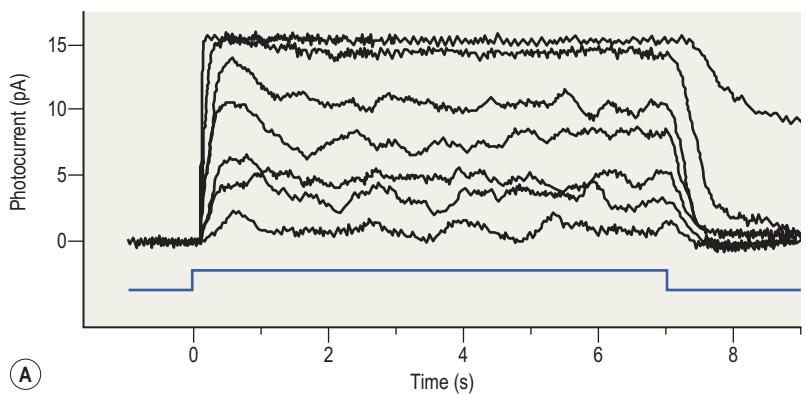

Figure 19.6 Adaptation of a rod to steady light. **(A)** The Poisson nature of light absorption causes the bumpiness in the responses to dim steps despite averaging. Midrange responses droop as the rod adapts. At the two highest intensities, both the droop and the bumpiness are compressed as the rod saturates so the traces become smoother. **(B)** In the stimulus-response relations for the rod in A and 14 other rods measured after several seconds of light exposure, light intensity on the abscissa has been divided by $I_{0.5}$, the intensity giving rise to a half-maximal response measured at the peak, for each rod. The continuous line plots the saturating exponential that would obtain in the absence of adaptation: $r/r_{max} = 1 - \exp(-k_s I)$, where $k_s = k_f t_i$, k_f is from eqn (1), t_i is the integration time (see above) and I is the intensity of the step. Thus lacking adaptation, rods would saturate at intensities that are lower by as much as an order of magnitude. (From T. Tamura, K. Nakatani and K-W. Yau, 1991. Originally published in The Journal of General Physiology 98: 95–130. Reproduced with permission.)

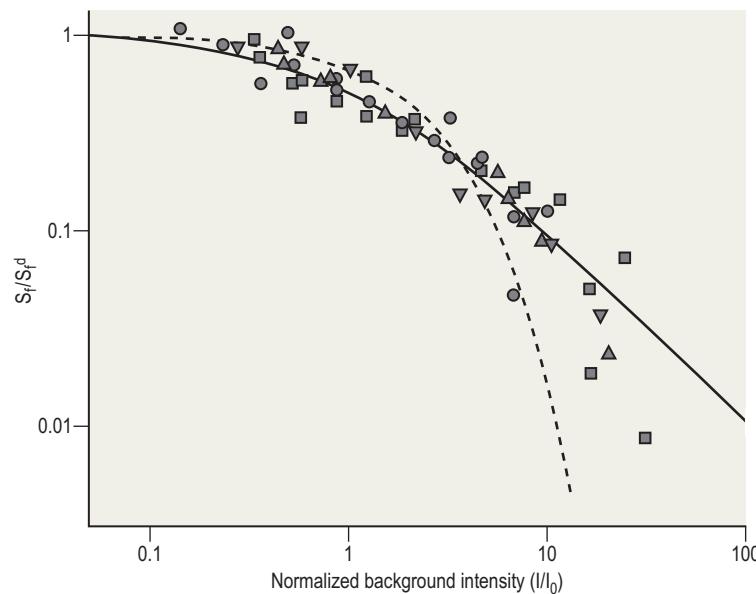

Figure 19.7 Loss in incremental flash sensitivity with background light. In the absence of adaptation, relative flash sensitivity, S_f/S_f^d , defined as response amplitude divided by flash strength for responses in the linear range normalized by its value in darkness, would drop off along a saturating exponential function (dashed line). Instead, rods exhibit Weber-Fechner behavior: $S_f/S_f^d = (1 + I/I_0)^{-1}$ where I_0 is the background intensity that reduces S_f/S_f^d to 0.5. Rods sacrifice some sensitivity at lower background intensities (symbols below dashed line) in order to maintain sensitivity at intensities that would otherwise be saturating (symbols above the dashed line). (From T. Tamura, K. Nakatani and K-W. Yau, 1991. Originally published in The Journal of General Physiology 98: 95–130. Reproduced with permission.)

actually manage to recover circulating current during the exposure as loss of some of their visual pigment by bleaching lowers the ongoing rate of photon capture. Even after extensive bleaching, cones regain their full circulating current and the reduction in sensitivity scales in proportion to the loss

in photon capture.^{14,44,46} Cone pigment regeneration is faster than in rods, with full sensitivity returning after complete bleach within minutes. So while cones lack the absolute sensitivity of rods, they are better equipped to operate over a wide range of brighter light intensities without saturating.

Action spectra of rods and cones

Rods and cones respond to a wide range of wavelengths (Fig. 19.10), their action spectra being determined by the spectral absorptions of the visual pigment they express. For a given number of photons, the response amplitude varies with wavelength because the probability of absorption by the visual pigment varies with wavelength. The response

itself to a photoisomerization is independent of wavelength.^{11,12} Rods respond maximally to ~493 nm (blue-green light).^{11,12} There are three types of cones, commonly referred to as blue, green and red with maxima near 430 nm (violet light), 530 nm (green light) and 560 nm (greenish-orange light), respectively.^{55,56} Since the names do not correspond to the colors of the maxima in every case, many prefer the designations: short-wavelength sensitive or S, middle-wavelength sensitive or M and long-wavelength sensitive or L (Box 19.2).

Box 19.1 Diseases caused by hyperactive signaling

Excessive phototransduction cascade activity in photoreceptors can interfere with vision and lead to retinal disease (see review⁴⁷). For example, mutations that target rhodopsin kinase (see Chapter 18), can cause a form of night blindness known as Oguchi disease. Mutant mouse rods lacking rhodopsin kinase generate aberrant single photon responses like those shown in Fig. 19.5 for every rhodopsin isomerization. Cones are only mildly affected in the disease,⁴⁸ because they express a second type of rhodopsin kinase.^{49,50} Patients with defects in the nuclear receptor NR2E3 develop enhanced S cone syndrome in which there is a higher prevalence of blue cones in the retina at the expense of red and green cones.⁵¹ Very interestingly, the blue cones in these patients fail to express both types of rhodopsin kinases. Hence flash responses of their blue cones (but not red or green cones) do take an abnormally long time to recover.¹⁵

Mutations in arrestin, the protein normally responsible for quenching photoexcited rhodopsin's activity (see Chapter 18), can also cause Oguchi disease. Flash responses from rods of mutant, arrestin knockout mice are very prolonged (Fig. 19.8). Since

longer-lasting responses enhance absolute sensitivity, it might at first seem surprising that the mutations in either rhodopsin kinase or arrestin should lead to night blindness. The problem is that the mutant rods saturate at very low light levels and then take an inordinately long period of time and much dimmer conditions to recover from saturation. In theory, Oguchi patients with rhodopsin kinase or arrestin mutations might actually see better than normal persons under the dimmest conditions when given adequate time for dark adaptation. Photopic vision is largely spared because cones express a unique arrestin.^{52,53}

Mutations in either RGS9 or R9AP can sabotage the timely shutoff of transducin (see Chapter 18). Because these two proteins are used in rods and cones, there is night blindness and a problem in daytime vision. The ability of cones to light adapt enables them to escape saturation, so photopic vision is still possible. But long lasting photoresponses translate into a disturbing persistence in sensation and the person has difficulty following moving objects and adjusting to luminance changes, a condition termed bradyopsia.⁵⁴

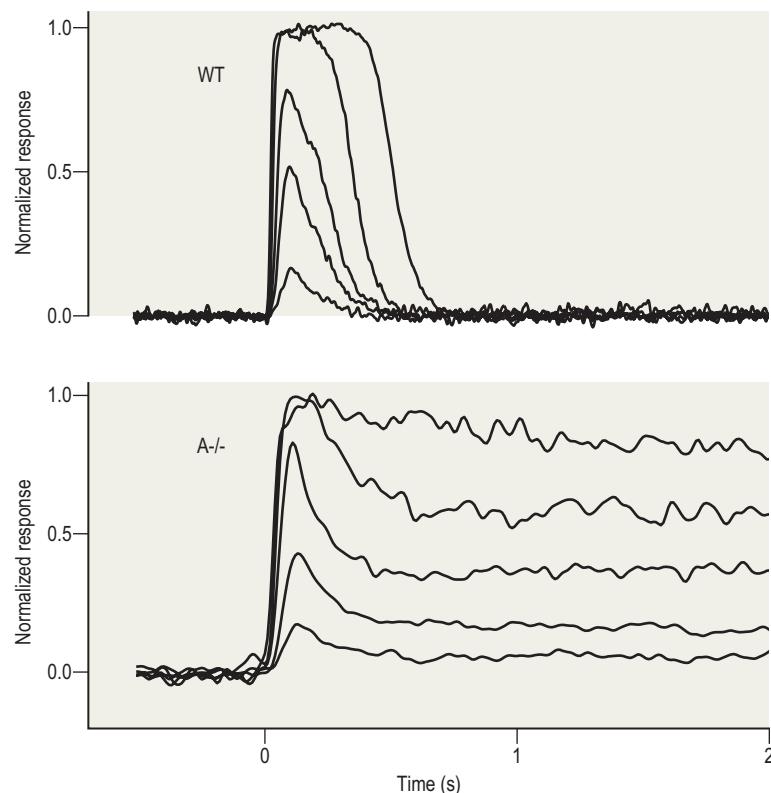

Figure 19.8 Murine model for Oguchi disease. Flash responses from a mutant rod lacking arrestin (A-/-, bottom) recover a hundred times more slowly than wild-type (WT, top) rod responses. (From Makino CL, Flannery JG, Chen J, Dodd RL. Effects of photoresponse prolongation on retinal rods of transgenic mice. In: Williams TP, Thistle AB, eds. Photostasis and related phenomena. New York: Plenum Press, 1998. Modified with permission from Springer Science and Business Media.)

Box 19.1 Diseases caused by hyperactive signaling—cont'd

Genetic defects in RPE65, the isomerase that converts all-trans to 11-cis retinal (see Chapter 13) can prevent the de novo synthesis of rhodopsin. The persistent presence of catalytically active apo-opsin (rhodopsin lacking 11-cis retinal – essentially equivalent to bleached rhodopsin)

gives rise to Leber congenital amaurosis, an especially severe form of retinal degeneration. RPE65 knockout mouse rods exist in an inescapable state of light adaptation, with greatly attenuated circulating current and smaller, faster flash responses (Fig. 19.9).

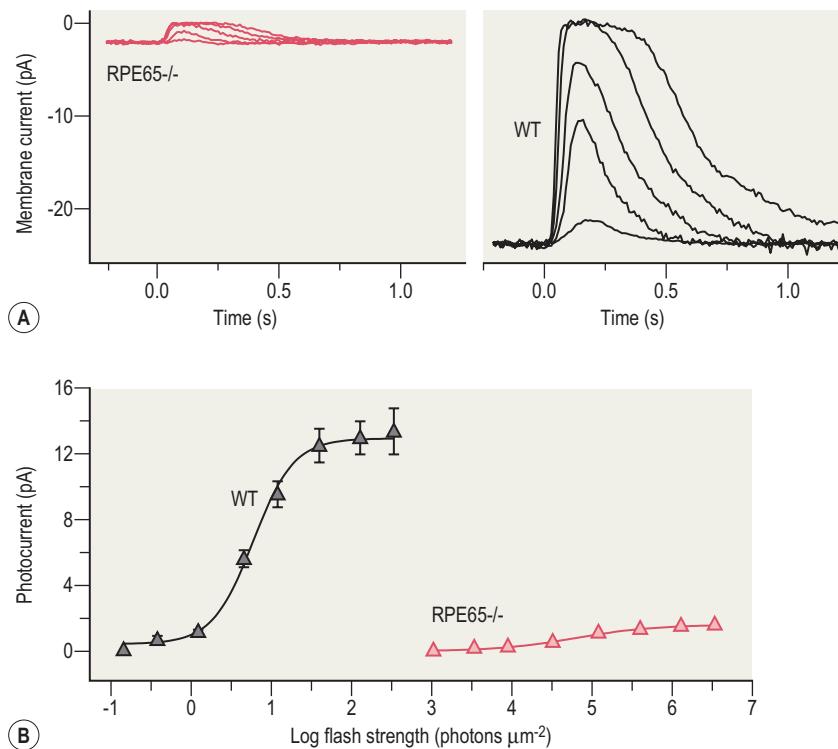

Figure 19.9 Murine model for Leber congenital amaurosis. **(A)** The outer segment membrane current and averaged flash responses of mutant rods lacking RPE65 ($n = 3$) are smaller than those of wild-type rods ($n = 4$). Mutant rods also generate flash responses with faster kinetics. **(B)** On average, the mutant rods ($n = 16$) are thousands of times less sensitive than WT rods ($n = 32$). (From Woodruff ML, Wang Z, Chung HY et al. Spontaneous activity of opsin apoprotein is a cause of Leber congenital amaurosis. *Nature Genetics* 2003; 35:158–64. Reprinted with permission from Macmillan Publishers Ltd.)

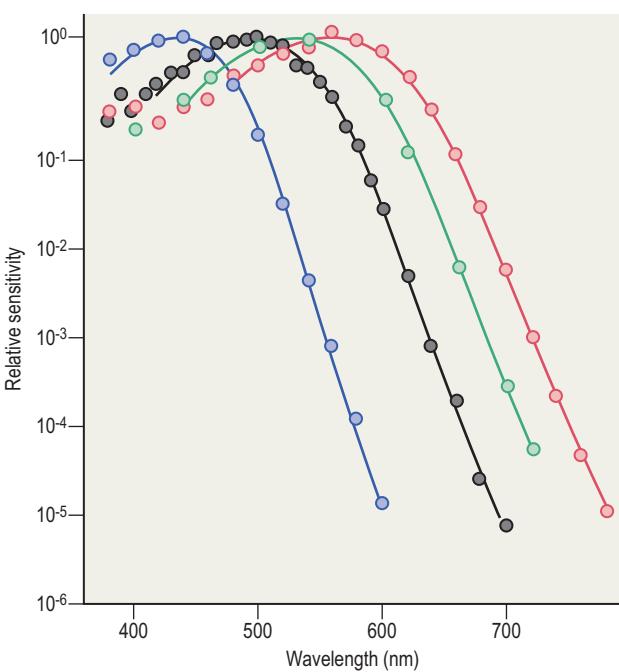

Figure 19.10 Spectral sensitivities of primate rod and cones. Rod (black symbols), green cone (green symbols) and red cone (red symbols) spectra are from human.^{12,56} The blue cone spectrum (blue symbols) is from a macaque monkey⁵⁵ whose color vision is very similar to that in humans.

Box 19.2 Population differences in the spectral responses of cones

Normal color vision requires the proper electrical signaling of light by all three cone types. Evolutionarily, the red and green cone pigment genes arose from a duplication event and they lie together on the X chromosome. Their high sequence similarity has caused “confusion” during crossing over in gametogenesis creating within the population, hybrid genes, fragmented genes and variable numbers of copies of pigment genes on the chromosome (Fig. 19.11). In persons with many genes in the array, expression of the first two predominates. Yet some of these

individuals and also women with different sets of pigment gene variants on their X chromosomes actually possess more than three cone types in their retinas. The genetics help to explain the substantial individual variation in color vision in “normal” persons, anomalous color vision as well as some forms of color “blindness” (see reviews^{57,58}). The last category includes extreme cases where failure to express one or both types of pigment genes on the X chromosome gives rise to dichromacy or blue cone monochromacy, respectively.

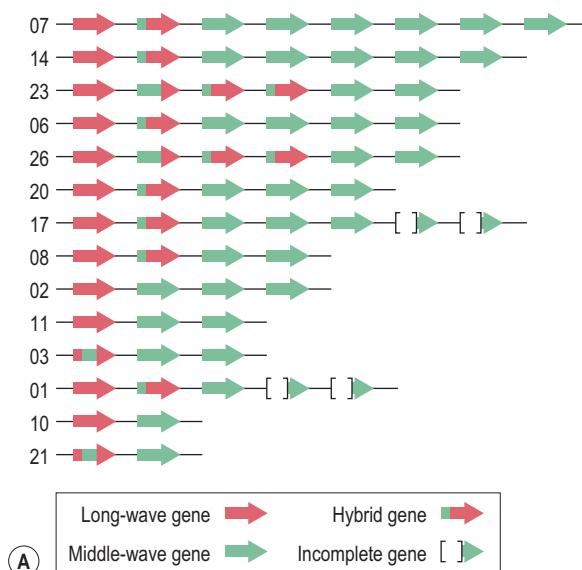

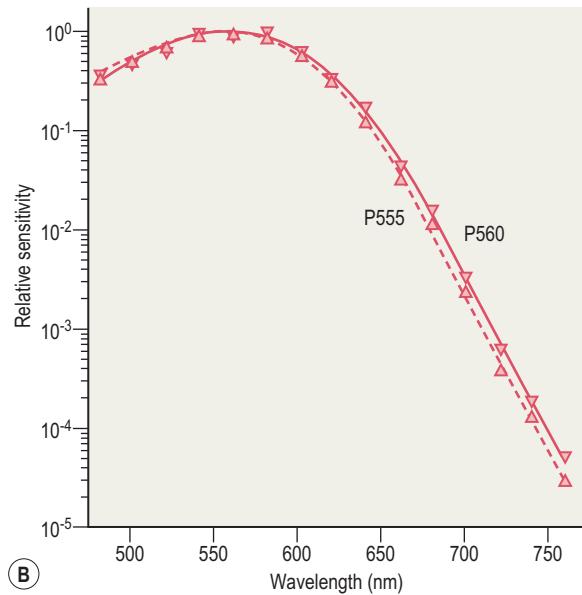

Figure 19.11 Genetic basis for heterogeneity in human color vision. (A) X-chromosome arrays of “red” (long-wave) and “green” (middle-wave) pigment genes are diverse, as shown by this small sample of male subjects with normal color vision. (Adapted from Neitz M, Neitz J, Grishok A. Polymorphism in the number of genes encoding long-wavelength sensitive cone pigments among males with normal color vision, Vision Research 35: 2395-2407. Copyright Elsevier 1995.) (B) Two common red cone pigment variants in the human population have maxima near 555 nm and 560 nm, as exemplified by the red cone spectral sensitivities of these two groups of individuals. (Adapted from Kraft TW, Neitz J, Neitz M. 1998: Spectra of human L cones, Vision Research 38: 3663-3670. Copyright Elsevier 1998.)

CNG channel and $\text{Na}^+/\text{K}^+/\text{Ca}^{2+}$ exchanger

Two types of molecules are the principal mediators of ionic movement across the outer segment plasma membrane: the CNG channel and the $\text{Na}^+/\text{K}^+/\text{Ca}^{2+}$ exchanger. CNG channels are heterotetramers consisting of CNGA1 and CNGB1 subunits (Fig. 19.12A) in a ratio of 3:1, respectively in rods^{59–61} and CNGA2 and CNGB3 subunits in a B3-B3-A3-A3 arrangement in cones.⁶² (Box 19.3) Although CNG channels are members of the same superfamily as voltage-gated K^+ channels,⁶³ they are only mildly voltage-dependent. Instead, CNG channels in rods and cones are directly gated by cGMP.^{64,65} Cyclic AMP also works, but with a 50-fold lower $K_{0.5}$ reflecting the reduced affinity of the channel for cAMP and the

reduced efficacy in opening once cAMP has bound.⁶⁶ While other ligand-gated ion channels in the body desensitize in the continued presence of their ligand, the CNG channel does not have any intrinsic mechanisms of desensitization and thus steadily monitors the [cGMP] in darkness.^{67,68}

The rod CNG channel allows many different cations to pass: Ca^{2+} , Mg^{2+} , Na^+ , even K^+ . Permeability is greatest for Ca^{2+} , but under normal conditions, Na^+ carries ~80 percent of the current while Ca^{2+} carries 15–20 percent^{69,70} because the extracellular concentration of Na^+ is ten times higher than that of Ca^{2+} . Mg^{2+} influx comprises a few per cent of the circulating current. The proportion of current carried by Ca^{2+} is twice greater through the cone channel because of its two-fold higher Ca^{2+} to Na^+ permeability ratio.^{71,72} Nevertheless, divalents are critical to the physiology of both rods and cones (see below and Chapters 18 and 20).

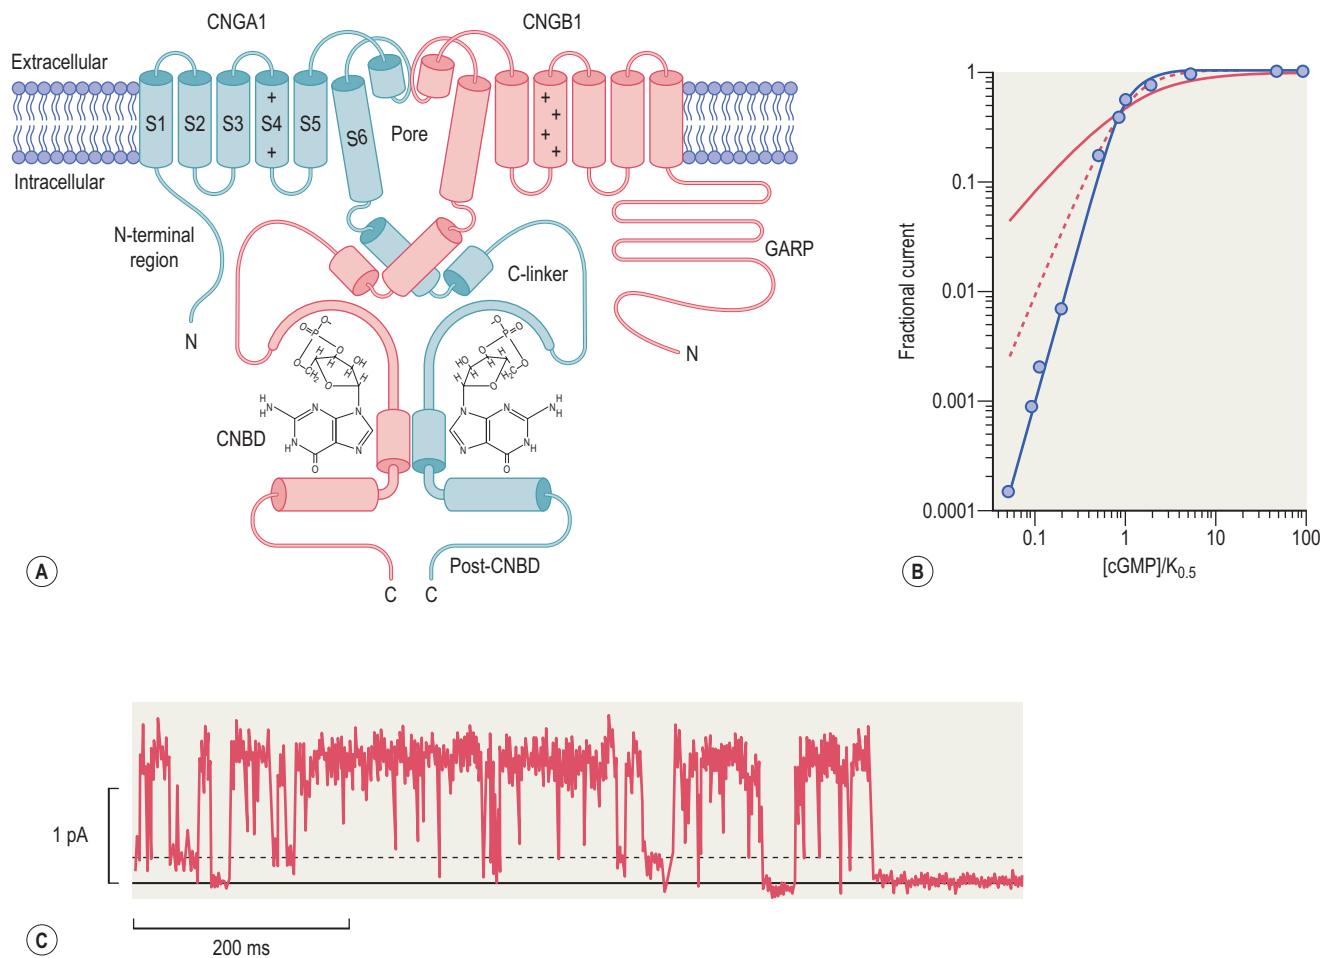

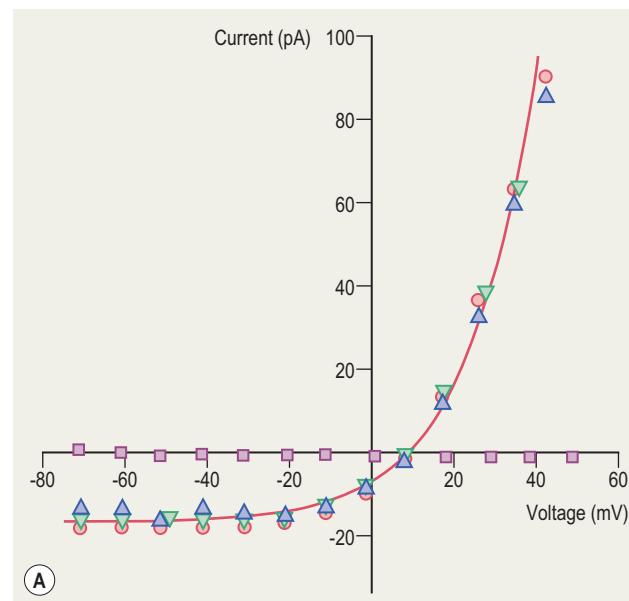

Figure 19.12 CNG channel. **(A)** The channel consists of 4 subunits, 2 of which are shown in this schematic diagram. Each subunit has six transmembrane segments, a pore-forming domain between helices 5 and 6 and a cyclic nucleotide binding domain (CNBD) on the carboxy terminus. Helix 4 contains lysine residues and functions as a voltage sensor. The carboxy and amino termini are located intracellularly. The amino terminus of the CNGB1 subunit contains a large glutamic acid-rich protein (GARP) segment. (Courtesy of W. Zagotta, University of Washington.) **(B)** CNG channel opening is steeply dependent on [cGMP]. Lines show Hill functions: fractional current = $[\text{cGMP}]^n / ([\text{cGMP}]^n + K_{0.5}^n)$, where $K_{0.5}$ is the concentration of cGMP that opens half of the channels and n is the Hill coefficient taking values of 1 (red, continuous line), 2 (red, dashed line) and 3 (blue line). Hill coefficients greater than 1 indicate cooperativity. (Courtesy of A. Zimmerman, Brown University and Denis Baylor, Stanford University.) **(C)** A single CNG channel in a patch of membrane excised from a salamander rod flickers between an open state, a second open state of lower conductance (dashed line) and a closed state (horizontal line). The “fuzziness” of the trace above the dashed line represents extremely brief transitions out of the open state that were unresolved by the recording. The activity was recorded in symmetric salt solutions containing low concentrations of divalent cations and 5 μM cGMP on the intracellular face with a voltage of +70 mV applied to the membrane. (From W.R. Taylor and D.A. Baylor: Conductance and kinetics of single cGMP-activated channels in salamander rod outer segments, Journal of Physiology 483: 567–582. Adapted with permission from Blackwell Publishing, copyright 1995.)

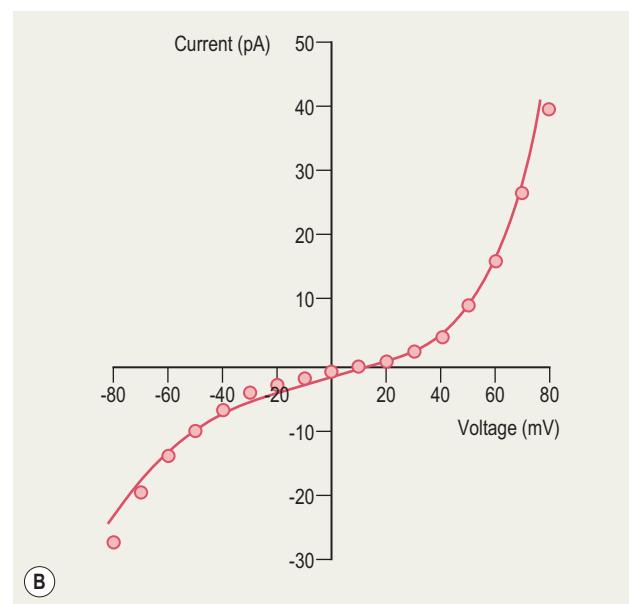

For fast responsivity to increases in [cGMP], it would be advantageous for the CNG channel to avidly bind cGMP. On the other hand, the channel would release cGMP too slowly and fail to detect decreases in cGMP rapidly. As a compromise, the channel has a fairly high $K_{0.5}$ for cGMP (i.e. moderately low sensitivity), on the order of 10 μM .^{64,65} The channel subunits work together in such a way that cGMP binding affinity increases with each cGMP bound, making channel opening steeply dependent on ligand concentration (Fig. 19.12B). This cooperativity is one of Nature's ways of building a biological switch. Cyclic GMP binding stabilizes the open state of the channel so by the law of microscopic reversibility, cGMP unbinds best from the closed state. Therefore, to be constantly vigilant for a decrease in [cGMP], the channel reverts incessantly to the closed state (see review²⁵). The channel can then respond to changes in [cGMP] on a time-scale that is considerably faster than the photoresponse kinetics. Flickering makes the channel extremely noisy though (Fig. 19.12C). To minimize the noise, the channel detains Ca^{2+} and Mg^{2+} during their passage through the pore.⁷³ As long as divalents reside in the pore, no other ions can pass and the conductance of the CNG channel drops by two orders of magnitude from about 25 pS to 100 fS. Given low channel conductance and relative insensitivity to cGMP, the cell must express a lot of channels (a few hundred per μm^2) in order to maintain a reasonable circulating current. The arrangement averages channel noise across many channels, but it also puts the cell at risk. Normally, the free [cGMP] in darkness is only a few micromolar and a small percentage of channels are open. Should the cell synthesize too much cGMP the number of open channels would increase by more than an order of magnitude and annihilate the transmembrane ion gradients.

For the purposes of photon counting, it would be desirable for the light-induced decrease in circulating current to be proportional to the number of channels closed. But CNG channel closure hyperpolarizes the rod and Ohm's law dictates an increase in current flowing through each of the remaining open channels. Two mechanisms conspire against a linear Ohmic relation between current and voltage. First, hyperpolarization enhances divalent block by increasing the driving force on Ca^{2+} and Mg^{2+} to enter the channel pore.^{74,75} Second, the CNG channel is slightly voltage dependent so hyperpolarization tends to close the channel. The net effect is that over the physiological range of membrane potentials, the inward current is nearly constant (Fig. 19.13). The CNG channel in cones is also outwardly rectifying over the physiological range of voltages, but to a lesser extent than the rod channel.⁶⁵ So in brighter light, as the cone becomes more hyperpolarized, the driving force sends more ions through the remaining open channels. Cones are not concerned with single photons and more interested in dynamic range. The reduced effect of closing channels at hyperpolarized potentials may contribute to their remarkable capacity to operate over a wide range of intensities. Another consequence is that the photocurrent in cones will not isolate events in the outer segment and can be influenced by voltage changes induced by external sources (see Chapters 21 and 22).

Diltiazem is a potent and reversible inhibitor of the CNG channel. Diltiazem blocks Ca^{2+} channels and is often prescribed as a vasodilator to treat hypertension. Fortunately, Ca^{2+} channels and CNG channels are sensitive to different

(A)

(B)

Figure 19.13 Outward rectification of the current-to-voltage relations of CNG channels in rods (A) and cones (B). Physiologically relevant voltages range from about -40 to -65 mV. The purple squares in A represent measurements made during exposure to light that closed all of the CNG channels. (Panel A from Baylor DA, Nunn BJ. Electrical properties of the light-sensitive conductance of rods of the salamander *Ambystoma tigrinum*. *Journal of Physiology* 1986; 371: 115–145. Adapted with permission from Blackwell Publishing. Panel B from L.W. Haynes and K.-W. Yau: Cyclic GMP-sensitive conductance in outer segment membrane of catfish cones, *Nature* 317: 61–64.⁶⁵ adapted with permission from Macmillan Publishers Ltd.)

diastereoisomers. Other CNG channel inhibitors include the Na^+ channel-blocking amilorides, the Ca^{2+} -activated K^+ channel-blocker dequalinium and the local anesthetic tetracaine (see review⁷⁶).

Ca^{2+} is removed from the outer segment by a special exchanger, consisting of a dimer⁷⁹ of NCKX1 in rods⁸⁰ and of NCKX2 in cones⁸¹ (Fig. 19.14A). Although there may be some exchangers at the cone synapse, the exchangers in rods are located exclusively in the outer segment⁸² where they are

physically coupled to the α -subunit of the CNG channel, roughly two exchangers per channel.⁸³ The exchangers in photoreceptors differ from Ca^{2+} exchangers found elsewhere in the body in that they couple the removal of Ca^{2+} to the entry of four Na^+ and the departure of one K^+ .⁸⁴ By taking advantage of the K^+ gradient as well as sending four Na^+ inside rather than three, photoreceptors could potentially take internal Ca^{2+} down to 0.2 nM, a level hundreds of times lower than that reachable, e.g., by the cardiac exchanger:

$$[\text{Ca}]_i = [\text{Ca}]_o \frac{[\text{Na}]_i^4 [\text{K}]_o}{[\text{Na}]_o^4 [\text{K}]_i} \exp(V_m F / RT) \quad (2)$$

where V_m is the membrane potential, F is Faraday's constant, R is Boltzman's constant and T is absolute

Box 19.3 Color blindness due to a channelopathy

Rod monochromacy is an autosomal recessive condition presenting with achromatopsia, poor visual acuity, photophobia and nystagmus. It is fairly rare, affecting fewer than 1 in 30,000 persons, although the prevalence is as high as 1 in 10 amongst the native population of Pingelap (see review⁷⁷ for an interesting account). In most cases, the condition is a channelopathy, caused by mutations in CNGA3 or CNGB3 channel subunits that disable phototransduction in cones (see reviews^{76,78}). Cases of incomplete achromatopsia or severe, progressive cone dystrophy have also been reported. Rods continue to function because they express distinct CNG channel subunits. In contrast, null mutations in the rod CNG channel cause autosomal recessive retinitis pigmentosa (see review⁷⁶), in which both rods and cones degenerate. Failure to express the CNG channel is lethal to rods and for reasons that are not yet known, death of the rods results in a secondary degeneration of cones so there is complete blindness rather than just night blindness.

temperature. In reality, internal Ca^{2+} never gets that low, possibly because the exchanger inactivates. Since there is a net movement of charge, the action of the exchanger comprises a small percentage of the dark current. To a first approximation, Ca^{2+} falls exponentially in the rod outer segment with a time constant between 40 and 90 ms (Fig. 19.14B).^{23,28} In cones, the combined properties of exchanger and CNG channel support a higher Ca^{2+} flux and faster light-induced changes in Ca^{2+} concentration.

Role of inner segment conductances

Closure of CNG channels in response to light hyperpolarizes rods and cones towards the equilibrium potential for K^+ , however, the transmembrane voltage is subject to modification by a variety of conductances located on the inner segment, cell body and synaptic terminal. A net inward current develops that increases in magnitude as the transmembrane potential becomes more negative. The effect of these conductances, referred to collectively as inner segment conductances, is readily apparent from a comparison of the photocurrents to the photovoltages for either a rod or a cone (Fig. 19.15). For dim flashes, the inner segment conductances are little affected so the time course of the voltage response is similar to that of the current response.^{4,7,11,14} But for bright flashes, the time courses differ; there is a prominent "nose" in the voltage response while there is no such nose in the current response.

Overall, activation of the inner segment conductances tends to return the membrane potential to the resting value. Such an action helps ensure that the membrane potential remains within the dynamic range of neurotransmitter release and prevents regenerative spiking.^{87,88}

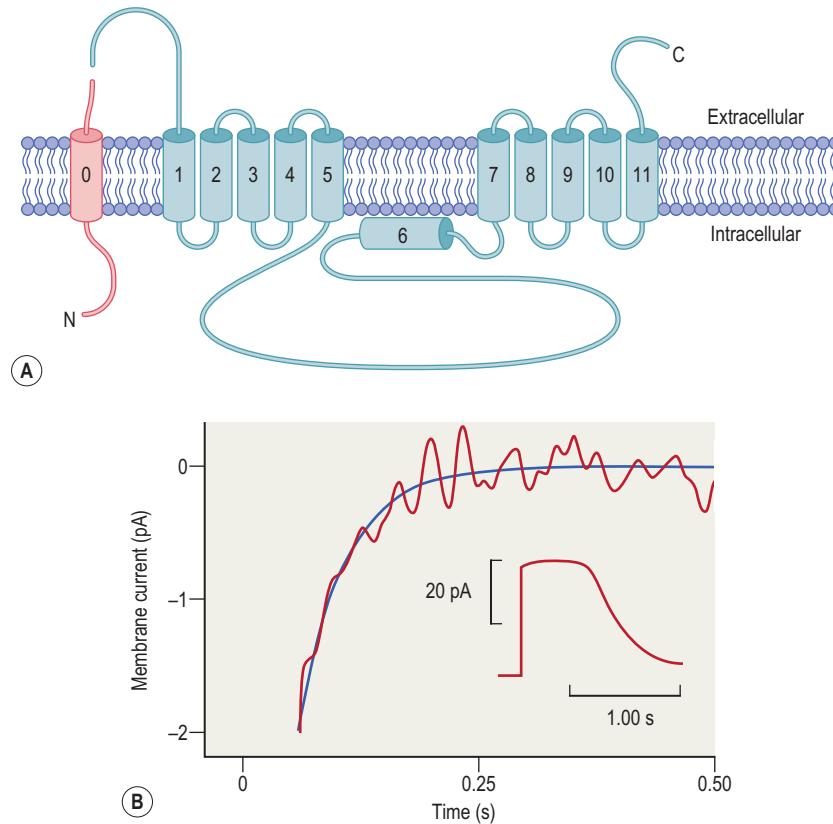

Figure 19.14 Calcium exchange. **(A)** The NCKX2 exchanger subunit in cones has an extracellular C terminus in contrast to the cardiac NCX, where it is intracellular.^{85,86} A leader sequence (red) is cleaved off prior to localization of the exchanger to the outer segment plasma membrane. **(B)** A bright flash given at time zero, that closes all of the CNG channels very suddenly, reveals a residual current due to the electrogenic removal of Ca^{2+} by the $\text{Na}^+/\text{K}^+/\text{Ca}^{2+}$ exchanger (black trace; inset: flash response in its entirety). The exchange current declines (exponential fit, blue trace) in this rod with a time constant of 59 ms, as the internal Ca^{2+} drops to a minimum. (From G.D. Field and F. Rieke: Mechanisms regulating variability of the single photon responses of mammalian rod photoreceptors, *Neuron* 35: 733–747. Reproduced by permission of Cell Press, copyright 2002.)

Large depolarizations that might arise from activation of voltage-dependent Ca^{2+} currents, particularly in small compartments, are thwarted by voltage- and Ca^{2+} -activated K^+ currents. Large hyperpolarizations that might arise for example, from the electrogenic Na^+K^+ -ATPase, are counteracted by a non-specific cationic current activated at voltages more negative than the resting potential. Changes in various of these currents at different voltages within the normal operating range of rods and cones occur slowly with respect to the photocurrent and therefore act to high pass filter the response to bright light (Fig. 19.15). A third role is to control the entry of Ca^{2+} , which in turn regulates transmitter release and other cellular activities. The intracellular concentrations of Ca^{2+} and other ions may also mediate effects in the cell beyond vesicular release. Five currents, three voltage-gated and two Ca^{2+} -activated, are described below.

Delayed rectifier potassium current, I_{KV}

The channels underlying I_{KV} activate at $V_m = -70$ mV in rods⁸⁹ and at $V_m = -50$ mV for monkey cones.⁹⁰ The outward flow of K^+ ions through I_{KV} together with a leak current constitute the inner segment leg of the circulating current and help to set the membrane potential of the photoreceptor in darkness. I_{KV} channels close slowly when the photoreceptor hyperpolarizes (Fig. 19.16). In so doing, they limit the light-induced hyperpolarization and may contribute to the nose in the response to brighter flashes and steps. This current is blocked by extracellular tetraethyl ammonium ions.

Hyperpolarization-activated current, I_H

A cationic conductance appears at potentials negative to -50 mV⁹⁰ (Fig. 19.17). It has a reversal potential of -30 to -40 mV, reflecting its permeability to K^+ , Na^+ and even Ca^{2+} . I_H turns on slowly and tends to counteract closure of the CNG channels in the outer segment by allowing the entry of Na^+ and depolarizing the photoreceptor. It therefore has an effect similar to closure of I_{KV} channels, but comes into play with brighter flashes since it has a more negative activation potential. The gradual building of I_H upon hyperpolarization precludes it from greatly affecting the initial rising phase of the photoresponse, though. It is primarily responsible for quickening the photovoltage response at its peak and creating the "nose." The channels are formed from HCN1 subunits⁹¹ that share structural similarities with CNG channel subunits (see review⁹²). As is the case with CNG channels,

HCN1 channels are gated by cyclic nucleotides that shift slightly the I_H current-to-voltage relation to the right, i.e. to voltages a few mV less negative.

Voltage-activated calcium current, I_{Ca}

The major calcium conductance is the "long-lasting" or L-type. The channel is composed of α_1 , $\alpha_2\delta$, β and γ subunits.

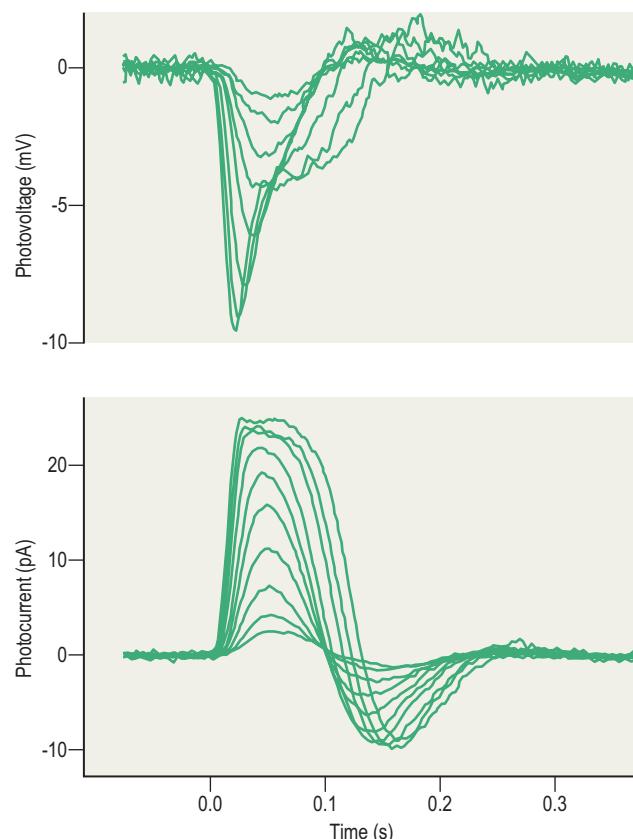

Figure 19.15 Differences in the current and voltage response waveforms. The photovoltages and photocurrents were recorded from different cones at 37°C . In the top panel (from Fig. 19.1C), flashes deflect the transmembrane potential from its resting level of -43 mV whereas in the lower panel, flashes decrease the circulating current from a value in darkness of -24.9 pA. (Lower panel from D.A. Baylor, B.J. Nunn and J.L. Schnapf. Spectral sensitivity of cones of the monkey *Macaca fascicularis*, *Journal of Physiology* 390: 145-160. Adapted with permission from Blackwell Publishing, copyright 1987.)

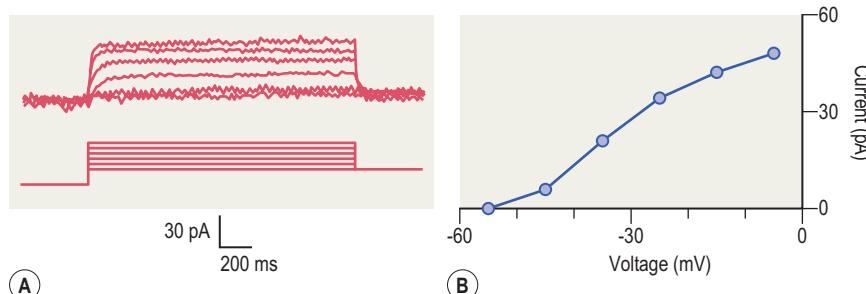

Figure 19.16 Voltage-dependent K^+ current. (A) I_{KV} turns on slowly in response to voltage steps from a holding potential of -105 mV to command voltages ranging from -55 mV to -5 mV at 33 – 36°C . The I_{KV} was isolated pharmacologically and by careful selection of the ionic composition of the bath and pipette solutions in voltage clamp experiments on monkey cone inner segments. (B) At steady state the current-to-voltage relations of I_{KV} indicate an outward current at potentials less negative than -60 mV in this cell. (From T. Yagi and P.R. MacLeish, 1994: Ionic conductances of monkey solitary cone inner segments, *Journal of Neurophysiology* 71: 656–665,⁹⁰ with permission from the American Physiological Society.)

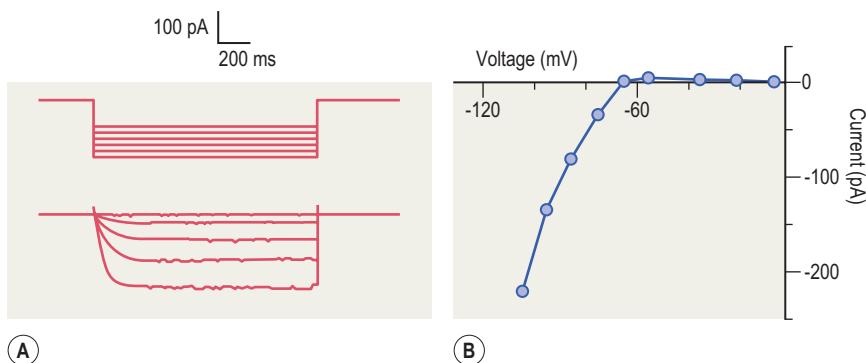

Figure 19.17 Slow development of an inwardly rectifying current (I_H) with hyperpolarization. **(A)** Stepping the membrane potential of an isolated, salamander rod under voltage-clamp from -5 mV to values between -55 and -105 mV turns on an inward current over a period of $\sim 100\text{ ms}$ at $33\text{--}36^\circ\text{C}$. Currents other than I_H were blocked pharmacologically and by manipulating the ionic composition of the bathing solutions or were subtracted from the records. **(B)** The current-to-voltage relations of I_H at steady state indicate an inward current at negative potentials. Under physiological conditions with proper ionic solutions and cyclic nucleotide concentrations, I_H activates at slightly less negative potentials. Nevertheless, I_H remains negligible at the dark resting potential. (From T. Yagi and P.R. MacLeish, 1994: Ionic conductances of monkey solitary cone inner segments, *Journal of Neurophysiology* 71: 656–665,⁹⁰ with permission from the American Physiological Society.)

Figure 19.18 Current-to-voltage relations for I_{Ca} . Measurements were made in porcine rods with Ca^{2+} to minimize interference from other currents. The physiological voltage range controls nearly the full span of I_{Ca} . (From Cia D, Bordais A, Varela C, et al. 2005: Voltage-gated channels and calcium homeostasis in mammalian rod photoreceptors, *Journal of Neurophysiology* 93: 1468–1475,⁹⁶ with permission from the American Physiological Society.)

Three isoforms of the pore-forming α_1 subunit are expressed in rods and cones: α_{1C} , α_{1D} and α_{1F} .^{93–95} Ca^{2+} channels are found on somata and synaptic terminals, the latter localization mediating synaptic transmission in rods and cones (Box 19.4). Studies on isolated salamander rods report an activation potential around -45 mV which is paradoxically close to the membrane potential in the dark. The activation potential for Ca^{2+} channels in primate rods and cones is more reasonable, close to -60 mV , leaving a wide operating range of voltage for modifying Ca^{2+} entry in response to light (Fig. 19.18). The Ca^{2+} channels in rods and cones react promptly to voltage changes and are non-inactivating, a property that is well suited for a high rate of sustained vesicular neurotransmitter release in darkness. The channels are blocked by diltiazem, verapamil and dihydropyridines such as nifedipine and nimodipine and are enhanced by Bay K 8644.^{88,96}

Calcium-activated potassium current, $I_{K(Ca)}$

Two currents in rods and cones are activated by a rise in intracellular Ca^{2+} : the Ca^{2+} -activated anion current and the Ca^{2+} -activated K^+ current.⁸⁹ The latter shows the N-shaped current-to-voltage relationship characteristic of other calcium-activated currents. The magnitude of the outward current is reduced by charybdotoxin^{99,100} indicating the involvement of maxi-K or BK channels. Although $I_{K(Ca)}$ is sizable in rods at positive voltages, the current is minimal within the physiological range and absent in cones. For that matter, $I_{K(Ca)}$ does not appear to be expressed in primate cones at all.⁹⁰ $I_{K(Ca)}$ may therefore serve as a safety net, capable of moving V_m towards the equilibrium potential for K^+ to guard against large depolarizations that would flood the rod interior with Ca^{2+} . Cones rely on other currents to fulfill that function.

Calcium-activated anion current, $I_{Cl(Ca)}$

Both rods and cones express a robust Ca^{2+} -activated anion current.^{88–90,100} The main permeant anion is Cl^- and given an equilibrium potential for Cl^- near -20 in rods¹⁰¹ and -45 mV in cones,¹⁰² $I_{Cl(Ca)}$ helps to set and stabilize the resting potential. Experimentally, the current is observed most prominently as a tail current following a step of voltage that opens Ca^{2+} channels and allows Ca^{2+} to enter the cytoplasm (Fig. 19.20). The time-course of the tail current reflects the time course of the restoration of free Ca^{2+} to basal levels. In the case of rods, the Ca^{2+} -activated Cl^- conductance is highly targeted to the synaptic terminal. Its strategic location near the site of transmitter release raises the possibility of local control over I_{Ca} by a direct effect of Cl^- on the Ca^{2+} channel itself¹⁰³ and by altering the membrane potential at the release site, indirectly affecting Ca^{2+} channel gating. Given the sizes of the pedicle and spherule and their separation from the soma by a thin fiber, the membrane potential in the terminal region could differ from that in the soma. After hyperpolarizations lasting hundreds of milliseconds, the absence of Cl^- efflux through $I_{Cl(Ca)}$ would prime Ca^{2+} channels and shift their activation potential to lower voltages.¹⁰³ This

Box 19.4 Night blindness resulting from a defective rod synapse

Incomplete Schubert-Bornstein congenital stationary night blindness is an X-linked, recessive condition that can result from genetic defects in *CACNA1F*.^{97,98} Over 57 disease-causing mutations have been documented (<http://www.hgmd.cf.ac.uk/ac/index.php>). Since the gene encodes the pore-forming α_{1F} subunit of the calcium channel in rods and cones, disruptive mutations

(Fig. 19.19) preclude rod signals from reaching second-order neurons. Transmission at the cone synapse is affected, but maintained nonetheless because cones also express the α_{1D} isoforms.⁹⁵ Night blindness is incomplete because gap junctions afford parallel albeit less-efficient rod signaling through the cone neural circuitry.

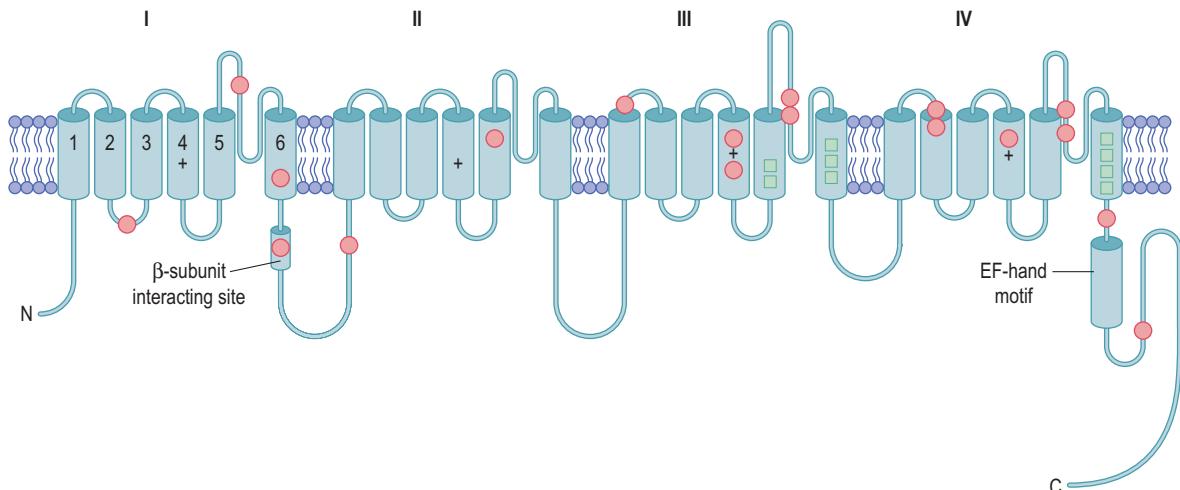

Figure 19.19 Partial spectrum of mutations in *CACNA1F* that cause night blindness. There are four repeating domains of six transmembrane segments in the α_{1F} -subunit. The S4 segment in each domain is a voltage sensor (pluses). Residues comprising the dihydropyridine binding site are present within repeats III and IV (green squares). Disease-causing mutations (red circles) are found in each of the four repeats. (From M. Nakamura, S. Ito, H. Terasaki and Y. Miyake: Novel *CACNA1F* mutations in Japanese patients with incomplete congenital stationary night blindness, *Investigative Ophthalmology and Visual Science* 42:1610–1616. Adapted with permission from the Association for Research in Vision and Ophthalmology, copyright 2001.)

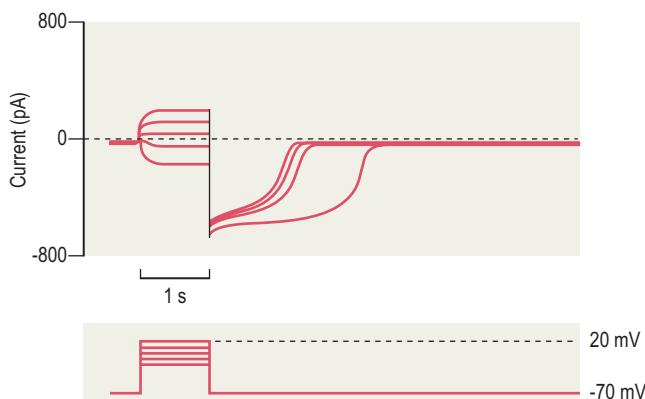

Figure 19.20 Ca^{2+} -activated Cl^- conductance. Depolarizations of salamander rods from -70 mV to voltages between -20 and $+20\text{ mV}$ at 10 mV intervals evoke an anionic current with a reversal potential near 0 mV , the equilibrium potential for Cl^- under the nonphysiological conditions of these experiments. The depolarization increases intracellular Ca^{2+} so upon return of the membrane potential to -70 mV , $I_{\text{Cl}(\text{Ca})}$ gives rise to an enormous tail current. Ca^{2+} currents have been subtracted and other currents blocked to isolate $I_{\text{Cl}(\text{Ca})}$. Tail currents do not appear if the cell is bathed in a Ca^{2+} -free solution. Recordings were made near 10°C . (From MacLeish PR and Nurse CA, 2007: Ion channel compartments in photoreceptors: evidence from salamander rods with intact and ablated terminals, *Journal of Neurophysiology* 98: 86–95,¹⁰⁰ adapted with permission from the American Physiological Society.)

mechanism could hasten the recovery after bright flashes and sensitize the synapse to bright steady light being turned off.

The approximate contribution of each inner segment conductance to the photovoltage response is summarized in Figure 19.21. Rapid closure of CNG channels hyperpolarizes the photoreceptor and slowly shuts down an outward current (I_{KV}) at voltages slightly more negative than the resting potential and activates an inward current at even more negative voltages (I_{H}) to carve out the nose in the response to a bright flash. Ca^{2+} -activated Cl^- currents may sharpen the voltage response at the synapse. Ultimately the light-induced cessation of Ca^{2+} -mediated synaptic release gets damped and proceeds over a faster time course.

Electrotonic coupling

In addition to inner segment conductances, the membrane potentials of rods and cones are influenced by neighboring cells via cell-cell coupling and synaptic feedback.^{5–7,104} Single photon responses from rods induce a voltage response in cones but with an amplitude that is eight times smaller. Time to peak is about twice as fast because the network behaves as a high pass filter. A consequence of coupling between rods and cones and between cones of different spectral types is that if the spot of light falling on the retina is large, the size and shape of the response in a given cone

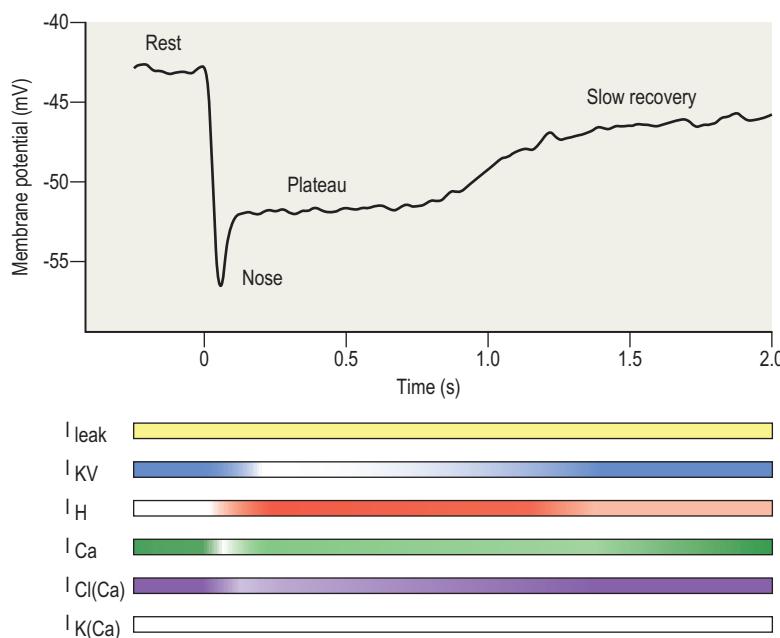

Figure 19.21 Influence of inner segment conductances on the photovoltage response to a bright flash in a rod.

will depend on wavelength. In addition, modulation by horizontal cells confers an antagonistic center-surround receptive field. These effects are described in greater detail in Chapter 22.

Summary

Rods and cones divide the intensity range for vision. Rods attain the ultimate in sensitivity by adeptly counting single photons. Their sensitivity is limited only by photon capture. To achieve high sensitivity, they sacrifice rapidity in their response kinetics and dynamic range. The photocurrent response generated in the outer segment is delayed, peaks in 200 ms and has an integration time of 300 ms. Since cones are not concerned with dim light, their photocurrent response to single photons is an order of magnitude smaller, time to peak is several times shorter and integration time is reduced over ten-fold. It is important that cones do not saturate, so their operating range not only shifts to the right, it also stretches out compared to rods and accommodations have been made to prevent bleaching from doing more than reducing photon capture. Higher intensities allow a point in visual space to be encoded by multiple receptors so that information about color may be extracted. Fast cone responses improve on temporal resolution. Inner segment conductances in rods and cones set the resting membrane potential, speed up the kinetics of the photovoltage response near its peak, and modulate intracellular Ca^{2+} . Certain heritable diseases may target rods, cones or both, depending upon their particular patterns of gene expression.

Light Adaptation in Photoreceptors

Trevor D. Lamb

1. Vision from starlight to sunlight

The human visual system operates effectively over an enormously wide range of intensities, of at least a billion-fold, from around 10^{-4} cd m $^{-2}$ under starlight conditions to around 10^5 cd m $^{-2}$ under intense sunlight. Changes in pupil area account for only about 1 log unit of this 9 log unit range, since the pupil diameter changes from a maximum of 8 mm to a minimum of 2.5 mm, corresponding to about a 10-fold reduction in area. Instead, the great bulk of the operational range is achieved by the combination of, firstly, a switch between the scotopic (rod-based) and photopic (cone-based) pathways in our duplex visual system and, secondly, the ability of each of these photoreceptor systems to operate over a range of 5 log units (100,000-fold) or more.

Light adaptation versus dark adaptation

This ability of the visual system (or of any of its component parts, such as a photoreceptor) to adjust its performance to the ambient level of illumination is known as "light adaptation". This adjustment typically occurs very rapidly (within seconds), whether the light intensity is increasing or decreasing. The term "dark adaptation" is reserved for the special case of recovery in darkness, following exposure of the eye to extremely bright and/or prolonged illumination that activates (and thereby bleaches) a substantial fraction of the visual pigment, rhodopsin or its cone equivalent. Dark adaptation occurs slowly, and full recovery of the scotopic visual system after a very large bleach can take as much as an hour.

Light adaptation and the changes that accompany it are beneficial to the possessor of the eye. At very low intensities, visual sensitivity is increased to the utmost that is possible, so that the rod photoreceptors reliably signal the arrival of individual photons and the scotopic visual system operates in a photon-counting mode. This ability of the scotopic system to operate at incredibly low intensities is enhanced by two deliberate trade-offs that permit more reliable detection of small signals in the presence of noise: firstly, reduced spatial resolution (i.e. increased spatial summation), and secondly reduced time resolution (i.e. increased temporal

integration). Similar trade-offs are used in the photopic system, so that as the ambient illumination decreases from daylight levels towards twilight levels, one's spatial and temporal resolution deteriorate, making it very difficult to play fast ball-games when the light fades.

In contrast, the changes that characterize dark adaptation are disadvantageous. To be effectively blind to dim stimuli, for some considerable time after intense light exposure, cannot in any way be useful to an organism. Indeed, for our ancestors (as well as ourselves) entering a cave from bright sunshine is likely to have been quite dangerous, given that visual sensitivity is greatly reduced for tens of minutes. Why should such an apparently unsatisfactory situation have persisted? One possibility is that this slowness of recovery represents an inevitable "cost" of the evolutionary changes that were needed to enable the scotopic system to signal individual photon hits.

Purposes of light adaptation

A photoreceptor that did not adapt to the ambient light intensity would have a very narrow operating range: low intensities would provide negligible response, whereas high intensities would saturate the cell. Accordingly, photoreceptor light adaptation can be viewed as a means for extending the operating range of the cell.

The purpose of light adaptation can be viewed more generally as being to permit the visual system (or any neuron within it) to provide the best possible performance at that particular level of illumination; however, in this context it is not always clear what constitutes "best". For example, it is difficult for us to specify the time-course of response that is best at any given level of illumination. A brief response is likely to provide a better reaction time for the organism, but it may result in very poor sensitivity; conversely, allowing the response to integrate for a longer period will provide greater sensitivity, but may result in a very poor reaction time.

In setting the best performance of a photoreceptor, one crucial task is to endow the cell with very high sensitivity at low light levels yet prevent it from saturating at higher light levels. Light adaptation accomplishes this by reducing the cell's sensitivity to light as the background light level

increases; however, this task needs to be performed in a manner that avoids excessive reduction in sensitivity. Cone photoreceptors excel in this capacity, and are able to avoid saturation no matter how intense the steady light becomes, and to continue to signal contrast effectively. Rods, on the other hand, are only able to adjust their sensitivity over a relatively narrow range of intensities, before they are driven into saturation, thereby becoming completely unresponsive. One advantage of this saturation of the rods, though, is that it substantially reduces the metabolic demand of the rods, at intensities where the cones are already functional, and where the metabolic demand for chromophore re-synthesis begins increasing.

In addition to the very important function of optimizing the photoreceptor's sensitivity over a broad range of light intensities, there are two other ways in which photoreceptor light adaptation optimizes the cell's response. Firstly, as will be explained below when eqn (1) is presented, Weber Law light adaptation permits automatic extraction of the contrast in the visual scene, independent of the absolute level of illumination. Secondly, light adaptation provides real-time adjustment of the time-course of the response to an incremental flash of light, in a manner that is presumed to be optimal for the visual system, though, as explained above, we are not yet able to quantify optimality in this regard.

2. Performance of the photopic and scotopic divisions of the visual system

Photopic vision: the cone system is the workhorse of vision

For humans, the photopic cone system can be considered the "workhorse" of vision, because it is operational under almost all of the conditions that we experience (in the 21st century). Thus, it is the photopic system that underlies our sense of vision at all light levels apart from the exceptionally low intensities experienced in moonlit and starlit conditions. Under moonlight levels of illumination, our scotopic and photopic systems are both functional, over an intensity range that is termed "mesopic". In order to determine whether you are using your photopic system under twilight or nighttime conditions, there is a simple test: if you are able to detect any color in the scene, then your cones are active; if you cannot, then it is likely that only your rods are active. As the ambient intensity increases at dawn, the photopic system remains functional, up to the brightest sunlit conditions that we ever experience.

Despite their enormous importance to our vision, cones make up only about 5 percent of the population of photoreceptors. The low density of cone photoreceptors in the peripheral retina is quite adequate for our peripheral vision, even in daytime, as we require only relatively low spatial acuity in the periphery. Even though the great majority of peripheral photoreceptors are rods, they are not in fact used under most of the circumstances that we think of as vision – instead, they are only used at exceedingly low ambient lighting levels. The reason for having a very high density of rods is to be able to capture every available photon under starlight conditions.

The responses of cones are rapid and moderately sensitive

One of the greatest advantages of cones over rods is their much faster speed of response. Our rods, even when they are light-adapted, have responses that are much too slow to allow us to function visually at the speeds that are required to escape predators and to capture prey. Cones, instead, are specialized so as to permit extremely rapid signaling of visual stimuli to the brain.

Cones are often described as being far less sensitive than rods, but this view is misleading especially when considered in terms of the rapidly changing visual stimuli that the cones are specialized for signaling. Although a cone may exhibit a *peak* sensitivity to a brief flash of light that is perhaps 30-fold lower than in a rod, the sensitivity to rapidly fluctuating stimuli is considerably *higher* in cones than in rods; thus, the slow response of the rod makes it very insensitive to rapidly changing stimuli. When calculated in terms of the efficacy of activation in the G-protein cascade of phototransduction, the "amplification" in cones and rods appears to be essentially indistinguishable. The observed difference in sensitivity measured at the peak of the response to a flash instead stems from a difference in the speed of response inactivation.

Comparison of photopic and scotopic light adaptation

A classical result comparing light adaptation in the photopic and scotopic divisions of the visual system is illustrated in Figure 20.1A, from the work of Stiles.¹ The threshold of a human subject for the detection of a flash is plotted against background intensity in double logarithmic coordinates. In this panel, the stimulus conditions provided a rod-based scotopic sensitivity that was only about 30× better than the cone-based photopic sensitivity – thus, the parafoveal region was tested with a small diameter yellow/green test flash (1° dia., 60 ms, 580 nm) on a green background. The measurements are well described by Weber Law curves, in both the scotopic (blue trace) and photopic (red trace) regions; see eqn (1) below. However, the "dark light" that will be described shortly is over 10,000× (4.1 log units) higher in the cone system compared with the rod system.

Scotopic vision: the rod system provides specialization for night vision

Light adaptation is examined under conditions that optimized detection by the scotopic (rather than photopic) system using the blue symbols of Figure 20.1B. To achieve scotopic dominance, the test stimulus was presented in the peripheral retina, and comprised a large area, long duration green flash (9° dia., 200 ms, 520 nm) on a red background. The measurements are from Fig. 3 of [2] and their troland values have been converted using a factor of $K = 8.6$ photoisomerizations s^{-1} per troland.

For comparison, the red symbols plot the desensitization of primate rod photoreceptors, obtained from Fig. 9A and Table III in [3]. Their measurements of sensitivity have been converted to desensitization by taking the reciprocal; in addition the symbols have been shifted vertically to provide

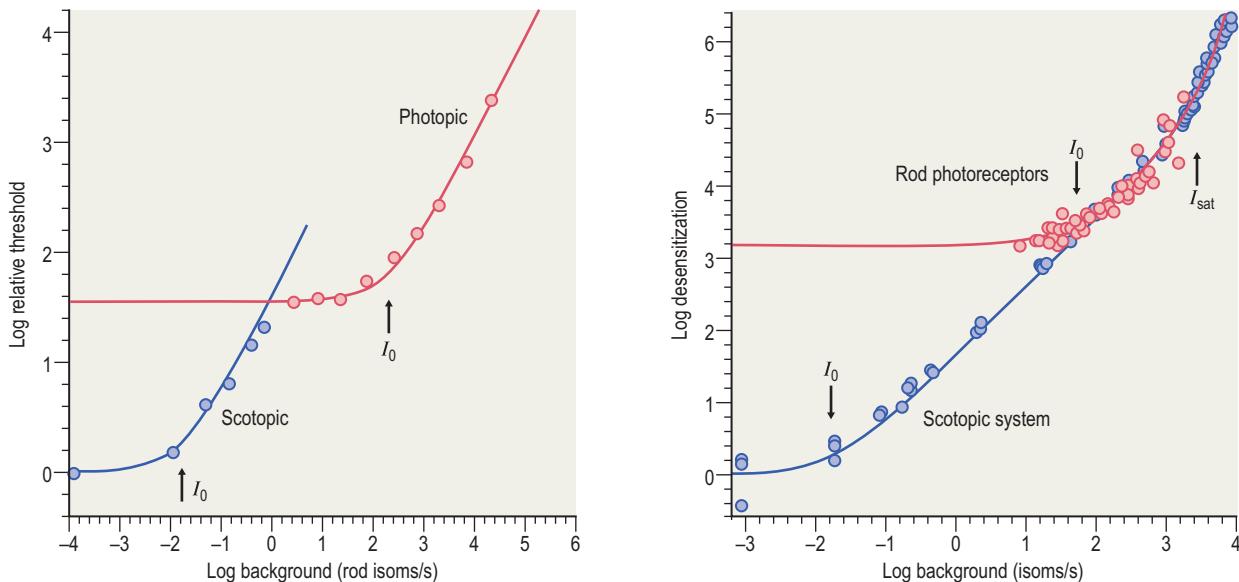

Figure 20.1 Light adaptation of the photopic (cone) and scotopic (rod) divisions of the human visual system. Both panels plot psychophysical threshold as a function of background intensity in double logarithmic coordinates. Left: Scotopic and photopic thresholds for a test flash that was only about 30x more sensitive to the scotopic system. Data are from [1], converted to isomerizations s^{-1} in the rods, horizontally, and to threshold relative to the dark-adapted scotopic value, vertically. Right: Blue symbols are for conditions that optimized scotopic detection; data from [2]. Red symbols are suction pipette measurements from isolated rod photoreceptors of monkeys (*Macaca fascicularis*), shifted vertically to align with the blue symbols in the upper intensity range; data from [3]. All curves plot Weber's Law; see text. (A: Data from Stiles WS. P Natl Acad Sci USA. 1959;45(1):100–114. B: Data from Aguilar M, Stiles WS. Optica Acta 1954;1:59–65 and Tamura T, Nakatani K, Yau K-W. J Gen Physiol 1991;98(1):95–130.)

a good fit to the psychophysical data in the high-intensity range.

The crucial difference between the blue and red symbols is that the overall scotopic visual system begins desensitizing at intensities around 1000 times lower than those required to begin desensitizing the rod photoreceptors. Thus, a considerable region at the lowest end of scotopic light adaptation is *post-receptoral*, rather than being internal to the rods. Because the post-receptoral scotopic system is able to integrate photon signals from large numbers of rod photoreceptors, and thereby gain increased sensitivity, it needs to begin desensitizing at much lower background intensities in order to avoid saturation. As a result the rod photoreceptors maintain their maximal sensitivity for several log units of the lowest-intensity regimen (up to ~ 10 isomerizations s^{-1}) over which the visual system exhibits gradual desensitization.

When the background intensity is reduced from relatively high scotopic intensities (moving from right to left along the x-axis in Fig. 20.1B) the desensitization of the rods, and of the scotopic visual system, steadily falls. However, below the intensities indicated by the red and blue arrows, the desensitization of first the rods, and second the visual system, fails to continue falling, as if the respective mechanism were experiencing a phenomenon equivalent to light. Accordingly, the arrowed intensities for the rods and for the scotopic visual system have been referred to as “equivalent background intensities”, or “dark light”. Clearly, the equivalent background for the scotopic system (around 50 photoisomerizations s^{-1}) is more than 1000x lower than the equivalent background intensity for the rods (around 50 isomerizations s^{-1}).

Each of the curves in Figure 20.1 plots desensitization according to Weber's Law, though the curves in Figure 20.1B additionally include saturation at high intensities, as described by the equation:

$$\frac{Desens}{Desens_D} = \{1 + (I/I_0)\} \exp(I/I_{sat}) \quad (1)$$

where $Desens$ is desensitization, $Desens_D$ is its dark-adapted value, and I is the background intensity. The first term on the right expresses Weber's Law, where I_0 is the equivalent background intensity mentioned above. This first term indicates that at low background intensities (when $I \ll I_0$) the desensitization approaches a constant level (its dark-adapted value, $Desens_D$), while for brighter backgrounds (when $I \gg I_0$) the desensitization increases linearly with background intensity.

At higher scotopic intensities, both the rods and the overall scotopic system exhibit saturation, characterized by a steep rise in desensitization with increasing background intensity. This behavior is described by the second term on the right in eqn (1), where I_{sat} is termed the saturation intensity. It is almost certain that saturation of the overall scotopic system results directly from saturation of the rods. Thus, for the blue and red curves in Figure 20.1B, the same value of saturation intensity, $I_{sat} = 2500$ photoisomerizations s^{-1} (black arrow), has been used. In contrast, the dark light is enormously different between the two curves, with $I_0 = 0.016$ and 50 photoisomerizations s^{-1} , respectively, for the psychophysical data (blue arrow) and the rod photoreceptor data (red arrow).

The span of intensities from I_0 (the dark light) to I_{sat} (the saturation intensity) represents the Weber region, and in this

range of background intensities the desensitization is directly proportional to background intensity. The reciprocal of desensitization is the sensitivity, $S = 1/\text{Desens}$, and hence within the Weber region the sensitivity declines inversely with background intensity; i.e. $S \propto 1/I$.

Since the contrast in a visual stimulus is likewise inversely proportional to background intensity (i.e. contrast = $\Delta I/I$), this Weber region is characterized by a fixed level of contrast sensitivity; that is, a given level of contrast elicits a fixed size of response. Hence, an important feature of Weber Law light adaptation is that it provides automatic extraction of visual contrast.

Figure 20.1B shows that for the overall scotopic system the Weber region covers a very wide range, of at least 5 log units (i.e. over 100,000-fold).

3. Light adaptation of the electrical responses of cones and rods

In the presence of background illumination, it is not only the overall visual system that adapts – the rod and cone photoreceptors themselves display light adaptation, characterized by desensitization and acceleration of their electrical response to an incremental flash.

For rods, though, such adaptation occurs over only a restricted range of intensities before saturation sets in. Thus, the red data in Figure 20.1B show that the Weber region for mammalian rods encompasses only 1–2 log units of intensity before saturation; for the larger rods of lower vertebrates the Weber region may encompass a slightly wider range of about 3 log units.

In contrast, cone photoreceptors undergo light adaptation over an enormously wide range of intensities, and they manage to escape saturation no matter how intense the steady light. In the overall photopic visual system it is likely that the observed adaptation results primarily from these changes at the level of the cones, rather than through post-receptor processing.

Saturation of the electrical response in rods and its avoidance in cones

The response of a salamander rod to the onset of steady illumination at different intensities is illustrated in Figure 20.2. At the beginning of the step of light, the rod's response begins rising according to the prediction from the time integral of the flash response (noisy traces). But under normal conditions (upper panel) the response very soon deviates, falling well below the linear prediction. Characteristically, the response to such a step of light typically exhibits an early peak followed by a sag. This deviation from the simplest linear prediction is a crucial aspect of light adaptation – if this deviation did not occur, then the rod would be driven into saturation by lights of very low intensity. Saturation can readily be induced by exposing the rod to a solution that clamps the cytoplasmic calcium concentration (lower panel); the measured responses then follow the predictions of the theoretical curves, and a very low intensity (labeled 2) saturates the rod. This result shows that at least a part of the rod's ability to continue operating in backgrounds of moderate intensity is a consequence of changes in cytoplasmic calcium concentration; the molecular mechanisms that contribute to this will be discussed in Section 4.

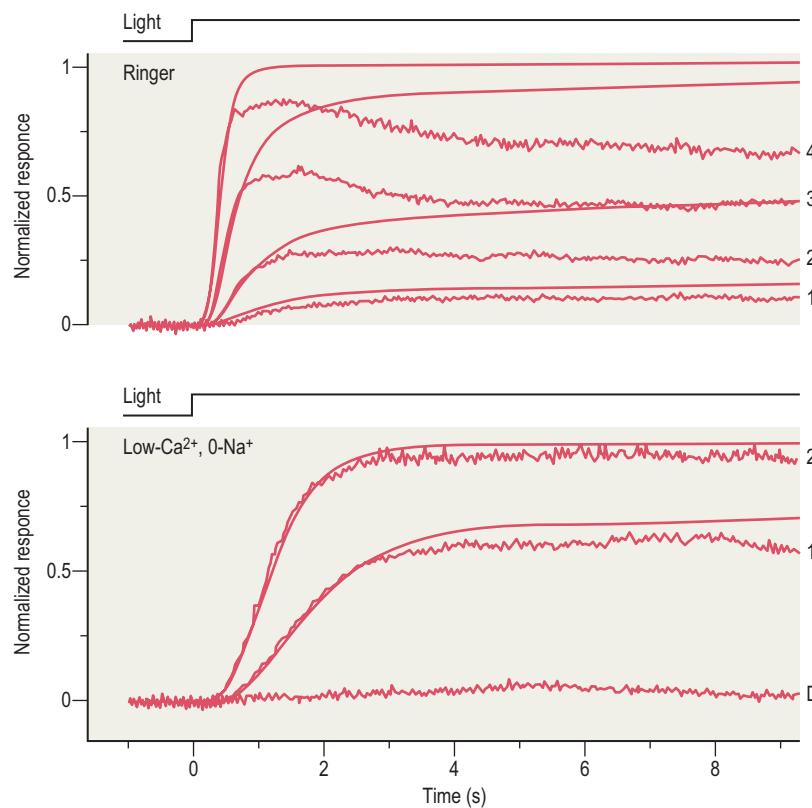

Figure 20.2 Responses of a salamander rod to onset of steps of light of different intensities. Upper panel: under control conditions (Ringer solution). Lower panel: in the presence of Ca^{2+} -clamping solution. The step intensities increased by factors of ~ 4 for traces labeled 1–4; D, darkness. The smooth curves are predictions obtained by integrating the measured dim flash response (not shown), and represent the step responses that are predicted in the absence of any adaptation. (From Fain GL, Lamb TD, Matthews HR, Murphy RLW. Cytoplasmic calcium as the messenger for light adaptation in salamander rods. *J Physiol* 416:215–243.²⁴)

At higher background intensities, though, the circulating current in the normal rod becomes completely suppressed. Thus, for the upper panel of Figure 20.2, intensities higher than that labeled 4 (not shown) causes the response simply to rise to its maximum level, corresponding to the closure of all cGMP-gated channels in the outer segment, with the consequence that incremental stimuli are unable to elicit any incremental response, and the cell's response is "saturated". Typically, such saturation sets in exponentially with increasing background intensity, as described earlier by the second term on the right of eqn (1).

Cone photoreceptors exhibit even more pronounced "sag" from an initial peak, when steady background illumination is turned on. An example is illustrated for modest steady intensities in the early region of the traces in Figure 20.3. The phenomenon is extremely robust in cones and, no matter how high the light intensity, the cone photoresponse always recovers to a reasonable operating level, even if it is transiently driven into saturation at the onset of intense illumination.

Desensitization and acceleration of the photoreceptor's electrical response

In addition to showing the transient nature of the responses elicited by the onset of backgrounds in cones, the main purpose of Figure 20.3 is to illustrate the desensitization of the responses to incremental flashes that is elicited by these backgrounds.

The traces illustrate the responses of a cone photoreceptor to an identical set of flashes presented under three different conditions. In panel (A) the flashes (*a*–*f*, of progressively greater intensity) were presented in darkness. In panel (B) the same flashes were presented on a dim steady background, and in panel (C) they were presented on a brighter background. In the presence of background illumination, the responses to dim flashes were smaller. For example, for the second flash intensity, *b*, the response amplitude became markedly smaller from panel (A) to panel (B) to panel (C). In other words, backgrounds of increasing intensity progressively desensitized the cone's incremental response. Such behavior is very characteristic of photoreceptors (both cones and rods).

The changes in the dim flash response elicited by backgrounds of different intensity are shown in Figure 20.4A. The largest trace is the response to a dim flash presented under fully dark-adapted conditions, while the other traces are for the same flash presented on backgrounds of progressively brighter intensity. (In fact, in order to maintain responses of measurable amplitudes, the flash intensities were increased in the presence of backgrounds, and the traces actually plot response divided by flash intensity; i.e. response sensitivity.)

The traces in Figure 20.4A demonstrate that the effect of increasing background intensity is both to desensitize and to accelerate the response to an incremental dim flash. This behavior of cones is very similar to that exhibited by rods, as illustrated in Figure 20.4B.

Unaltered rising phase but accelerated recovery

For the incremental flash responses of the rod illustrated in Figure 20.4B, the vertical scale has been adjusted to take

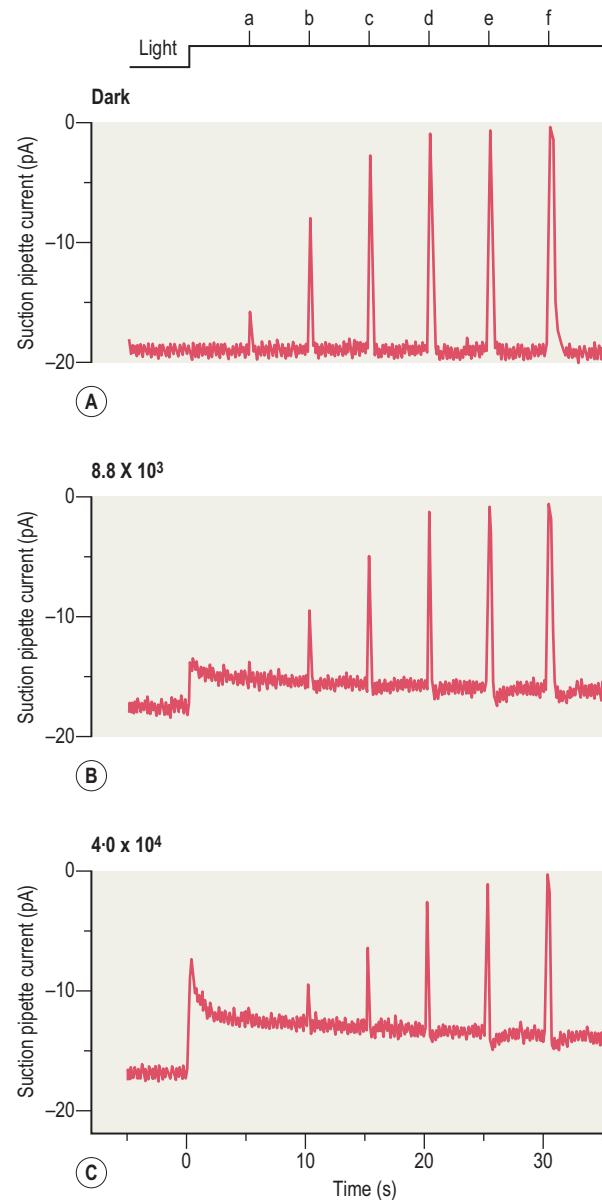

Figure 20.3 Circulating current of a salamander cone in response to flashes and steps of illumination. Timing of illumination is indicated by the marker trace at the top; flashes *a*–*f* increased in intensity by factors of ~4, and were the same intensity in each of panels (A)–(C). In panel (A) these flashes were presented in darkness; in panels (B) and (C) the same flashes were presented on steady backgrounds that had been switched on at time zero; the background in (C) was ~4 times brighter than in (B). (From Matthews HR, Fain GL, Murphly RLW, Lamb TD. Light adaptation in cone photoreceptors of the salamander: a role for cytoplasmic calcium concentration. *J Physiol* 420:447–469.²⁵)

account of changes in the level of circulating current remaining in the presence of the different background intensities. Thus, rather than plotting raw sensitivity (response per photoisomerization), as was done in panel A for the cone, panel B for the rod instead plots the fractional response (i.e. the incremental response as a fraction of the circulating current at that background) per photoisomerization. This has been done in order to provide a direct measure of the level of activation of the guanine nucleotide binding protein (G-protein) cascade of phototransduction; thus, it can be shown

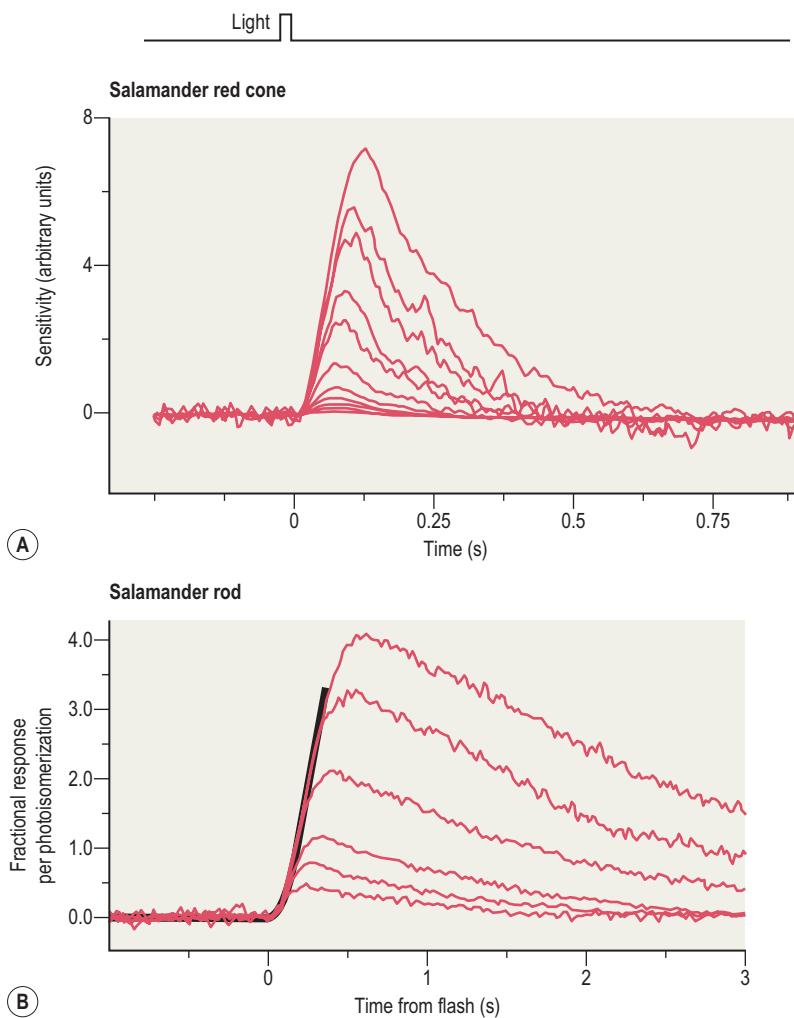

Figure 20.4 Incremental responses of cone and rod photoreceptors to test flashes presented on backgrounds of progressively higher intensity. In each panel, the largest trace is for a dim flash presented in darkness, while the other traces correspond to the same test flash presented on backgrounds. **(A)** Salamander red-sensitive cone. **(B)** Salamander rod. Smooth black curve indicates common rising phase. (A: From Matthews HR, Fain GL, Murphly RLW, Lamb TD. Light adaptation in cone photoreceptors of the salamander: a role for cytoplasmic calcium concentration. *J Physiol* 420:447–469. B: From Pugh EN, Nikonorov S, Lamb TD. Molecular mechanisms of vertebrate photoreceptor light adaptation. *Curr Opin Neurobiol* 9(4):410–418, 1999.^{25,26})

that the level of cascade activation is best measured by the fractional channel opening, which in turn is measured by the incremental response expressed as a fraction of the existing circulating current.

When plotted in this manner, the incremental responses in Figure 20.4B demonstrate the remarkable property that the onset phase of the response is invariant; i.e. the traces for different background intensities exhibit a common rise at early times, indicated by the smooth black trace. This behavior indicates that the amplification parameter describing the activation steps in phototransduction is unaltered during light adaptation; in other words, light adaptation causes no change in the efficacy of the activation steps in phototransduction. Instead, what light adaptation does is to cause a marked speeding-up of the shut-off steps in the transduction cascade. The molecular identity of the steps that are accelerated is considered in Section 4.

Dependence of sensitivity on background intensity: Weber's Law

By plotting the peak amplitude of each of the traces in Figure 20.4A as a function of the background intensity on which it was measured, one obtains a sensitivity versus background plot of the kind illustrated in Figure 20.5.

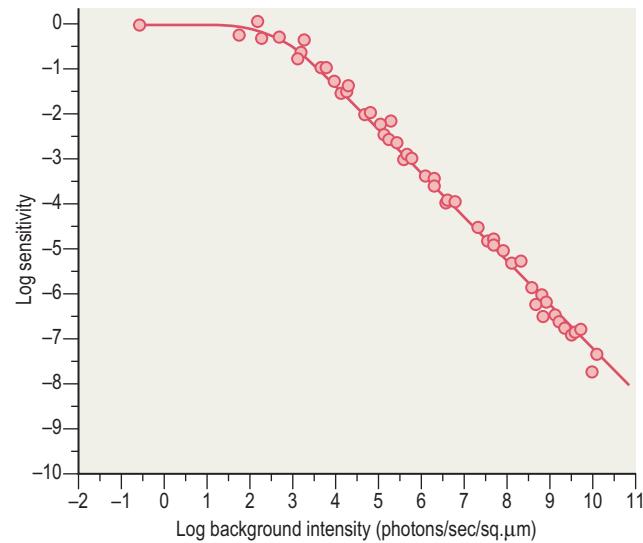

Figure 20.5 Cone sensitivity as a function of background intensity. Results are plotted in double logarithmic coordinates, and were obtained from intracellular measurements averaged from 15 cones in the turtle eye-cup preparation. These experiments monitored step sensitivity rather than the more conventional flash sensitivity. The smooth curve plots Weber's Law, given by eqn (2). (Reproduced with permission from [4].)

The results plotted in Figure 20.5 were obtained over an extremely wide range of background intensities by Burkhardt,⁴ using a laser source of illumination. Importantly, the preparation was the intact eye-cup (of the turtle), so that the photoreceptors remained in contact with the retinal pigment epithelium and thereby experienced normal regeneration of visual pigment, so that physiological results could be obtained even at very high background intensities.

For background intensities from 10^3 to 10^{11} photons $\mu\text{m}^{-2} \text{s}^{-1}$, the relationship between log sensitivity and log background intensity is a straight line with a slope of -1 ; in other words, over roughly 8 log units of background, the turtle cone's sensitivity declines inversely with background intensity. The curve plotted near the points in Figure 20.5 represents Weber's Law, described by:

$$\frac{S}{S_D} = \frac{1}{1 + (I/I_0)} \quad (2)$$

where S is flash sensitivity, S_D is its dark-adapted value, I is the background intensity, and I_0 is the half-desensitizing intensity, also known as the dark-adapted equivalent background intensity. This is the same equation as used in Figure 20.1B for light adaptation of human rods, though without the saturation term (and in coordinates of sensitivity rather than its reciprocal). The good fit of the Weber Law expression shows, very importantly, that cone photoreceptors in the intact eye-cup are able to completely avoid saturation, even at enormously high intensities of steady illumination. This feature represents a crucial distinction between the properties of cones and rods. As illustrated earlier in Figure 20.2, the circulating current of rods is shut off at quite low background intensities so that the rods become unresponsive to superimposed stimuli in the presence of background illumination of moderate intensity.

In the same set of experiments, Burkhardt⁴ measured the intensity at which 90 percent of the pigment was in the bleached state, and found this to be around 10^6 photons $\mu\text{m}^{-2} \text{s}^{-1}$. Hence, for all intensities above that level, the observed Weber Law behavior can be accounted for in terms

of pigment bleaching. For each additional 10-fold increase in intensity there will be a 10-fold reduction in the amount of pigment remaining available to absorb light, and hence there will necessarily be a 10-fold reduction in sensitivity in the absence of any other change of parameters of transduction in the outer segment. In other words, if the photoreceptor is able to avoid saturation up to intensities that cause substantial bleaches, then it will be able to exhibit Weber Law desensitization at all higher intensities purely by means of pigment bleaching. Cones are able to function up to this critical intensity, whereas rods saturate at much lower intensities.

Extremely rapid recovery of human cone photocurrent

Experiments on photoreceptors at high intensities must be undertaken in a preparation in which the retina is in contact with the retinal pigment epithelium (as was the case in the experiments above on turtle cones), so that visual pigment is regenerated. Thus, it is not possible to investigate cone responses at high intensities using single-cell or isolated retina preparations. Instead, to assess the performance of human cones at high background intensities, one is essentially restricted to experiments measuring the electroretinogram (ERG) in the intact eye.

Figure 20.6 illustrates results from an experiment designed to measure the kinetics of recovery of the circulating current of human cone photoreceptors upon extinction of steady illumination that bleached 90 percent of the visual pigment. The traces show recordings of the human photopic ERG *a*-wave, which monitors the massed response primarily of the cone photoreceptors.

The four colored traces plot ERG responses from two subjects, at two different flash intensities, while the light stimulus is monitored by the black trace at the top. The left panel is for an intense flash presented on the intense steady background, while the right panel is for extinction of that background. The "ON" *a*-wave and *b*-wave elicited by the bright flash are indicated by the red arrows, while the "OFF"

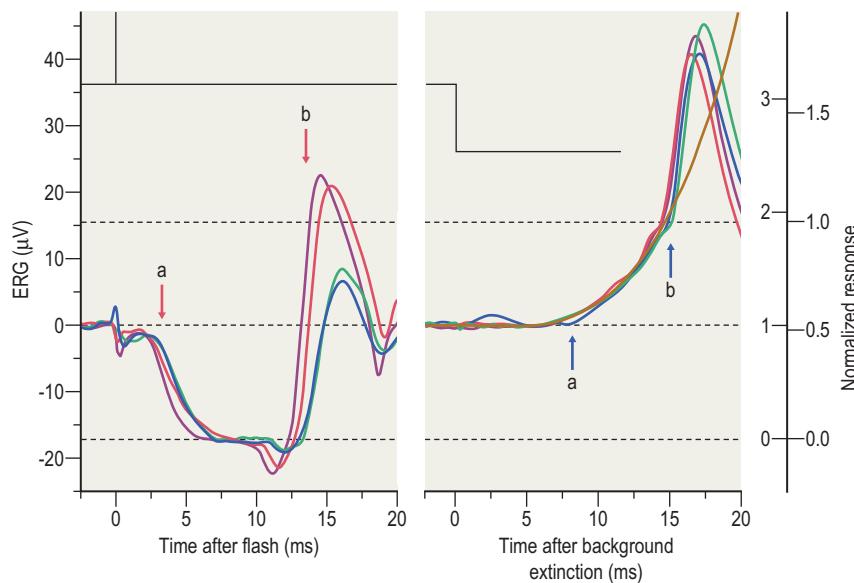

Figure 20.6 Extremely rapid recovery of human cone photocurrent upon extinction of intense illumination, measured with the ERG. The left panel shows the response to a bright flash superimposed on the intense steady background, while the right panel shows the response obtained at the extinction of that background. Dashed horizontal lines represent the following levels of cone circulating current (from bottom): zero level, steady level during intense background, dark level, as indicated by the two normalized scales on the right. See text for details. (From Kenkre JS, Moran NA, Lamb TD, Mahroo OAR. Extremely rapid recovery of human cone circulating current at the extinction of bleaching exposures. *J Physiol* 567(1):95–112.²¹)

a-wave and *b*-wave elicited by extinction of the background are indicated by the blue arrows. The *b*-wave is roughly similar in the two cases, and arises from post-receptoral activity. The OFF *a*-wave represents recovery of the cone circulating current, and begins around 7 ms after the intense background is turned off.

Figure 20.6 shows two very important results relating to human cone responses in the presence of extremely bright illumination. Firstly, the amplitude of the ON *a*-wave in the left panel shows that the steady cone circulating current remained at roughly 50 percent of its original level in darkness. Secondly, the early time at which the OFF *a*-wave in the right panel begins rising (indicated by the blue arrow at ~7 ms) shows that the cone circulating current begins recovering extremely rapidly.

Thus, although little change occurs for the first 7 ms, thereafter a substantial upward response occurs until about 15 ms after extinction of the background; at this point the *a*-wave is obscured by spike-like activity of the *b*-wave. There is compelling evidence that the *a*-wave traces for these subjects monitor the recovery of the cone circulating current. On this basis, the cone circulating current is essentially fully recovered within about 15 ms after extinction of illumination so intense that it bleaches 90 percent of the cone pigment. This is extremely rapid recovery. Section 4 considers the speed of the phototransduction shut-off reactions responsible for generating this rapid recovery, and the smooth curve near the measured traces in the right-hand panel of Figure 20.6 was calculated from the model presented there, using the short time constants listed in Table 20.1 below.

Extremely rapid recovery of cone circulating current, as inferred from the results of Figure 20.6, is required in order to account for classical experiments on the flicker fusion frequency of human subjects. Even at quite low photopic intensities, human subjects are able to detect square-wave flicker at a frequency of around 50 Hz using peripheral vision. But at higher intensities the flicker fusion frequency increases, to 100 Hz or more; at this frequency the illumination is being switched on and off for durations of 5 ms each. Thus, in order for the flicker to be detectable, some degree of recovery of cone circulating current must have occurred within 5 ms. Hence, human flicker sensitivity is broadly consistent with the time-course inferred from Figure 20.6.

4. Molecular basis of photoreceptor light adaptation

The phototransduction cascade

For a full description of the biochemistry of phototransduction, see Chapter 18. Figure 20.7 presents a simplified schematic of these steps, emphasizing the shut-off reactions using red arrows. The lifetimes (or turnover times) of the important shut-off steps are: τ_R , the lifetime of activated rhodopsin; τ_E , the lifetime of activated transducin/PDE; $\tau_{cG} = 1/\beta$, the turnover time of cyclic GMP; and τ_{Ca} , the turnover time of cytoplasmic free Ca^{2+} .

In summary, activation and recovery occur as follows. Light (of intensity I) activates the visual pigment, and the activated pigment (R^*) is inactivated with a time constant

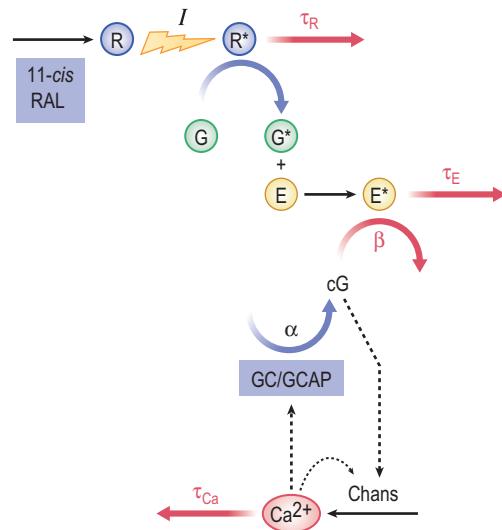

Figure 20.7 Simplified schematic of reaction steps underlying the recovery steps in phototransduction. See text for details. (From Lamb TD & Pugh EN. Avoidance of saturation in human cones is explained by very rapid inactivation reactions and pigment bleaching. Invest Ophthalmol Vis Sci 47:e3714.¹⁰ Reproduced from Association for Research in Vision and Ophthalmology.)

τ_R . R^* catalyzes activation of the guanine nucleotide binding G-protein transducin to G^* , which then binds to phosphodiesterase (E) to form the activated G^*-E^* complex (indicated E^*), which has a lifetime τ_E . The activated E^* catalyzes hydrolysis of cGMP (cG) with a rate constant β . The increase in β is proportional to steady intensity I , with a scaling factor set by the product of the R^* and E^* lifetimes; i.e. $\beta = \beta_{Dark} + (A/n_{cG}) \tau_R \tau_E I$ (see [5]). cGMP formation is catalyzed by guanylyl cyclase (GC), under the regulation of Ca^{2+} -sensitive guanylyl cyclase activating proteins (GCAPs). When present, cG causes the opening of ion channels (chans) in the plasma membrane, admitting Ca^{2+} ions. Cytoplasmic Ca^{2+} has a powerful negative-feedback action via GCAPs onto the rate α of cGMP synthesis. Ca^{2+} ions are removed from the cytoplasm with a turnover time for free Ca^{2+} concentration of τ_{Ca} . Finally, and very slowly, visual pigment (R) is re-formed by delivery of 11-cis retinaldehyde (11-cis RAL) from the retinal pigment epithelium.

The mechanisms that contribute to light adaptation in photoreceptors (i.e. to the alteration in response properties of the photoreceptors upon exposure to background illumination) are closely associated with the mechanisms of response recovery (see Chapter 18). These mechanisms of adaptation can be classified broadly as (1) those that are calcium-dependent, and (2) those that do not involve calcium. Both categories play major roles, and here the less well-known category of non-calcium-dependent mechanisms will be treated first.

Photoreceptor light adaptation independent of calcium

There are at least three classes of non-calcium-dependent phenomena that represent mechanisms of light adaptation in photoreceptors, where light adaptation is interpreted as an alteration of response properties in comparison with the

dark-adapted state. First, there is response compression, whereby the reduced level of circulating current in the presence of steady background illumination reduces the size of the flash response. This phenomenon will not be discussed here, in part because it is both very well known and very simple, but also because (in philosophical terms) it can be viewed as a failure of light adaptation. Cones substantially avoid response compression through powerful feedback mechanisms that maintain the circulating current. Second, there is pigment depletion, which is relevant to cones at high intensity; however, it is never relevant to rods, because they are driven into saturation by even very low levels of bleached pigment (see [Section 6](#)). Third, there is a direct effect of PDE activation, which is now considered.

Accelerated turnover of cGMP

In darkness the activity of the PDE is relatively low, so that the turnover rate of cGMP hydrolysis (denoted β) is low and the turnover time for cGMP ($\tau_{cGMP} = 1/\beta$) is long. Under dark-adapted conditions, τ_{cGMP} is around 1 s in amphibian rods, and around 200 ms in mammalian rods. The magnitude of this parameter has a major effect on both the sensitivity and the kinetics of the photoreceptor's response to a flash. Thus, when the PDE activity increases in steady illumination, the shorter turnover time for cGMP contributes both to desensitization and to acceleration of the photoresponse.

To provide an intuitive understanding of this mechanism, it is helpful to consider what we have referred to previously as the "bathtub analogy".⁵ Imagine a container of water, such as a tall cylinder, and let the height of water in the cylinder represent the level (concentration) of cGMP in the outer segment. The rate at which water runs out of the cylinder, through a drain-hole at the base, is proportional both to the height of water and to the size of the opening, representing the cGMP level and the PDE activity, β , respectively. Likewise, the rate at which water flows in to the cylinder through a tap at the top represents the activity of guanylyl cyclase, α . When a steady state is reached, the height of water will equal the rate of influx divided by the size of the drain-hole; i.e. $cGMP = \alpha/\beta$. Importantly, whenever the water level is perturbed from this steady-state level (e.g. upon a brief opening of an additional drain-hole), the level will re-equilibrate with a time constant $\tau_{cGMP} = 1/\beta$ (provided that the rate of influx through the tap remains constant). Hence, if the drain-hole is small (and the inflow via the tap correspondingly small) then any perturbation in water level elicited by a transient additional outflow will be corrected only slowly; if the drain-hole is large (and the inflow correspondingly large) then any perturbation will be rapidly corrected. Furthermore, though perhaps less intuitively, it can be shown that for a non-instantaneous perturbation, corresponding to the normal flash response, not only will the kinetics of recovery be faster but also the peak will be smaller.

Hence the effect of the increased PDE activity during steady illumination is both to accelerate the response kinetics and to reduce the peak amplitude to an incremental flash. Calculations show that, in amphibian rods, the 20-fold increase in β during steady illumination provides the primary mechanism underlying the measured shortening of time-to-peak and the decrease in flash sensitivity.⁵

Calcium-dependent mechanisms of rapid light adaptation: re-sensitization through prevention of saturation

When cGMP-gated ion channels in the outer segment are closed in response to light, the cytoplasmic concentration of calcium drops (see Chapter 19). This drop in Ca^{2+} concentration is vitally important to light adaptation, though it is crucial to emphasize that it does not cause the desensitization that characterizes photoreceptor light adaptation. Quite the contrary: the drop in Ca^{2+} concentration actually rescues the rod from the saturation that would otherwise be induced by light, and thereby prevents the onset of massive desensitization at relatively low intensities of background illumination. Thus, the light-induced drop in Ca^{2+} acts to increase the rod's sensitivity above the drastically reduced level that would occur, either if the Ca^{2+} concentration did not alter, or if the rod's calcium-dependent mechanisms were inoperative.

Powerful negative feedback loop mediated by calcium

Calcium is the cytoplasmic messenger for a very powerful negative feedback loop that tends to stabilize the photoreceptor's circulating current. If ever the Ca^{2+} concentration drops (e.g. in response to light, or as a result of some other perturbation) then, as described in Chapters 18 & 19 and below, a number of changes occur very rapidly. These changes are stimulated by the unbinding of Ca^{2+} from at least three classes of calcium-sensitive protein: (1) guanylyl cyclase activating proteins (GCAPs 1 and 2), which activate guanylyl cyclase; (2) recoverin, which regulates the lifetime of activated R*; and (3) a protein that modulates the opening of cGMP-gated channels – in rods this is calmodulin. Calcium's action via each of these pathways leads to the opening of cGMP-gated channels, thereby increasing the circulating current and admitting Ca^{2+} ions from the extracellular medium. This influx of Ca^{2+} ions tends to counteract the initial reduction in Ca^{2+} concentration, thereby completing a negative feedback loop.

Each of these molecular mechanisms involved in the calcium negative feedback loop contributes towards extending the cell's operational range of light intensities, by helping to prevent saturation of the circulating current. Thus, each of these three molecular mechanisms assists in *rescuing* the photoreceptor from saturation and hence *increasing*, rather than decreasing, the sensitivity compared with the case that would exist if the mechanism were absent. Each of the three mechanisms is most effective over a particular range of calcium levels, and hence over a particular range of light intensities. The most powerful of the three (at least in rods) is the GCAP activation of guanylyl cyclase.

Because the various components of the calcium negative feedback loop act quite rapidly, they contribute not only to determining the photoreceptor's sensitivity in the presence of background illumination, but also to determining the kinetics of its response to an incremental flash presented on the background. The importance of altered Ca^{2+} concentration in setting the incremental flash response kinetics can be demonstrated by incorporating a calcium buffer (such as BAPTA) into the outer segment. [Figure 20.8A](#) shows that, although the flash response begins rising exactly as in control

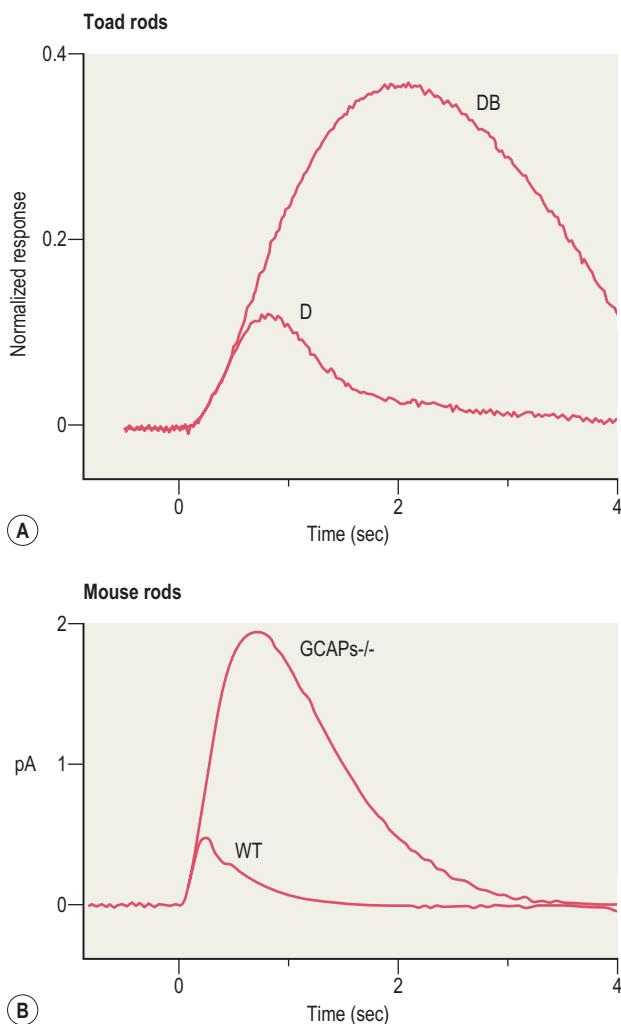

Figure 20.8 Comparison of calcium buffering and GCAPs knockout on the rod's dim-flash response. Both panels plot suction pipette recordings from single rods. (A) Salamander rod response to a flash in darkness (D) and to the same flash after incorporation of the calcium buffer BAPTA (DB).

(Reproduced with permission from [27]) (B) Mouse rod single-photon responses, for wild type (WT) and GCAPs knock-out (GCAPs $-/-$) animals. (A: From Torre V, Matthews HR, Lamb TD. Role of calcium in regulating the cyclic GMP cascade of phototransduction in retinal rods. Proc Natl Acad Sci USA. 83:7109–7113.²⁷ B: From Burns ME, Mendez A, Chen J, Baylor DA. Dynamics of cyclic GMP synthesis in retinal rods. Neuron 36(1):81–91.²⁸)

conditions, it does not recover as rapidly, and instead rises to a substantially larger and later peak with slower final recovery. The three calcium-sensitive molecular pathways will now be described.

Guanylyl cyclase activation

In response to a drop in calcium concentration, Ca^{2+} will unbind from the GCAP proteins (GCAP1 and GCAP2), thereby activating guanylyl cyclase and stimulating the production of cGMP at a greatly increased rate, leading to the opening of cGMP-gated channels.

The cyclase activity increases roughly as the fourth power of the drop in Ca^{2+} concentration, and furthermore (as for the other two routes considered below) the number of channels open increases approximately as the cube of the cGMP concentration. Because of the cascading of two such steep dependencies, any small fractional change in Ca^{2+}

concentration stimulates a large and opposite fractional change in channel opening; that is, the fractional change in channel opening is opposite in sign to, and up to 12 \times the magnitude of, the originating fractional change in Ca^{2+} concentration. As a result, this molecular mechanism is the most potent of the three that contribute to the calcium negative feedback loop and hence to setting the adaptational state in rods. It is especially dominant at relatively bright background intensities, corresponding to low Ca^{2+} concentrations, and is therefore the most important in extending the rod's operating range to high intensities.

The role of the GCAP/guanylyl cyclase component of the Ca^{2+} feedback loop in setting the waveform of the incremental flash response is illustrated in Figure 20.8B, where averaged responses are shown for rods from WT and GCAPs knockout mice. In a manner very similar to that seen in amphibian rods containing the calcium buffer BAPTA, the response in the GCAP knockout case begins rising exactly as for the control (WT) case, but it does not recover as soon, so that the response continues rising and reaches a larger and later peak.

Shortened R* lifetime

Activated rhodopsin (R^*) is inactivated by multiple phosphorylation steps mediated by rhodopsin kinase (GRK1) followed by binding of arrestin (for details, see Chapter 18). It is generally assumed that the decline in R^* activity follows exponential kinetics, and can therefore be described by a characteristic lifetime, τ_R ; however, it is worth bearing in mind that there is no direct evidence for this assumption. It was established by Kawamura⁶ that GRK1's phosphorylation of R^* is calcium-dependent and that the effect is mediated by the calcium-binding protein recoverin (termed S-modulin in frog). The molecular mechanism of this dependence is not entirely clear, but some evidence suggests that the calcium-bound form of recoverin binds to GRK1, thereby preventing it from interacting with R^* . In any case, it is proposed that a reduction in Ca^{2+} concentration leads to a shortened R^* lifetime, τ_R .

The slowest time constant in the phototransduction cascade (the so-called dominant time constant, τ_{dom}) can be estimated from the steepness of the relationship between the duration that the rod is held in saturation by a bright flash and the flash intensity (see [7]). Over the years there has been considerable debate as to whether this dominant time constant is set by the R^* lifetime, τ_R , or instead by the lifetime τ_E of the transducin-phosphodiesterase (PDE) complex (the effector). The situation may differ between rods and cones, and may also be species dependent. But in mouse rods Burns and colleagues have now clearly established that under dark resting conditions the dominant time constant is that of transducin-PDE, with $\tau_E \approx 200$ ms, while the R^* lifetime is shorter, with $\tau_R \leq 80$ ms⁸ (see Table 20.1). In this scenario, where the R^* lifetime is shorter than the transducin-PDE lifetime, then further light-induced shortening of τ_R is likely to have very little effect on the response kinetics, but it will instead cause a reduction in sensitivity, because fewer molecules of transducin will be activated during the R^* lifetime.

Although it remains difficult to establish the effectiveness of any individual mechanism in an intact photoreceptor with a functional calcium feedback loop, it appears that in rods the recoverin-mediated reduction in R^* lifetime plays a moderate role, especially at relatively low background intensities.

Channel reactivation

In response to a drop in calcium concentration, Ca^{2+} unbinds from calmodulin (in the case of the rods), leading to a lowered dissociation constant ($K_{1/2}$) for the binding of cGMP to the channels. The effect of the lowered $K_{1/2}$ is that any given concentration of cGMP will cause the opening of a larger fraction of the cGMP-gated channels, leading to an increase in circulating current and an influx of more calcium. However, the potency of this effect is low in rods, and the mechanism contributes only weakly to rod adaptation. In contrast, cone channels possess a more powerful regulatory mechanism, mediated by a different calcium-sensitive protein⁹ (see Chapter 19).

Molecular basis of the cone's incredibly rapid recovery from light exposure

The speed of recovery of human cones from prolonged intense illumination is extremely rapid (Section 4), and the time constants of the various shut-off reactions shown in the schematic of Figure 20.7 have been estimated in a number of recent studies of primate cones using intact preparations. In the case of monkey cones, the parameters were extracted via theoretical modeling of results obtained from intracellular recordings of horizontal cells in the retina-RPE-choroid preparation. In the case of human cones, the parameters were extracted via theoretical modeling of ERG results, including those of the kind illustrated in Figure 20.6. The shut-off reactions have been found to be extremely rapid, and the parameters that have been reported are summarized in Table 20.1.

The collected estimates in Table 20.1 are consistent with the notion that all four of the shut-off time constants in human cones are extremely short, with three of the time constants around 5 ms or less, and one around 10–15 ms. Hence the shut-off time constants for both the activated visual pigment (R^*) and the activated G-protein/PDE (E^*), τ_R and τ_E , are around 20-fold shorter in human cones than in mouse rods, where values of ~70 and ~200 ms have been reported. It has recently been discovered that disruption of a molecular step involved in shut-off of phototransduction can lead to slowed light adaptation in cones (see Box 20.1).

Cone avoidance of saturation

A theoretical analysis¹⁰ has shown that the ability of mammalian cones to avoid saturation is explicable in terms of

the combination of these two 20-fold shorter time constants, together with the bleaching of cone visual pigment.

In human rod photoreceptors *in vivo*, the circulating current is halved at a steady intensity of ~70 scotopic trolands or $600 \text{ R}^* \text{ s}^{-1}$,¹¹ with complete saturation occurring at ~1000 scotopic trolands ($\sim 10^4 \text{ R}^* \text{ s}^{-1}$) (see also Fig. 20.1B). On the assumption that the gain of activation in transduction is the same in human cones as in human rods, then the two very short cone time constants would elevate the intensities required for half- and full-saturation by some ~400×, to

Box 20.1 Altered light adaptation when phototransduction shut-off is disrupted

Changes in light adaptation performance as a result of retinal disease are uncommon – any disturbance of the phototransduction cascade tends to cause major disruption of signaling, rather than a subtle change in adaptation. For example, Oguchi disease, which impairs the shut-off of the transduction cascade (through mutations in either rhodopsin kinase or arrestin), leads to symptoms resembling stationary night blindness.

Recently, it has been discovered that altered light-adaptation behavior can result from impairment of the reactions that inactivate the light-activated phosphodiesterase (PDE6). Thus, mutations in the *RGS9-1* or *R9AP* genes have been shown to affect light adaptation,^{29,30} though in a manner that may appear counter-intuitive.³¹

Patients with mutations in the *RGS9-1* or *R9AP* report difficulty in adapting to sudden changes in photopic luminance, and experience difficulty seeing moving objects, especially at low contrast. This stationary condition has been termed bradyopsia (slow vision).^{29,30} This slowness is expected, because disruption of the PDE shut-off process should lead to an extended time-course of the photoreceptor response to illumination.

Paradoxically, at low light levels the responses of cones lacking *RGS9-1* are actually faster than those of normal cones.³¹ When a second effect of PDE is taken into consideration, this result turns out to be exactly as predicted. Not only is the PDE involved in shutting off the light response, by hydrolyzing cyclic GMP, but it is also involved in light adaptation and in response acceleration by shortening the “turnover time” for cyclic GMP.⁵ Thus, with *RGS9-1* absent, there is more PDE active at low light levels, and hence a shorter turnover time for cyclic GMP and thereby a “more adapted” state than in the normal case. Accordingly, although these patients will have slower than normal vision at high lighting levels, they will have faster than normal vision (i.e. apparent light adaptation) at dim lighting levels.

Table 20.1 Shut-off time constants estimated for primate cones and mouse rods

	τ_R ms	τ_E ms	τ_{Ca} ms	$\tau_{\text{cG}} = 1/\beta$ (Intense) ms	Preparation	Reference
Cone		18			Human ERG	[20]
	5	13		4	Human ERG	[21]
	3	9	3	4	Monkey retina	[22]
	3	10	3	6	Human ERG	[23]
Rod	70	200			Mouse suction pipette	[8]

Estimates for the shut-off time constants, τ_R , τ_E , τ_{Ca} , and τ_{cG} , obtained from recent experiments. It is not usually possible to determine which of the two time constants τ_R and τ_E is which; however, in the case of the mouse rod results, this identification was made using other experiments. Note that the turnover time for cyclic GMP, τ_{cG} , represents the value applicable during very intense illumination; under dark-adapted conditions, when the light-stimulated activity of the PDE is much lower, this time constant will be much longer.

levels of $\sim 240,000$ and $\sim 4 \times 10^6 \text{ R}^* \text{ s}^{-1}$ in human cones. An additional factor is that the cGMP-gated channels of mammalian cones show increased cGMP binding affinity when Ca^{2+} falls,⁹ thus further increasing the R^* rate required for saturation.

How do these estimated rates of isomerization compare with the maximum rate at which the cone visual pigment can be bleached during steady illumination? At steady-state, the rate of photoisomerization equals the rate of pigment regeneration, which is set by the delivery of 11-cis retinal to opsin. For human L/M cones, the maximal rate of regeneration has been measured as ~ 45 percent min^{-1} , or 0.75 percent s^{-1} . If the outer segment contains ~ 40 million pigment molecules, then the maximal rate of photoisomerization during intense steady light will be $\sim 300,000 \text{ R}^* \text{ s}^{-1}$. This rate simply cannot be exceeded in the steady-state, because a higher initial rate of isomerization would deplete the available pigment thereby lowering the rate.

Hence, from the numbers in the preceding paragraphs, the rate of photoisomerization required to saturate the human cone current exceeds the highest rate of isomerization of cone pigment molecules ($\sim 300,000 \text{ R}^* \text{ s}^{-1}$) that can be elicited by a steady light of arbitrarily high intensity. Therefore, the human cone photoreceptor cannot be saturated by steady lights, no matter how bright they are. This does not mean that the cone can never be saturated; if an intense light is presented from dark-adapted conditions (when the cone initially has a full complement of visual pigment), then it will transiently be driven into saturation until bleaching reduces the amount of visual pigment to a suitably low level.

Modeling of human cone light adaptation

A computational model of human cone light adaptation has been developed,¹² that puts factors of the kind described in the preceding section into a comprehensive theoretical/numerical model. The molecular description that they use is closely similar to that illustrated in Figure 20.7, including pigment bleaching, and they express the system as a set of differential equations. Their simulations confirm that human cones will indeed not saturate with steady intensities of any level, and predict that the sensitivity will conform to Weber's Law over a very wide range of background intensities.

5. Slow changes in rods: light adaptation or dark adaptation?

In addition to the conventional features of rod photoreceptor light adaptation that occur extremely rapidly (on a sub-second time-scale), other changes have been reported to occur over a time frame of minutes of exposure, in response to lights that saturate the cell's response. As the effects of these changes are very slow, and can only be observed in darkness when the adapting exposure is extinguished, there is a semantic issue as to whether these phenomena should be thought of as light adaptation or as dark adaptation.

Light-induced change in the dominant time constant

Exposure of mouse rods to a just-saturating intensity of around 1000 photoisomerizations s^{-1} , for 1 min or more,

leads to a persistent speeding of the bright-flash response upon extinction of the background.¹³ The change does not involve any reduction in the activation phase of transduction, but instead involves a reduction in the dominant time constant of response recovery; typically, the dominant time constant τ_{dom} drops from around 200 ms under dark-adapted conditions to around 100 ms immediately after extinction of the saturating light. This adaptational effect develops relatively slowly, building up over 60 s or so, and it requires a rhodopsin bleach level of around 2 percent for full effect. The effect is relatively long-lasting, declining with a time constant of around 80 s.

The molecular mechanism giving rise to this adaptational effect is not known, though some evidence suggests that it corresponds to a reduction in lifetime of the activated transducin-PDE complex. If so, it represents a phenomenon distinct from the actions of dimmer adapting lights.

Light-induced translocation of proteins

Light-induced translocation of transducin, recoverin, and arrestin in photoreceptors is considered in Chapter 18 and will briefly be mentioned here. Movements of protein are elicited only at quite high intensities (generally in the saturating range), and they occur over a time-scale of many minutes. In mouse rods, intensities above 3000 photoisomerizations s^{-1} for 30 min (which bleach a substantial fraction of the rhodopsin) trigger the movement of transducin from the outer segment to the inner segment, while slightly lower intensities of 1000 photoisomerizations s^{-1} or more trigger the movement of arrestin in the opposite direction; recoverin also leaves the outer segment in bright light.

Protein movements of these kinds may well affect the adaptational state of the rod, though this has not yet been definitively established. Because the movements are triggered only by saturating light intensities, the electrical effects cannot readily be observed during the illumination, because the circulating current is completely suppressed. One possibility is that the changes help prepare the rod for its return to lower intensities, as occurs around dusk. Interestingly, in one attempt that was made to detect any change in the amplification constant of human rods (using the ERG) following exposures to intensities that elicit transducin translocation in mouse rods, no change in amplification was detectable.¹⁴

6. Dark adaptation of the rods: very slow recovery from bleaching

After our eye has been exposed to very intense illumination, our visual threshold is greatly elevated and may take tens of minutes to recover fully.¹⁵ Comparable effects can be also measured at the level of the rod bipolar cells¹⁶ or the rod photoreceptors.¹¹ The slow recovery of sensitivity is referred to as "dark adaptation" or "bleaching adaptation", but this use of the term "adaptation" is misleading. Adaptation normally refers to beneficial adjustments, yet the changes that persist after extinction of intense illumination are distinctly disadvantageous – thus, there can be no advantage in having one's vision greatly compromised following exposure to intense light.

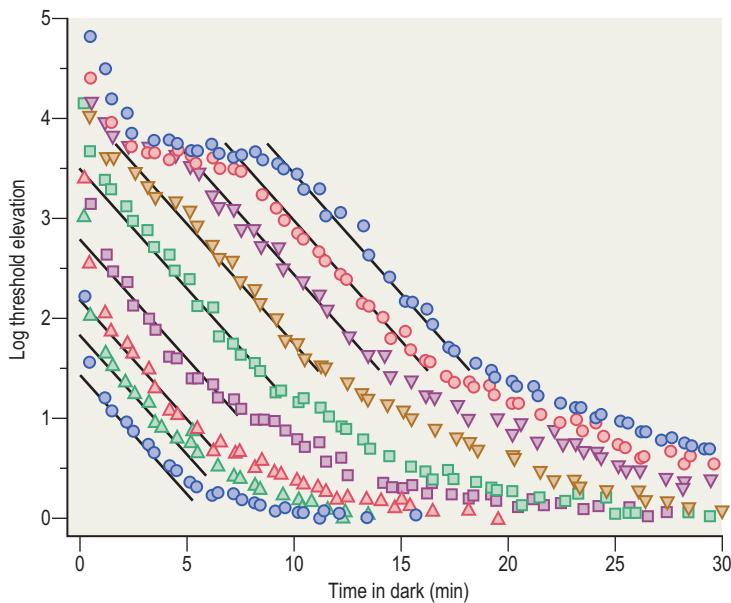

Figure 20.9 Human psychophysical dark adaptation. Recovery of log threshold elevation in a normal human observer is plotted as a function of time in darkness, after a wide range of bleaching exposures (from 0.5 percent to 98 percent). Parallel black lines represent component S2, with a slope of $-0.24 \text{ decades min}^{-1}$ (see text). The lateral shift between the lines is consistent with the rate-limited delivery of 11-cis retinal from the RPE to opsin in the outer segments. (From Lamb TD & Pugh EN. Phototransduction, dark adaptation, and rhodopsin regeneration. The Proctor Lecture. Invest Ophthalmol Vis Sci 47(12):5138–5152. Reproduced from Association for Research in Vision and Ophthalmology.¹⁸)

The recovery of visual threshold for a human subject is plotted in Figure 20.9, following the cessation of nine light exposures that bleached from 0.5 percent to 98 percent of the rhodopsin.^{17,18} For a bleach of 20 percent, the visual threshold was initially elevated by 3.5 log units. This indicates that the elevation of threshold is out of all proportion to the fraction of pigment remaining unbleached; even though 80 percent of the rhodopsin remained functional, the threshold was raised 3000-fold. Instead, there is now overwhelming evidence that the phenomenon arises from the presence within the outer segment of unregenerated opsin (i.e. the presence of the protein part of the visual pigment, prior to its recombination with the regenerated 11-cis retinal).

Remarkably, the recovery of scotopic (rod-mediated) threshold exhibits a region of common slope across all the bleach levels, as indicated by the parallel black lines in Figure 20.9. This region is termed the S2 component of recovery, and has a slope $\Psi_{S2} = -0.24 \text{ log unit min}^{-1}$ that is characteristic of dark adaptation recovery in normal (young adult) human eyes. Also characteristic is the nature of the rightward shift of the recovery traces as a function of increasing bleach level – the form of this shift is as expected for a rate-limited (zero-order) recovery process, as distinct from an exponential (first-order) recovery process.

From a detailed analysis of results of this kind, in combination with knowledge of the retinoid cycle, Lamb & Pugh¹⁹ developed a cellular model that can account for human dark adaptation behavior. They postulated (1) that the presence of opsin (without chromophore) gives rise to a phenomenon closely equivalent to light, through activation of the G-protein cascade of transduction, and (2) that the elimination of opsin via its reconversion to rhodopsin follows rate-limited kinetics because of a limitation in the supply of 11-cis retinal that results from the diffusion of this substance from a pool in the retinal pigment epithelium.

Application of this cellular model has provided an accurate account of: (i) the regeneration of visual pigment in

Box 20.2 Diseases exhibiting slowed dark adaptation

A variety of diseases lead to slowed dark adaptation, and the great majority of these do so by affecting reactions of the retinoid cycle, and thereby reducing the effective concentration of 11-cis retinal in the retinal pigment epithelium.¹⁸

Mild cases of systemic vitamin A deficiency (VAD) lead to a slowing of the S2 component of dark adaptation, yet without any alteration in the final fully dark-adapted visual threshold.³² This occurs because all the bleached opsin is able (eventually) to recombine with retinoid – the recombination is simply slowed. In these mild cases, supplementation with vitamin A can lead to a rapid and complete recovery of dark adaptation, showing that no other pathology was present. With more pronounced or extended deficiency, the final visual threshold becomes elevated, and eventually the photoreceptors may degenerate.

Fundus albipunctatus typically results from mutation of the 11-cis retinol dehydrogenase *RDH5* gene. The S2 component of rod dark adaptation is greatly slowed, but (as in vitamin A deficiency) the final visual thresholds are entirely normal.³³

Sorsby fundus dystrophy is caused by a mutation in *TIMP3*, a metalloproteinase of the matrix in Bruch's membrane. All the features of this disease are consistent with the slowing of dark adaptation being caused by ocular VAD.³²

Bothnia dystrophy is one of a group of rare diseases that involve mutations in *CRALBP*, the chaperone protein for 11-cis retinal. In these patients, loss of CRALBP leads to enormously slowed dark adaptation.³⁴

humans and other mammals, measured by retinal densitometry; (ii) normal human dark adaptation behavior (as in Fig. 20.9); and (iii) the slowed regeneration of pigment and the slowed dark adaptation that is characteristic of a number of diseases that affect the photoreceptors and/or RPE (see Boxes 20.2 and 20.3).¹⁹

Box 20.3 Slowed dark adaptation as an early indicator of age-related maculopathy (ARM)

The speed of dark adaptation is slowed in age-related maculopathy (ARM).^{35–37} Thus, the slope of the S2 component of recovery is noticeably lower in patients with early ARM than in healthy subjects of similar age. Characteristic changes in ARM include a thickening of Bruch's membrane and the deposition of neutral lipids. Hence, the likely explanation for the slowing of dark adaptation in ARM is that the transport of vitamin A from the choroidal circulation is hindered, so that the RPE/retina becomes vitamin A deficient; i.e. that there is ocular VAD.

As a result, measurement of the slowing of dark adaptation is likely to provide a valuable and non-invasive bioassay, both as a diagnostic tool for predicting the likelihood of onset of macular degeneration, and as a means of assessing the efficacy of treatments of the disease.

The Synaptic Organization of the Retina

Robert E. Marc

The basic architecture, signal flow, and neurochemistry of signaling through the vertebrate retina is well-understood: photoreceptors, bipolar cells (BCs), and ganglion cells (GCs) are all thought to be glutamatergic neurons¹ and the fundamental synaptic chain that serves vision is photoreceptor → BC → GC.² But, our understanding of detailed signaling is far from adequate and a complete description of synaptic interactions or signaling mechanisms is lacking for any retinal network.³ For example, GCs express different mixtures of ionotropic glutamate receptors (iGluRs) and each receptor can be composed of many different subunits leading to a vast array of possible functional varieties.¹ At a larger scale, network topologies are too numerous to resolve with current physiological or pharmacologic data.⁴ Each GC contacts many different amacrine cells (ACs) and a full description of the inputs to any given GC does not yet exist.⁵ Physiology can screen only a limited parameter space for any cell. Pharmacology is still an emergent field with many incomplete tools and an immense diversity of neurotransmitter receptor subunit combinations, modulators, and downstream effectors remains to be screened for any cell type. Molecular genetics, despite its power to modulate signaling elements, remains an ambiguous tool for analyzing retinal networks. Morphology, augmented by immunocytochemistry and physiology, remains the core tool in discovering new details of retinal organization.

Nothing has been as powerful as transmission electron microscopy for discovering retinal networks. Mammalian night (scotopic) vision is a prime example. Its unique pathways were described by Kolb & Famiglietti using electron microscopy.⁶ Subsequent physiological analyses^{7,8} provided clarification of how the network functions but would not have yielded the correct network architecture. Further complexities have been discovered by anatomical studies,^{9–11} including the fact that the network rewrites in retinal degenerations (Box 21.1).¹² But, electron microscopy has not kept pace with the demands for high-throughput imaging until recently. We are now on the verge of a new era in imaging that will provide a deluge of new information about retinal circuitry.⁴ Finally, the basics of retinal development and new findings in neuroplasticity are beyond the scope of this chapter,^{13,14} but the implications should be held in mind

throughout: the connections we have long considered as static or hard-wired in retina display many of the same molecular attributes as plastic pathways in brain.

The basic signal flow in retina is overlaid on a well-studied cell architecture (Fig. 21.1). Retinal ON and OFF BC polarities are generated in the outer plexiform layer and mapped onto the inner plexiform layer into largely separated zones. The distal sublamina *a* receives inputs from OFF BCs and therein the dendrites of OFF GCs collect signals via BC synapses. The proximal sublamina *b* receives inputs from ON BCs and therein the dendrites of OFF GCs collect signals via BC synapses. ON-OFF GCs thus collect inputs from both sublayers.

Kinds of neurons

The retina is a thin, multilayered tissue sheet ... an image screen ... containing three developmentally distinct, interconnected cell groups that form signal processing networks:

- Class 1 :: sensory neuroepithelium (SNE) :: photoreceptors and BCs
- Class 2 :: multipolar neurons :: GCs, ACs, and axonal cells (AxCs)
- Class 3 :: gliaform neurons :: horizontal cells (HCs)

These three cell groups comprise over 60–70 distinct classes of cells in mammals^{2,3,15–17} and well over 100–120 in most non-mammalian retinas.¹⁸

The SNE phenotype includes photoreceptors and BCs. These cells are polarized neuroepithelia with apical ciliary-dendritic and basal axonal-exocytotic poles.¹⁹ They form the first stage of synaptic gain in the glutamatergic photoreceptor → BC → GC → CNS vertical chain. This aggregates photoreceptor signals into BC receptive fields and amplifies their signals. The basal ends of the BCs form the inner plexiform layer. There are at least 12 kinds of BCs in mammals^{16,20} and BCs delimit different functional zones in the IPL, suggesting nearly 1 micron precision in lamination. Both photoreceptors and BCs use high fusion-rate synaptic ribbons as their output elements, fueled by hundreds to thousands of

Box 21.1 Retinal Remodeling in Retinal Degenerations

- Primary photoreceptor or RPE degenerations leave the neural “inner” retina deafferented
- The neural retina responds by remodeling in phases, first by subtle changes in neuronal structure and gene expression and later by large-scale reorganization
- In *Phase 1*, expression of a primary insult activates photoreceptor and glial stress signals
- In *Phase 2*, ablation of the sensory retina via complete photoreceptor loss or cone-sparing rod loss triggers revision in downstream neurons
- Total photoreceptor loss triggers wholesale bipolar cell remodeling
- Cone-sparing degenerations trigger BCs reprogramming, down-regulating mGluR6 expression and up-regulating iGluR expression
- Loss of cone triggers *Phase 3*: a protracted period of global remodeling, including:
 - neuronal cell death
 - neuronal and glial migration
 - elaboration of new neurites and synapses
 - rewiring of retinal circuits
 - glial hypertrophy and the evolution of a fibrotic glial seal
- In advanced disease, glia and neurons may enter the choroid and emigrate from the retina
- Retinal remodeling represents the pathologic invocation of plasticity mechanisms
- Remodeling likely abrogates or attenuates many cellular and bionic rescue strategies
- However, survivor neurons are stable, healthy, active cells
- It may be possible to influence their emergent rewiring and migration habits

nearby vesicles. The retina is the only known tissue where SNE cells are arrayed in a serial chain.

As summarized in Figure 21.2, most mammals possess three classes of photoreceptors: rods expressing RH1 visual pigments, blue cones expressing SWS1 visual pigments, and green cones expressing Long-Wave System green (LWSG) visual pigments.²¹ Conversely, the most visually advanced and diverse vertebrate classes (teleost fish, avians, reptiles) possess up to seven known classes of photoreceptors (RH1 rods, SWS1 UV/violet cones, SWS2 blue cones, LWSR and RH2 green members of double cones, LWSR and RH2 green single cones).²²

Similarly, the diversity of BCs in mammals is lower (10–13) than non-mammals (>20). This reduced diversity is a result of the Jurassic collapse of the mammalian visual system, where over half of the visual pigment genes, half of the neuronal classes and almost two-thirds of the photoreceptor classes were abandoned to exploit nocturnal niches. In addition, the disproportionate proliferation of rods in the mammalian retina was accompanied by the loss of mixed rod-cone BCs in mammals and their replacement with pure rod BCs. How this occurred is unknown, but it cannot be due to an absolute selectivity of rod BCs for rods, as they will readily make contacts with cones when rods are lost in retinal degenerations. As we will see, the mammalian

retina has exploited a re-entrant use of synapses to enhance scotopic vision. The relationship between BCs and photoreceptors is still unclear, but there is both anatomical and molecular evidence that BCs were initially photoreceptors. For example, many non-mammals possess BCs Landolt clubs, which are apical extensions extending from a BC primary cilium, extending past the outer plexiform layer into the outer nuclear layer, and containing packets of outer-segment-like membranes. Whether they are photosensitive has never been determined. Further, SWS1 blue cones and cone BCs share some SWS1 *cis*-regulatory sequences.²³

The multipolar neuron phenotype

The multipolar neuron phenotype² includes ACs, AxCs, and GCs. Multipolar neurons can be further divided into axon-bearing (GCs, AxCs) and amacrine cells (ACs). Mammals display ≈ 30 kinds of ACs.¹⁵ The 15–20 kinds of mammalian GCs^{3,17} are classical projection neurons. GCs are postsynaptic at their dendrites and presynaptic at their axon terminals in CNS projections. So far, all are presumed to be glutamatergic. ACs are local circuit neurons similar to periglomerular cells in the olfactory bulb. ACs lack classical axons and often have mixed pre- and postsynaptic contacts on their dendrites, though some ACs partition inputs and outputs into different parts of their dendritic arbors. Most ACs are GABAergic and the remainder are glycinergic.²⁴ Several classes of ACs are dual transmitter cells, expressing both acetylcholine and GABA, serotonin and GABA (in non-mammals) or peptides and GABA or glycine.¹ In between are the AxCs, also known as polyaxonal cells and intraretinal GCs, which have distinct axons that project within the retina.^{25–27} One dramatic example of the AxC phenotype is the TH1 dopaminergic AxC.²⁸ This cell releases dopamine at unknown but probably axonal sites and likely glutamate at others,²⁹ similar to nigrostriatal neurons.³⁰ Some polyaxonal cells are GABAergic. There is no evidence for a glycinergic AxC. Multipolar neurons are characterized by numerous neurites branching in the plane of the retina, most collecting signals from BCs. Multipolar neurons are among the earliest to develop in the retina and quickly define the borders of the IPL and its stratifications. Multipolar neurons all manifest somewhat classical “Gray”-like synapses, generally with small clusters of less than 200 vesicles.

The gliaform cell phenotype

This phenotype contains the horizontal cells (HCs), whose somas and processes are restricted to the outer plexiform layer.³¹ Though HCs are multipolar, neuron-like, and may display axons, they do not spike. Further, they express many glial features such as intermediate filament expression and very slow voltage responses. Further, HCs produce high levels of glutathione and make direct contact with capillary endothelial cells in some species, suggesting they play homeostatic roles similar to glia. Even so, HCs clearly mediate a powerful network function, collecting large patches of photoreceptor input via AMPA receptors and providing a wide-field, slow signal antagonistic to the vertical channel. The mechanism of HC antagonism remains a matter of uncertainty and debate. HCs do make conventional-looking synapses onto neuronal processes in the outer plexiform layer, and in fishes these synapses are made onto

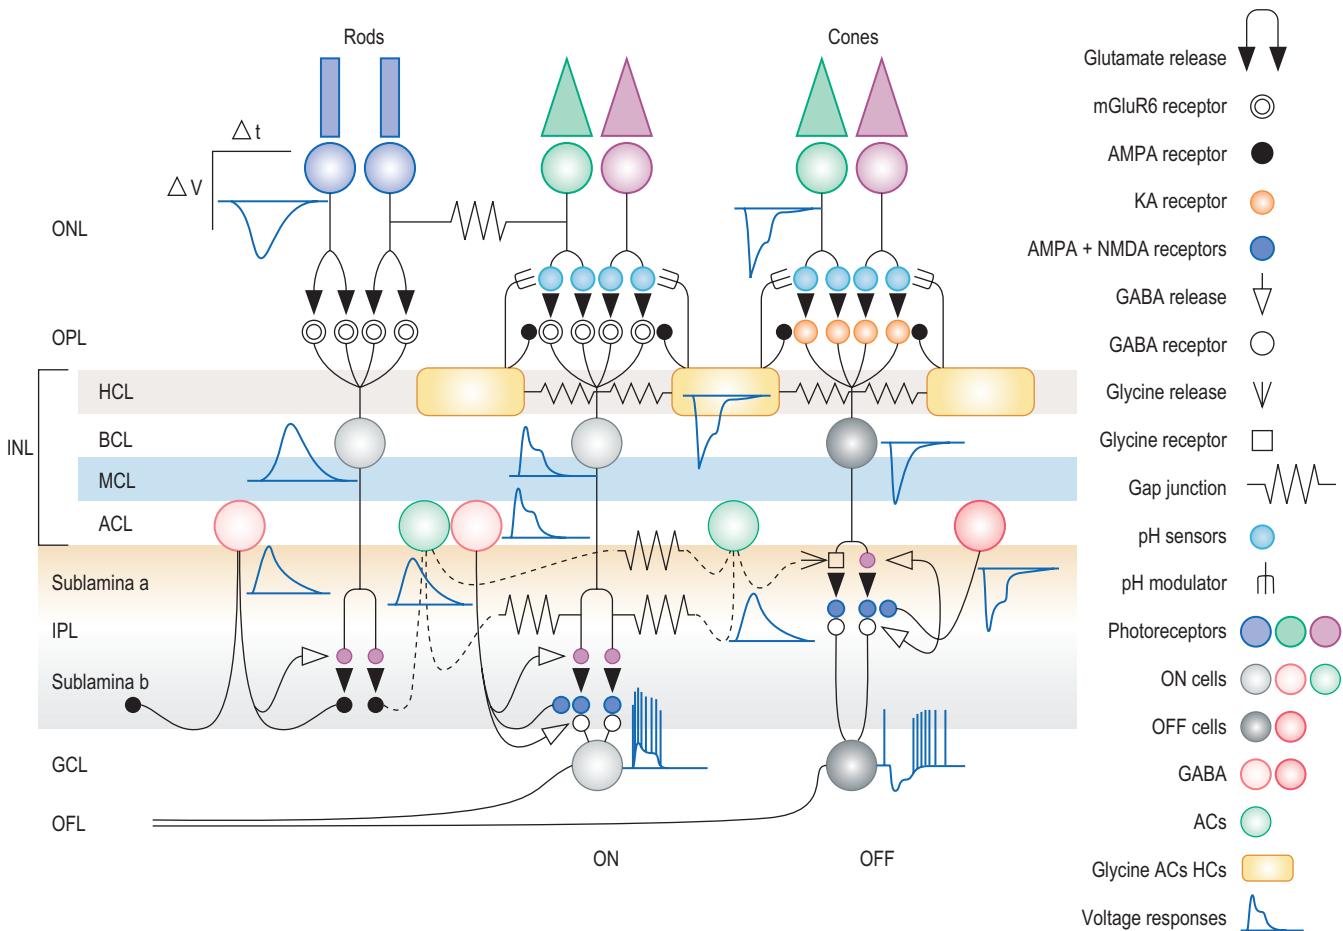

Figure 21.1 A summary of major cell superclasses and synaptic connections in the mammalian retina. Photoreceptors include rods (cyan) and cones (green, blue) that hyperpolarize in response to light. All photoreceptors are glutamatergic and drive HC AMPA receptors on HCs, ON BC mGluR6 receptors, and OFF BC KA or AMPA receptors. All BCs are glutamatergic and drive either predominantly AMPA receptors on rod pathway interneurons or various mixtures of AMPA and NMDA receptors on cone pathway ACs and GCs. Homocellular gap junctions are formed between like pairs of cells (HCs, certain ACs) and heterocellular gap junctions are formed between different cell pairs (rods and green LWS cones; glycinergic rod ACs and ON cone BCs; some ACs and certain GCs). Two classes of feedback pathways exist. There is a putative HC → cone feedback path mediated by a pH-sensitive process. AC → BC feedback is primarily GABAergic, as is AC → GC feedforward. Mammalian rod pathways are unique and not shared by any other vertebrate class. Rod BC signals are collected by a glycinergic rod AC that mediates a reentrant bifurcation into cone ON BC channels via gap junctions and cone OFF BC channels via glycinergic synapses. The outflow from the retina is largely split into ON GC channels that spike in response to light increments and OFF GC channels that spike in response to light decrements. The retina is precisely laminated into cellular and synaptic zones distal-to-proximal starting with the outer nuclear layer (ONL), the outer plexiform layer (OPL), the inner nuclear layer (INL), the inner plexiform layer (IPL), ganglion cell layer (GCL), and optic fiber layer (OFL). The INL is subdivided into the horizontal cell layer (HCL), bipolar cell layer (BCL), Müller cell layer (MCL) and amacrine cell layer (ACL). The IPL is subdivided into sublamina a that receives the output of OFF BCs and sublamina b that receives the output of ON BCs.

dendrites of glycinergic interplexiform cells, a form of AxC.³² However, these are so sparse in all species and contain so few vesicles that they *cannot* be the source of the large sustained opponent surrounds of retinal neurons that HC generate. HCs must use some other mechanism.

The phylogenetics of HCs has been thoroughly reviewed.³³ HCs in mammals are postsynaptic to cones at their somatic dendrites. One class of HCs common in mammals (foveal type I in primates, type A in rabbits and cats, and absent in rodents) contacts cones alone. A second class of HCs (extrafoveal type I in primates, type B in rabbit and cats, and the only known HC in rodents) displays axons several hundred microns long that branch profusely and form massive arborizations contacting hundreds to thousands of rods. Another class of primate HC (type II) has axon terminals contacting

cones and rods. Importantly, the axon of HCs appears to be electrically inactive and these somatic and terminal regions are believed to act independently. HCs also appear to be early-developing pioneer cells that define the outer plexiform layer. After the GCs and HCs define the layout of the inner and outer plexiform layers respectively, photoreceptors and BCs mature and search for connections.

True glia and vasculature

The neurons of the retina are embedded in an array of vertical Müller glia that span the entire neural retina, forming one-third to one-half of the retinal mass and generating high-resistance seals at the distal and proximal limits of the retina. Most mammalian retinas are vascularized in three

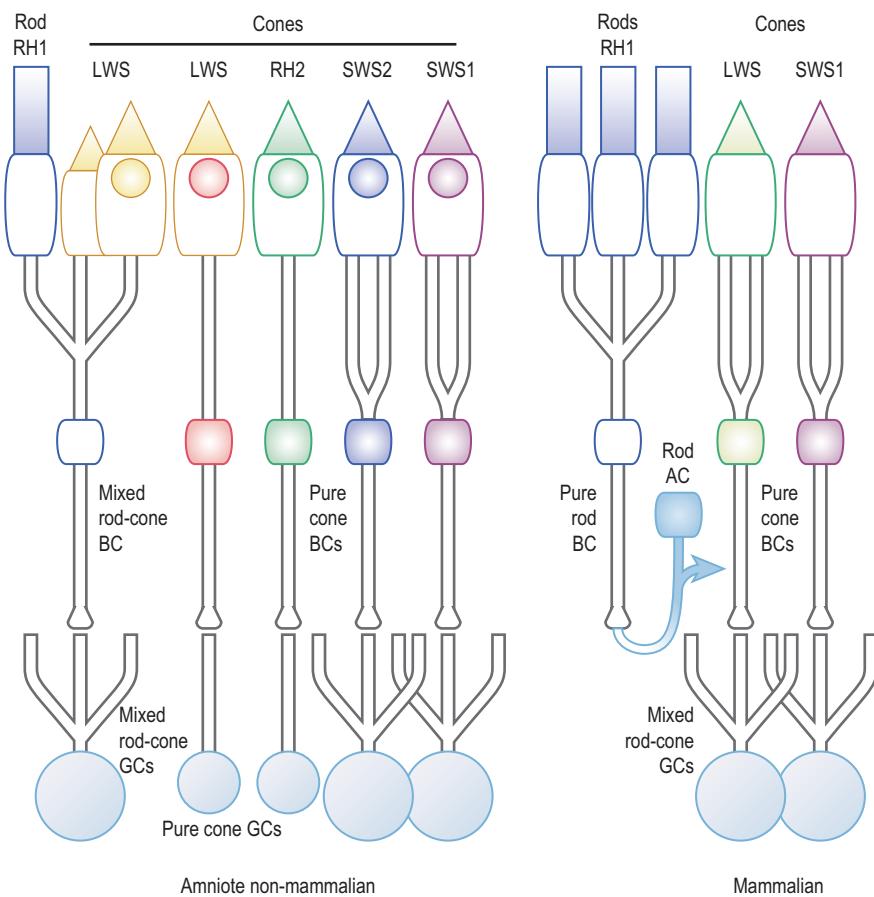

Figure 21.2 Photoreceptor cohorts and connections in vertebrates. Non-mammilians display multiple pigment classes and cone types. There are five pigment classes and seven photoreceptor types for a fresh water turtle, including rods (comprising less than 10 percent of the photoreceptors) expressing class RH1 rhodopsins, three kinds of LWS cones (short members of double cones, long members of double cones with orange oil droplets, single cones with rod oil droplets), single cones expressing RH2 green cone pigments and a yellow oil droplet, single cones expressing SWS2 blue cone pigments and a UV-opaque clear oil droplet, and single cones expressing SWS1 UV cone pigments and a UV-transparent clear oil droplet. The connection patterns for non-mammilians are mixed rod-cone BCs and pure cone BCs, leading to mixed rod-cone GCs and pure cone GCs. Mammals display three pigment classes (one rod and two cone), two cone color types in non-primates and three color types in primates, including RH1 rods, SWS1 cones, and LWS cones. The LWS cone class forms one green type in most mammals, and red (LWSR) and green (LWSG) chromatopes in primates. The main connection rules for mammals are pure rod BCs and pure cone BCs, with only cone BCs driving GCs, with rod ACs (cyan) providing the re-entrant crossover.

capillary beds: at the GC-inner plexiform layer border, the AC-inner plexiform layer border, and the outer plexiform layer. Squirrels (Sciurids) display two beds (at the GC-inner plexiform layer and AC-inner plexiform layer borders; and rabbits (Lagomorphs) have none at all, similar to all other non-mammalian vertebrates. The GC layer of many species also displays classical astrocytes, though their role remains unclear. In brain, astrocytes carry out some of the operations attributed to retinal Müller glia, including transport of spill-over K⁺ and glutamate, and glucose supply via vascular > glial cell > neuron transcellular transport. Why and how most vertebrate retinas function without vasculature remains uncertain, but it is likely that Müller glia act as a surrogate vascular system with the added ability to accumulate large glycogen stores (like hepatocytes) as part of a glucose-skeleton homeostasis. The segregation of retinal astrocytes away from the inner plexiform layer remains a mystery.

Basic synaptic communication

With the discovery of the signaling mechanisms of the neuromuscular junction decades ago,³⁴ one might have thought that the archetypal synaptic format had been discovered. Yet it has become clear, especially in retina, that every kind of synapse is subtly different, with diverse physics, topologies, and molecular mechanisms leading to very different forms

of synapses, most of which do not follow the single presynaptic "bouton" → single postsynaptic target pattern of brain. Further, the arrangement of these systems into synaptic chains in retina is unlike any other known network, including olfactory bulb. In retina, the first stage of synaptic signaling is a direct SNE → SNE synapse (Fig. 21.3): photoreceptor → BC. No other instance of this topology has been discovered in any organism. There are at least six modes of presynaptic–postsynaptic pairing in retina.

1. Photoreceptor ribbon synapses: small-volume multi-target signaling

It is thought that all photoreceptor signaling is glutamatergic, but sporadic indications of cholinergic physiology and molecular markers have been found in many non-mammilians.¹ Glutamate release from photoreceptors is effected by high rates of vesicle fusion at active sites on either side of a large synaptic ribbon³⁵ positioned close to the pre-synaptic membrane. The presynaptic zone is a protrusion or ridge with vesicle fusion sites positioned on the slopes of the ridge (Fig. 21.4). The releasable vesicle pool is so large that photoreceptors and BCs are capable of maintaining continuous glutamate release in response to steady depolarizations. This, among other things distinguishes photoreceptors and BCs from ACs, which have very small presynaptic vesicle clusters.

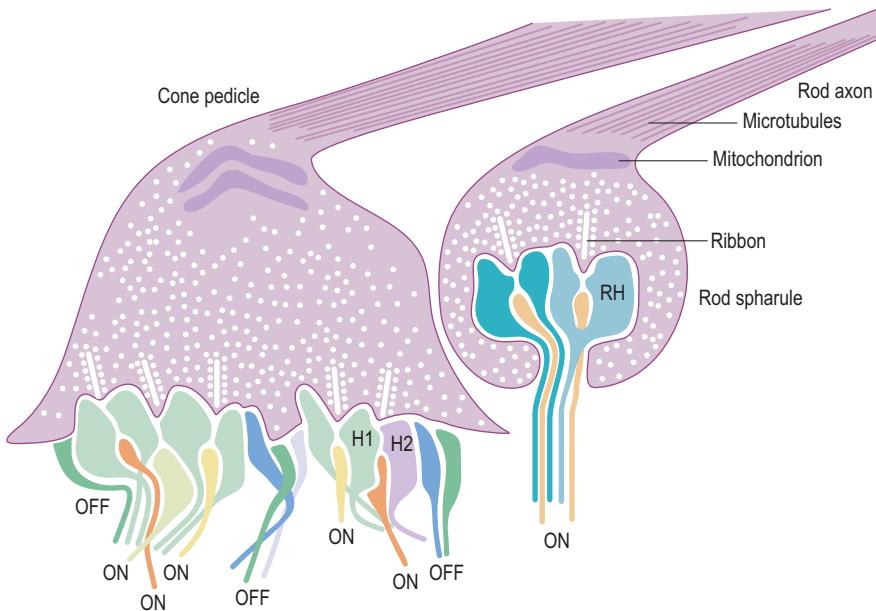

Figure 21.3 Basic organization of mammalian photoreceptor synaptic terminals. Primate cone terminals contain many ribbons, mitochondria clustered at the head of the pedicle and thousands of synaptic vesicles (white dots), some of which form organized zones near the plasma membrane opposite an array of cone-specific postsynaptic processes including type H1 and H2 HCs as lateral invaginating elements (primate H1 cells tend to avoid SWS1 cones, while H2 cells contact all cones). Cone ON BCs tend to center their dendrites between the lateral HC processes at varying distances from the synaptic ribbon, forming so-called invaginating and semi-invaginating contacts. Most cone OFF BCs position their dendrites outside the HC processes at so-called flat contacts. It is thought that most of these express KA receptors. Some occasional OFF BCs processes invaginate, and they may express AMPA receptors.

Various vertebrate rods and cones differ greatly in the number of ribbons and postsynaptic targets arrayed within the presynaptic terminals. For example, most mammalian and teleost fish rods have small grape-like presynaptic spherules $\approx 3 \mu\text{m}$ in diameter with a small entrance aperture leading to an enclosed extracellular invagination or vestibule in which thin postsynaptic dendrites are contained (Fig. 21.3). Importantly, glial processes are excluded from the interior of the spherule and any glutamate release must diffuse out of the spherule to reach the Müller glia. However, mammalian rods express the EAAT5 glutamate transporter¹ and likely regulate their own intrasynaptic glutamate levels. Each spherule contains one or two synaptic ribbons and a few postsynaptic targets.³⁶ In fishes, the postsynaptic targets are the dendrites of roughly five kinds of mixed rod-cone bipolar cells³⁷ and one kind of rod horizontal cell.³³ Thus each ribbon serves no less than six different types of postsynaptic targets. In mammals, only two targets are common: the dendrites of one kind of rod BC and the axon terminals of HCs. There are some instances of sparse OFF BC contact in mammals, but this seems to vary with species and may be an evolutionary relict with variable expression rather than a major signaling pathway.^{38–40} In sum, rod spherules form a sparse-ribbon \rightarrow small volume, sparse-target architecture.

Cones and rod terminals in some non-mammilians (e.g. urodele amphibians) adopt a different topology, with the presynaptic ending expanding to form a foot-piece or pedicle some 3–5 μm wide shaped either like a cupola (fishes) whose broadly concave interior admits some 50–100 or more fine dendrites served by roughly 12 synaptic ribbon sites,⁴¹ or like a true pediment (e.g. primate cones) whose shallow concavity is studded with up to 50 ribbon sites (Fig. 21.3).⁴² Cone pedicles in primates target at least ten different kinds of BCs and at least two kinds of HCs. Mouse cone pedicles are smaller but still

target 11 kinds of BCs²⁰ and one kind of HC. In sum, cone pedicles form a multi-ribbon \rightarrow small volume, multi-target architecture.

2. BC ribbon synapses: semi-precise target signaling

Like photoreceptors, BC signaling is generally considered glutamatergic.¹ Sporadic evidence of exceptions exists. In mammals (especially primates) and amphibians, some BCs contain biomarkers of GABA-related metabolism.²⁴ In contrast to photoreceptors, BC synaptic endings are topological spheroids, usually multiple (depending on BC type), with dozens to hundreds of ribbons abutting the surface. BCs form no invaginations, so there is no restricted volume into which glutamate is injected by vesicle fusion. In most cases each ribbon is directly apposed to a pair of postsynaptic targets, usually ACs. This is termed a dyad and, while monads, triads and tetrads do occur, dyads dominate. Large BC terminals such as those found in teleost fishes can drive up to 200 distinct processes. Mammalian BCs drive many fewer targets and most BCs have elaborate, branched terminals with connecting neurites often as small as 100 nm. In contrast to photoreceptors, the targets of BCs are focal. BC terminals are largely fully encapsulated by neuronal processes at their release sites to which they are presynaptic or postsynaptic, with rarely direct contact between the terminal and Müller glia near the synaptic release zone. This means that any glutamate that escapes from the synaptic cleft may travel some distance before glial glutamate transporters can clear it. Thus the potential for glutamate overflow at BC synapses is substantial. This may be particularly important for the activation of NMDA receptors, as they are suspected to be displaced from primary AMPA receptors. Thus, BCs form multi-ribbon \rightarrow semi-precise target architectures.

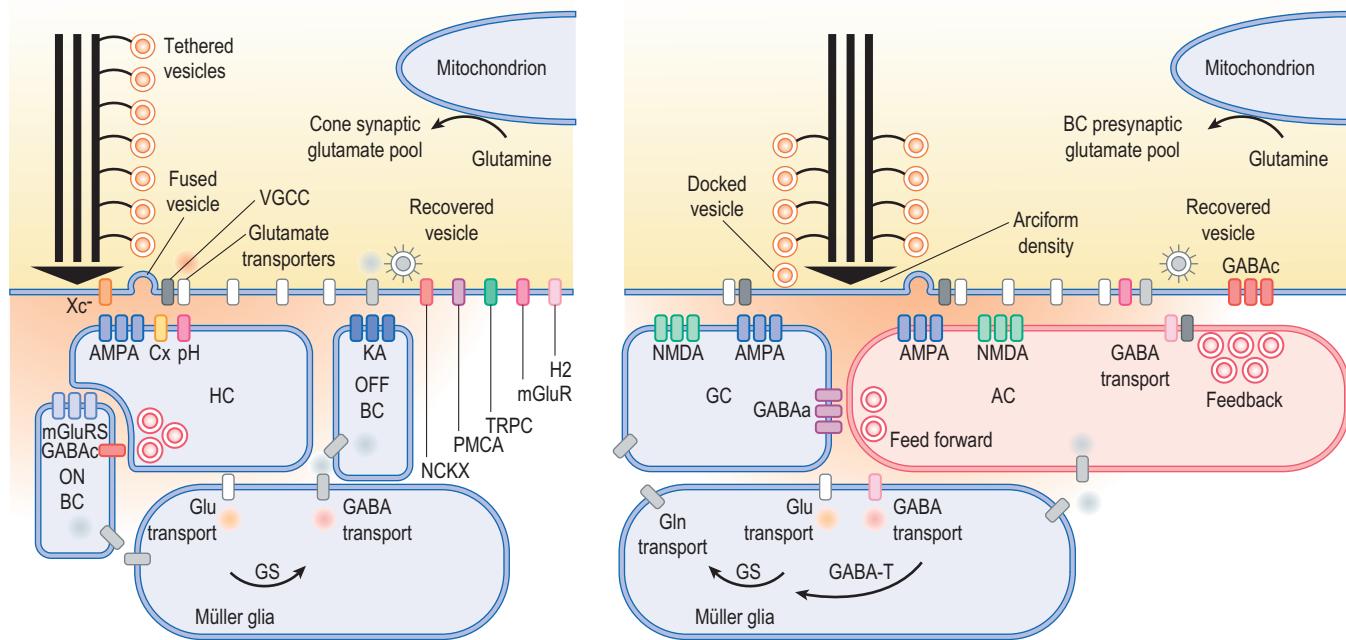

Figure 21.4 A detailed schematic of synaptic organization at cone (left) and BC (right) ribbon synapses. Each synaptic ribbon is a pentalaminar structure in cross-section, in reality a disc or lozenge-shaped solid with its two broad faces serving as attachment sites for tethered vesicles and its small paramembrane face attached to a dense structure known as the arciform density (composition unknown). Ribbons serve as the major site for the “readily releasable” pools of synaptic vesicles for continuous glutamate transmission, and facilitate high-speed formation of docked vesicles. Upon depolarization of the presynaptic membrane, voltage-gated calcium channels (VGCCs, black barrels) open, allowing docked vesicles to fuse and release glutamate into the synaptic cleft. At some distance from the ribbon, endocytosis mediates vesicle recovery. BC ribbons tend to be shorter than photoreceptor ribbons. Cytoplasmic glutamate (orange) is formed glutamine via mitochondrial phosphate-activated glutaminase and loaded into vesicles via vGlut vesicular transporters. Glutamate release by vesicle fusion diffuses away from the release site (shaded orange) and is cleared by both presynaptic and distant Müller glia glutamate transporters (white barrels). Müller glia synthesise glutamine from glutamate via glutamine synthetase (GS) and exports glutamine via transporters (grey barrels). Similarly, neurons import glutamine via transporters. Vertebrate photoreceptors also express presynaptic cystine-glutamate (Xc^-) exchangers (orange barrels) whose function is unknown. Glutamate released by cones activates ON BCs via mGluR6 receptors (light blue barrels), HCs via AMPA receptors (dark blue barrels) and OFF BCs via either AMPA or KA receptors (bright blue barrels). HCs are positioned at the highest glutamate concentration zone and OFF BCs at the lowest. Glutamate released by BCs activates ACs and GCs via AMPA receptors (dark blue barrels) and NMDA receptors (gold barrels). Feedback at photoreceptors appears to be mediated by either focal connexin (yellow barrel) or a pH modulator (magenta barrel) close to the photoreceptor VGCC. Feedforward from HCs to BCs may be GABAergic in some species and mediated by GABAC receptors (dark red barrels). Feedback at BCs is mediated by vesicular GABA (red shading) release from ACs targeting largely GABAC receptors. Feedforward from ACs to BCs is mediated by largely by GABA_A receptors (bright red barrels). ACs and mammalian Müller glia also have GABA transporters that clear the synaptic space. GABA is converted via the GABA-transaminase (GABA-T) complex to glutamate in glia. Cone synaptic terminals also have a number of other proteins including Na-Ca exchangers (NCKX), plasma membrane Ca transporters (PMCA), transient receptor potential channels (TRPC), metabotropic glutamate receptors (mGluR) and possibly histamine receptors (H2). BC terminals may share some of these.

3. AC and AxC conventional fast synapses: precise presynaptic → postsynaptic signaling

ACs and AxCs are the only retinal cells that make synaptic contacts resembling CNS “Gray”-like, non-ribbon conventional synapses. ACs target BCs, GCs, or other ACs. The targets of most AxCs are not well known but appear likely to be ACs and GCs. Though each AC may make many hundreds of synapses, each synapse contacts only and only one postsynaptic target, similar to classical multipolar neurons in CNS and spinal cord.⁴³ The dominant fast transmitters of AC systems are GABA and glycine, with GABAergic neurons making up half to two-thirds of the AC population depending on species.¹ Additional transmitters such as acetylcholine, peptides, or serotonin (in non-mammalians) are also associated with GABAergic (in most cases) or glycinergic systems.^{1,44} Acetylcholine (ACh) is a fast excitatory transmitter and is found in paramorphic starburst ACs in mammals

and also uses conventional synapses.¹ However, we know of no distinguishing anatomical differences between GABA- and ACh-utilizing synapses in retina.

4. AC, AxC, and efferent slow transmitter synapses: large volume signaling

Dopamine (and possibly norepinephrine/epinephrine) as well as peptides in retina appear to be released by a non-focal, Ca^{2+} -dependent vesicular system,⁴⁵ but without any clear postsynaptic associations. Dopamine and the other slow transmitters likely act via volume conduction⁴⁶ and modulate a range of cellular responses largely via G-protein coupled receptors (GPCRs). In non-mammalians, efferent systems from CNS target ACs with fast neurotransmitter synapses, especially GABA.⁵ In mammals, all known efferents appear to release either histamine or serotonin, likely as volume signaling systems.⁴⁷

5. HC non-canonical signaling

HCs generate potent, large-field, slow surround signals in retinal GCs, BCs, and even in non-mammalian cone photoreceptors.^{48–50} There is evidence for both feedforward signaling via the cone → HC → BC path⁵¹ and feedback signaling via the cone → HC → cone → BC path^{52,53} and, now, the rod → HC → rod path.⁵⁴ The efficacy and sustained nature of the feedback signal is such that no known vesicular mechanism could maintain it (other than a ribbon-style synapse). Vesicular HC synapses are very rare and small. Several models of non-canonical signaling have been proposed including synaptic pH regulation,⁵⁵ hemi-junction mediated ephaptic signaling,⁵⁶ and even transporter-mediated signaling. Some of these will be discussed in detail below, but this unusual functionality is further evidence that HCs are not classical neurons.

6. Coupling types and coupling patterns

While gap junctional coupling was first discovered between HCs, only in the past decade has it become clear how powerful and pervasive intercellular coupling is in retina.^{57,58} There are two simple classes of coupling: homocellular and heterocellular (between like and different classes of cells, respectively). The participant connexins in each case are respectively likely to be homo- or heterotypic (similar or dissimilar connexin types).³⁷ The strength of coupling is associated with the size of the junctions, as they represent summed parallel conductances, and with functional modulation by various signaling pathways. Activated dopamine D1 receptors decrease conductances between coupled HCs^{45,59} and coupled ACs,⁶⁰ and dopamine D2 receptors modulate rod-cone coupling.⁶¹ The significance of coupling is clear in certain cases, such as the ability of HCs to spatially integrate signals over large fields (> 1 mm diameter) or the crossover of rod signals into cones via heterocellular rod-cone and rod AC-cone BC coupling. However, such knowledge does not readily extrapolate, and other coupling patterns are poorly understood, such as heterocellular AC-GC coupling and even HC-BC coupling.

Fast, focal neurochemistry, synaptic currents, and amplification

One of the most powerful discoveries of the last two decades has been the diversity of the primary fast neurotransmitter receptors of the vertebrate nervous system. Again, the primary signaling channel of retina is the vertical glutamatergic chain from photoreceptors to brain.¹ Rods, cones, and BCs encode their voltage responses as time-varying glutamate release. The targets of photoreceptors and BCs, in turn, decode time-varying extracellular glutamate levels as time-varying currents with glutamate receptors. There are two major classes of glutamate receptors: ionotropic and metabotropic (iGluRs and mGluRs, respectively). The iGluRs are separable into two distinct families: the AMPA/KA receptors and NMDA receptors. AMPA and KA receptors are related but pharmacologically and compositionally distinct. Four basic classes of glutamate receptor subunits (GluR1, 2, 3, 4) can be recruited to form a tetrameric AMPA receptor. Similarly, five

basic classes of KA receptors (GluR5, 6, 7 and KA1, 2) can be assembled into tetrameric KA receptors. With some exceptions, these receptor assemblies can have nearly any stoichiometry. NMDA receptors are a distinct group of iGluRs in several ways. First, they have an obligate tetrameric subunit composition. Second, they are coincidence detectors that require dual activations by glutamate and by a glycine-like endogenous agonist. There is substantial evidence that this co-ligand may be D-serine released from Müller glia.⁶² Finally, the mGluRs represent a complex collection of GPCRs whose functions are far from clear.

Different classes of neurons express different types or different combinations of receptors and, in the end, the glutamate receptor profile of a cell is diagnostic for its class. Mammalian BCs are unique in expressing either mGluR6, KA, or AMPA receptors as their glutamate decoding system. BCs seem functionally monolithic in having their signals dominated by one of these three receptor systems. But immunochemical and mRNA expression analysis suggest that these associations are not so precise, and iGluR subunit expression occurs in nominally mGluR6-driven cells.⁶³ HCs predominantly express AMPA receptors, but show no NMDA-mediated responses. Finally, ACs and GCs resemble CNS neurons in expressing AMPA receptors augmented by varying amounts of NMDA receptors.

The key glutamate receptor systems of retina operate on the principle of cation permeation.^{1,64} When activated, iGluRs generate increased channel conductances and carry inward currents, carried mostly by Na^+ and Ca^{2+} . Thus the canonical iGluR AMPA, KA, and NMDA families of receptors are nominally *sign-conserving* (>) depolarizing systems that "copy" the polarity of the presynaptic source voltage input in the postsynaptic target. The facts that many inputs converge on one postsynaptic cell; that small presynaptic voltages can modulate the release of many vesicles (in SNE cells); and that glutamate gates large postsynaptic conductance changes to cations with a positive reversal potential means that such synapses have high gain. Signals from photoreceptor to brain are successively amplified by a chain of glutamate synapses.

The group III mGluR6 system is unique and, in retina, is expressed by ON BCs (Box 21.2). No known multipolar neuron in the CNS uses this receptor as its primary signaling modality. As a classical GPCR, with Go_α as its cognate G-protein,⁶⁵ the binding of glutamate triggers a cascade of signals that ultimately leads to the *closure* of cation channels on BC dendrites, thus moving the BC membrane potential closer to the K^+ equilibrium potential. Thus mGluR6 receptors are nominally *sign-inverting* (>i) hyperpolarizing systems that invert the polarity of the input in the postsynaptic target. The modulation of a strong cation current renders the mGluR6 mechanism high-gain in spite of its inverted polarity.

The differential expression of iGluRs and mGluR6 in BCs creates the two fundamental signal-processing channels of the retina: OFF and ON BCs respectively.¹ Unknown mechanisms regulate the expression of glutamate receptors in BCs. In general, BCs that express iGluRs such as KA or AMPA receptors do not express *functional* mGluR6 receptor display, and vice versa. However, there is evidence that BCs expressing mGluR6 also express low levels of iGluR protein, but there is as yet no evidence that such iGluR

Box 21.2 The mGluR6 receptor and vision

- The retina expresses mGluR6 receptors in both rod and cone ON BCs
- The human mGluR6 gene GRM6 is expressed predominantly in retina
- The mGluR6 receptor converts rod/cone hyperpolarizations into depolarizing BC signals
- The mGluR6 receptor dominates scotopic, but may not be essential for photopic vision
- Some human night-blind patients have GRM6 mutations,¹⁰⁹ with no photopic deficit
- The mGluR6 drives blue ON center cone BCs and GCs
- fMRI in rodents¹¹⁰ shows that blockade of mGluR6 receptors attenuates blue-driven signals in the LGN
- Simultaneously, blue-driven cortical signals are enhanced, suggesting that blue percepts are effectively or even primarily carried by OFF channels
- OFF center BCs can support photopic vision
- The perceptual world under pure OFF vision is yet unknown

Box 21.3 Glutamate excitotoxicity

- Glutamate excitotoxicity has often been invoked as a mechanism in retinal diseases
- The evidence is mixed and controversial. On balance:
 - Elevations of vitreal glutamate in glaucoma¹¹¹ have not been validated
 - Glaucoma-mediated loss of GCs does not match known excitotoxic patterns in retina
 - Starburst ACs are the most glutamate sensitive cells in the retina⁶⁴
 - There are no established AC losses in primate glaucoma
 - NMDA receptor antagonists appear neuroprotective in models of glaucoma¹¹²
 - The mechanism of NMDA neuroprotection may be indirect
 - retinal GC death in glaucoma likely involves Ca^{2+} -mediated apoptosis
 - NMDA antagonists (like many drugs) will decrease Ca^{2+} loads in neurons
 - weak NMDA antagonists likely have no lasting role in glaucoma therapeutics
- Glutamate is likely a major player in retinal damage in diabetes and ischemic insults
- Neuroprotection is difficult to achieve in those cases as it involves AMPA receptors
- Excitotoxicity in hypoxic retina is likely initiated by reverse transport of glutamate by BCs
- Competitive, non-translocated transporter ligands may be safer ocular neuroprotectants

subunits contribute to an electrically detectable signaling event.⁶³

There are additional mGluRs expressed in retina, including both the group I mGluR1 and mGluR5 and group III mGluR 4, 7, and 8, all largely expressed in varying patterns in the inner plexiform layer.⁶⁶ Their roles are thought to be associated with presynaptic glutamate feedback.

Global neurochemistry and modulation

There are a number of alternative neurochemical mechanisms that appear to operate on a larger spatial scale than conventional synapses. The most thoroughly described, though incompletely understood, is the dopamine.⁴⁵ In mammalian retinas, dopaminergic neurons are largely AxCs that arborize primarily in the distal-most layer of the IPL, appear to receive direct inputs from BCs, and have predominantly ON-type responses.⁶⁷ The exact sites of dopamine release are not known, although these cells clearly have small accumulations of synaptic vesicles distributed sparsely in their processes. Data from many species suggest that dopamine acts largely via volume conduction:⁴⁶ i.e. dopamine diffuses throughout the retina and targets high-affinity type D1 and D2 receptors distributed on almost every class of cell, including Müller cells. Actions triggered by D1 receptors include the uncoupling of HCs,⁶⁸ the uncoupling of rod-driven glycinergic ACs,⁶⁰ and enhanced spike speeds⁶⁹ (faster waveforms). All of these are consistent with the process of converting the retina from a scotopic to a photopic state. Dopaminergic neurons are also thought to contain a fast transmitter. Previous evidence in the mouse suggested that they were GABAergic, but other studies support the possibility that they are glutamatergic.

A similar role is posited for the rapidly diffusing neuroactive gas NO. A variety of retinal cells are posited to produce NO via the neuronal NO synthase (nNOS) pathway, activated by binding of Ca-activated calmodulin.⁷⁰ Thus synaptic currents with high Ca-permeability (e.g. those mediated by NMDA receptors) can turn on nNOS, which catalyzes the oxidation of one of the guanido nitrogens of arginine to NO. NO appears to have the capacity to diffuse through transcellular regimes (how far is in debate) and activate soluble guanyl cyclases to produce cGMP. Acting via cGMP-dependent protein kinase G or directly on cyclic-nucleotide gated cation channels, cGMP can effect a number of modulatory actions. One site of action is thought to be the heterocellular coupling of ON cone BCs and glycinergic rod ACs,⁶⁰ and increased cGMP appears to uncouple this network, again a light-adaptive action. While many cells appear to be able to produce NO, the best-known architecture for NOS-containing neurons is a wide-field GABAergic AC.⁷¹

Many retinas contain a number of neuropeptides as cotransmitters, largely in wide-field GABAergic ACs with cone BC inputs. These peptides include somatostatin, substance P, and neuropeptides, with many more in non-mammalian, such as enkephalins.⁴⁴ This is probably the least understood neurochemical aspect of the retina. In general, it is thought that peptides act via specific peptide receptor GPCRs to modulate various ion channels. However, very little research on retinal peptides has been carried out in recent years.

Modulation by transporters

An important part of every signaling process is termination. Given the ability of glutamate to activate excitotoxic processes, the expression of high-affinity sodium-glutamate transporters by Müller glia likely represents the last line of

defense.¹ A molecule of glutamate must have already left the synaptic cleft by diffusion to encounter glial glutamate transporters. However, both photoreceptors and BCs express glutamate transporters, presumably near the sites of synaptic release¹ and these likely play a major role in determining the temporal dynamics of extracellular glutamate levels, though this has been difficult to quantify. Even so, every fast transmitter has a corresponding presynaptic transporter mechanism. Though numerous studies support the roles of transporters in signal termination, the precise localization of transporters has not been achieved.

Signal processing

The roles of synaptic networks are to convert graded sensory photoreceptor potentials into patterns of action potentials for long-range transmission to the CNS, and perform spatial, temporal, and spectral signal processing on the input signals of the photoreceptors. This latter action converts the retinal image into the parallel signaling behaviors of 15–20 different classes of retinal GCs in mammals. The concept of signal processing, as derived from electrical engineering, is particularly relevant.⁴⁹ Each kind of synapse, each kind of cell, and each topology of network is invoked in various ways to generate the kinds of “filters” through which the visual scene must be encoded. The physiological analysis of retina in the 1970s (especially as carried out by Naka) represented a sea-change in thinking; a move away from Sherringtonian concepts of spinal excitation, inhibition, and circuits (loops) and towards engineering notions of polarity, inversion, networks, and filters.

Sign-conserving (>) and sign-inverting (>i, >m) transfers

The behavior of a photoreceptor is neither excitatory nor inhibitory. Photoreceptors encode time-varying changes in light intensity with fairly faithful (though nonlinear) time-varying changes in voltage. As glutamatergic neurons, one would normally think of them as “excitatory” in brain, but a more robust concept is derived by looking at the behaviors of target neurons. HCs (driven by AMPA receptors) and OFF BCs (driven by AMPA or KA receptors) merely copy the polarity of presynaptic photoreceptors (see Fig. 21.1). When light hyperpolarizes photoreceptors, this decreases the rate of synaptic glutamate release and (in conjunction with glutamate transport) leads to a decrease in synaptic glutamate levels. Since AMPA and KA receptors are iGluRs, decreased synaptic glutamate means that AMPA and KA receptor-gated currents will decrease and the HCs and OFF BCs will hyperpolarize. Conversely, when a fly navigates across the visual field, local darkening will depolarize some photoreceptors and the HCs and OFF BCs will follow. Thus photoreceptor → HC and OFF BC signaling is termed sign-conserving (>). In addition, iGluRs typically mediate high-gain responses (i.e. strong amplification) and, over modest voltage ranges this amplification is symmetric and polarity-invariant. ON BCs behave in a totally different manner. In mammals, all ON BCs express functional mGluR6 receptors that activate a cation channel when unbound and close it upon binding of glutamate. Thus, when photoreceptors decrease their glutamate release, this leads to decreased mGluR6 receptor

binding and the opening of cation channels and depolarization of ON BCs (see Box 21.3). This is an explicit, high-gain, metabotropic sign-inverting (>m) synaptic transfer.

Non-mammalians display a twist on this mechanism that perhaps reveals the evolutionary history of mammalian ON BCs. The apparent homolog of the ancestral mammalian rod BC exists in the retinas of modern fishes as the mixed rod-cone BC. This cell has an unusual behavior in that it has different reversal potentials and conductance changes for different stimuli. Scotopic lights that activate rods generate ON responses that display a positive reversal potential (like a cation) and an increase in conductance (like a channel opening). This is very like mammalian rod and cone ON BCs, and indeed it appears to have the same pharmacology: 2-amino-4-phosphonobutyrate (AP4) is an agonist at mGluR6 receptors⁷² and blocks rod ON BCs responses in fishes. However, upon light adaptation, fish ON BCs change their behaviors. In response to photopic lights that activate cones, the “ON” reversal potential moves to very negative values (like an anion) and the cells display a decrease in conductance (like a channel closure). In fact, the cone-driven ON responses of fish BCs are mediated by an anion channel coupled to a glutamate transporter.^{73,74} Thus, in photopic “dark”, glutamate release activates the transporter and its coupled chloride current, leading to hyperpolarization of the BC. Thus the fish cone → ON BC synapse is sign-inverting, but not metabotropic. The degree of its amplification is also unknown.

In the inner plexiform layer, BC → AC and GC signaling is all mediated by AMPA or AMPA+NMDA receptors.^{3,64,75} Thus all BC output synapses are sign-conserving (Fig. 21.1). The bulk of AC → BC, AC or GC signaling is either GABAergic or glycinergic via increased anion conductances.⁷⁶ Thus these synapses are characteristically sign-inverting (>i). GABAergic and glycinergic transmission is also usually very low gain, often because the reversal potential is very close to the membrane potential and/or the total conductance change experienced by a target cell leads to a tremendous decrease in total cell input resistance, thus decreasing signal efficacy. In any case, it takes a significant amount of inhibition to control glutamate synapses. Some inhibitory mechanisms involve the metabotropic GABAB receptor, which is a GPCR that can lead to a tremendous increase in potassium currents, but can also show paradoxical excitation.⁷³ Since potassium currents are usually outward (positive current flowing outward), GABAB can produce a strong and long-lasting inhibition near threshold. Different GABA receptors tend to be expressed at different sites (ionotropic GABA_A on ACs and BCs, ionotropic GABA_C on BCs), but the distribution of GABAB receptors is less well understood.

Synaptic chains and polarity

The effect of cascading synapses through various pathways can be estimated in terms of polarity and gain. For example, though the mechanism of HC action is very poorly understood, its efficacy is not in doubt. As first established in fish retinas, currents injected into HCs have stereotyped actions on different GCs. The net pathway from HCs to ON GCs is sign-conserving. The net pathway from HCs to OFF GCs is sign-inverting.^{48,49} From a signal processing perspective, this means that the polysynaptic chain from a given HC,

somehow reaching a BC and thence to an ON GC must contain either no sign-inverting elements or an even number of them. The path to an OFF GC must contain an odd number of sign-inverting elements. This poses fundamental constraints on where and how signals flow in the retina and can be used as a model for network investigations. Similarly, we know that there are chains of two and three serial ACs in the inner plexiform layer of most retinas.⁵ While there are no network models that use such chains, the minimum architecture for such a chain is BC → AC → AC → BC or GC. If the AC outputs are sign-inverting, the net transfers of the chain are $>i >i >$ (sign-conserving). Importantly, the low gain of GABAergic and glycinergic synapses prevents such chains from being runaway excitations.^{5,77} What roles might such networks play? In non-mammalian, the bulk of GABAergic ACs also receive some form of GABAergic input as evidenced by their pharmacology. It was presumed that similar networks existed in mammals, but recently Hsueh et al⁷⁸ argued that in rabbit, the only synaptic crossover networks are glycine → GABA.

Feedback, feedforward, and nested feedback/feedforward

Designing analog operational amplifier networks is very similar to evolving a retina: every stage of forward amplification needs feedback control.⁷⁹ In retina, sign-inverting GABAergic mechanisms are used as feedback and feedforward control systems. Feedback is the most powerful way to set synaptic gain, improve signal-to-noise ratios, and improve synaptic bandpass. We will skip the mathematical demonstration of this, but note that it has been widely discussed.^{76,80} On the other hand, feedforward is an effective way to generate strong antagonistic mechanisms in target cells. These architectures are clearly at play in retina but we have only a hazy idea of their importance. For example, blocking GABAergic inhibition converts directionally selective GCs into non-selective cells, but has little effect on the center-surround organization of other GCs, despite the abundance of GABAergic synapses in the inner plexiform layer. Thus is it hard to generalize function from anatomy. Conversely, it is impossible to understand function without anatomy.

Caveats

Three major problems have emerged in understanding how GABAergic (or any classical inhibitory transmitter) works in retina. The first is the chloride reversal potential. We have a very poor idea of which way GABA receptor-gated anion currents will flow: inward or outward. Small retinal cells may have the ability to adjust intracellular chloride levels with various ion transport systems. The KCC2 system tends to export Cl while the NKCC system tends to import it.⁵¹ If intracellular Cl is locally high, opening an anion channel may evoke an outward negative current and depolarize the cell. However, most studies of GABAC receptors at the synaptic terminals of retinal BCs support the view that it is inhibitory.¹ A second problem is temporal delay. Imagine a cell responding to a light input with a sinusoidal voltage. Then imagine a surrounding cell giving a similar response and providing feedback with a sign-inverting polarity. If the

feedback was delayed so that the phase is shifted by 180 degrees, the “inhibitory” local surround would sum with the center response. There is much evidence to suggest that simple AC → BC inhibitory feedback cannot explain all BC responses.⁸¹ Finally, it has been long assumed that BCs were effectively isopotential, and that simple lumped-parameter calculations would suffice to model their network functions. But reconstructions of BCs in mammals⁴ suggest that the isopotentiality assumption is not correct and that complex local information processing can be effected at the synaptic terminals without any evidence of that filtering appearing at the BC soma.

Networks

The synaptology of center-surround organization

The long-standing view of any BC or GC receptive field is that it has antagonistic center-surround organization (Fig. 21.5). Where does the surround come from? Anatomically, the vast number of AC synapses at the BC synaptic terminal, as well as evidence of GABAC receptor function, suggested that ACs should have a powerful surround effect.⁵ Conversely, direct current injection into non-mammalian HCs clearly shows an effective, low-frequency dominated, sustained path from HCs to GCs. Reconciling the mechanism has been problematic but is likely simple. HCs and ACs function on very different time and space scales. HCs are slow, sustained (beyond the capacity of any normal neuron) and have immense receptive fields due to strong coupling by gap junctions. Thus the presence of very large antagonistic surrounds in GCs is likely driven through HCs. Experiments using fast pH buffers such as HEPES block these surrounds.⁵⁵ Conversely, GABAergic drugs have no effect on these large surrounds (in mammals). So what about ACs and all those synapses? Why don’t they create the large surrounds of GCs? First, ACs have much smaller receptive fields than HCs and their range of action will thus be smaller. Second, many ACs themselves show antagonistic center-surround organization, likely due to AC $>i$ AC chains.^{82,83} Third, ACs are very fast and their actions at the BC terminal likely have more to do with feedback stabilization of synaptic gain than creating large, slow antagonistic surrounds. ACs work in a highly time-and-space-restricted domain.

The synaptology of mammalian rod pathways – evolution of a new amplification scheme

As we have described earlier, the synaptic chains that drive GCs in all retinas are grouped into ON and OFF pathways. In non-mammalian, rod and cone pathways both use this direct chain to target the CNS. Thus rod signals undergo two-stage amplification before being encoded as a spike train: rods $>m$ ON BCs, rods $>$ OFF BCs and BCs $>$ GCs. In mammals, a new amplification scheme evolved using cone BCs as the output stages, with rod BCs and glycinergic (gly) rod ACs as interneurons. Mammalian rod BCs are homologous to non-mammalian mixed rod-cone BCs, but have lost both cone inputs and the ability to target GC dendrites.

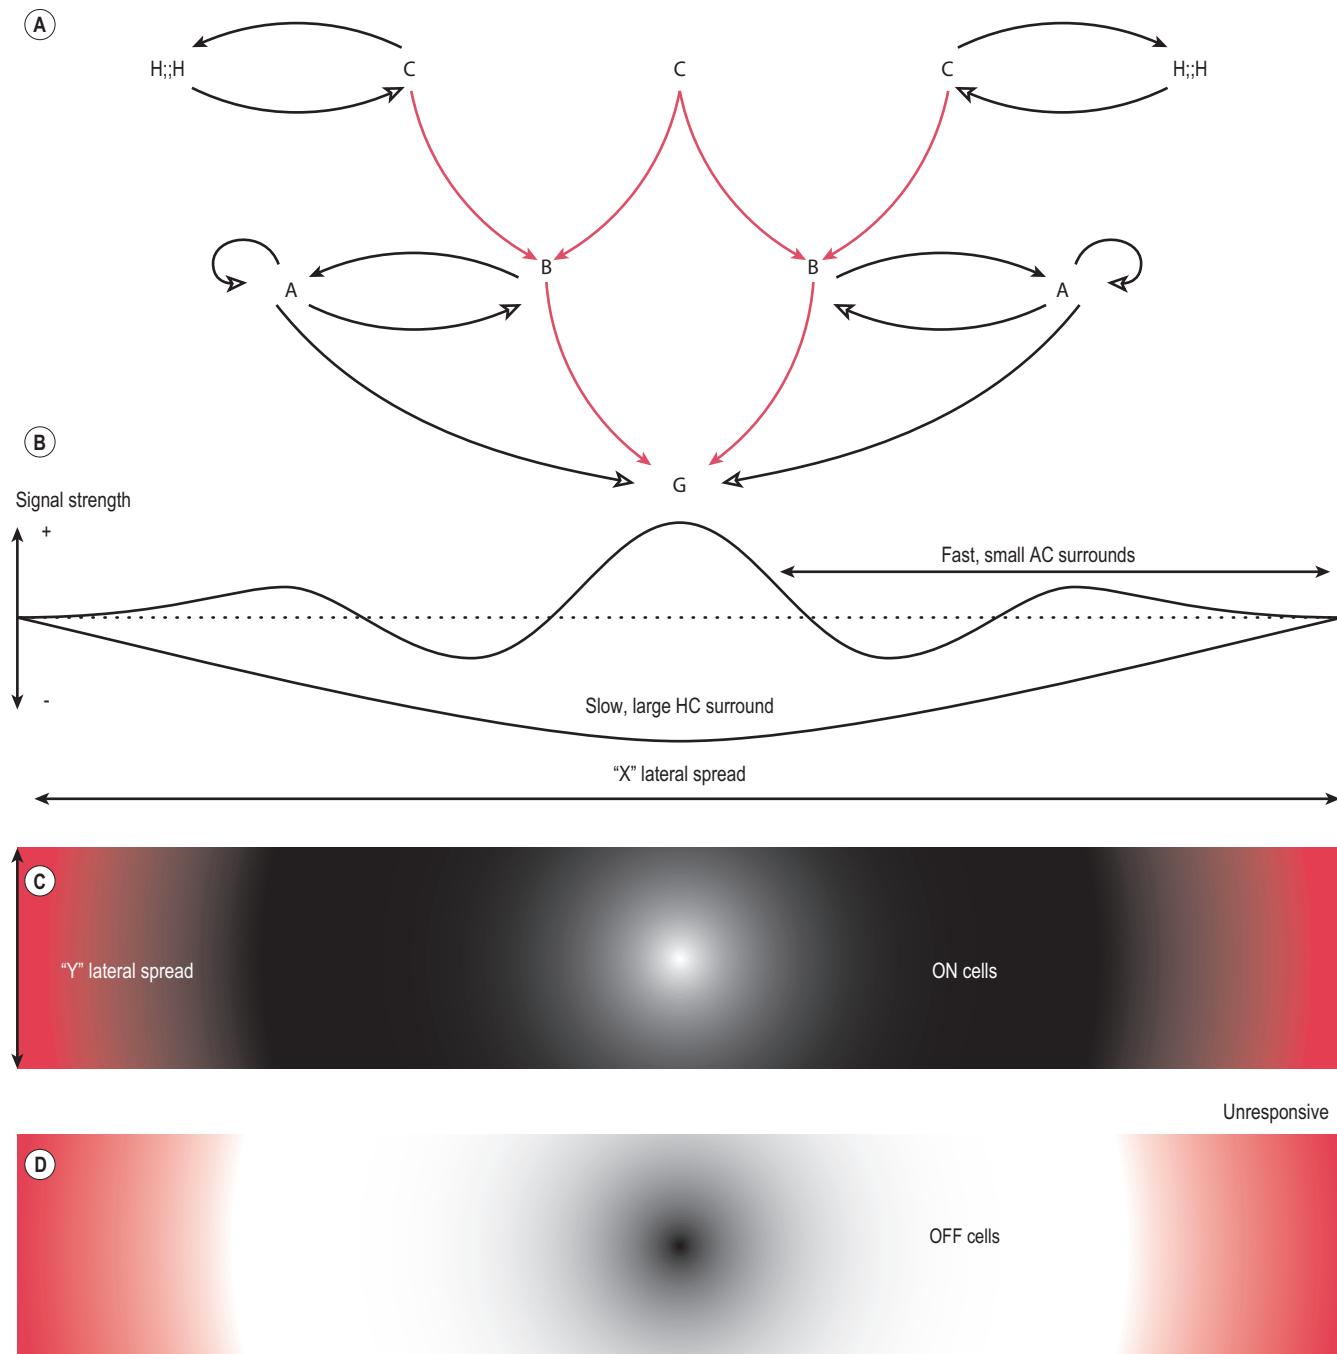

Figure 21.5 The synaptic flow that forms GC receptive fields. Cone signals (C) converge on BCs (B) which then converge on GCs (G), creating the canonical receptive field center, represented by a peak in the signal strength from the GC. The coupled HC layer (H:H) forms the large, slow antagonistic surround, while narrower ACs (A) form fast, small surrounds with damp oscillatory wings. The HCs dominate sustained signaling, so typical receptive field maps of the light required to excite cells represent BC+HC contributions. For ON cells, a spot of bright light will excite, while flanking regions of darkness will excite. For OFF cells, a spot of darkness will excite, while flanking regions of light excite. The red zones indicate regions outside the field where neither excites.

Nevertheless, six possible rod networks arising from three primary pathways (Fig. 21.6) exist in mammals, here grouped by amplification.

Three-stage amplification:

- (1) rods >m ON rod BCs > gly rod ACs::ON cone BCs > ON GCs
- (2) rods >m ON rod BCs > gly rod ACs >i OFF cone BCs > OFF GCs.

Two-stage amplification:

- (3) rods::cones >m ON cone BCs > ON GCs
- (4) rods::cones > OFF cone BCs > OFF GCs
- (5) rods > OFF cone BCs > OFF GCs (sparse and species variable)
- (6) rods >m ON cone BCs⁸⁴ > ON GCs (sparse).

Thus, rod vision is parsed into ranges served by different networks: (i) the gly rod AC network with two arms of

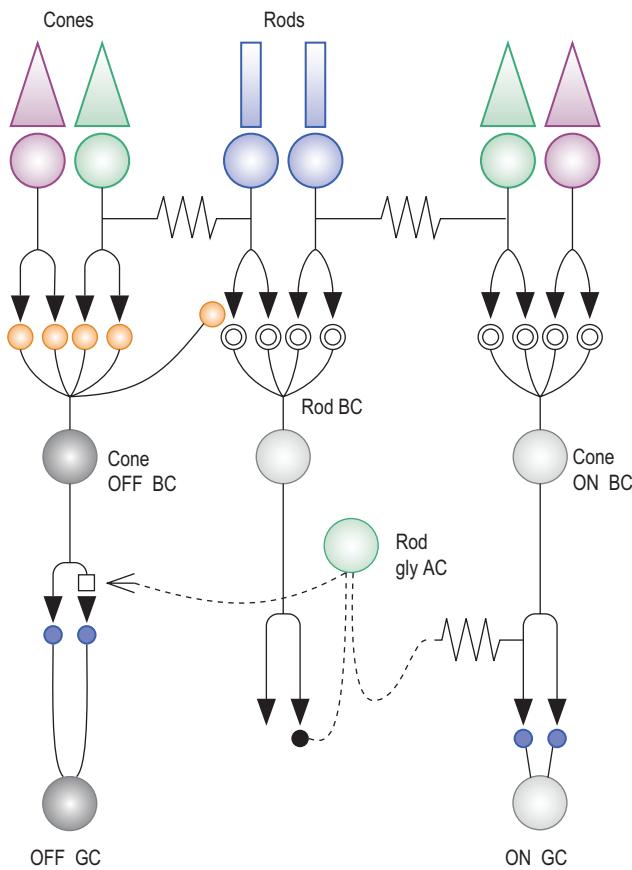

Figure 21.6 The synaptology of the mammalian scotopic network. Rod signals predominantly reach GCs by three pathways. The main dark-adapted pathway flows from rods → rod BCs → glycinergic rod ACs which then redistributes the signal back into the cone BC channels via gap junctions (ON BCs) or glycinergic synapses (OFF BCs), and thence to GCs. The second, less-sensitive path is via rod:cone gap junctions. A rarer path, not found in all mammals, is the occasional sampling of rod signals by OFF BCs. (Symbols as in Fig. 21.1.)

three-stage amplification for threshold scotopic vision and (ii) the rod:cone → cone BC → GC two-stage amplification for high brightness (moonlit) scotopic vision. Additional rod > cone BC contacts have been shown in some mammals,^{38,39} but whether these additional pathways are structural errors in evolution or functional is not certain, as their incidences vary across mammalian species.⁸⁴

The rod circuit is all the more complex for the involvement of GABAergic ACs, also known as S1 and S2 classes.¹¹ These γ rod ACs have dendritic arbors 1 mm in diameter and contact over 1000 rod BCs with reciprocal feedback synapses, with S2 cells providing twice the number of feedback synapses as S1.⁸⁵ This feedback likely further speeds the initially sluggish rod threshold response.

The synaptology of motion – AC surrounds from afar

While the roles of ACs in forming the center-surround features of sustained GCs are cryptic, their primacy in encoding motion is established. Directionally selective (DS) GCs respond to targets moving in a preferred direction, but

remaining silent when targets move in the opposite, “null” direction.^{86–88} DS GCs come in two classes: ON-OFF and ON GCs. These networks engage BCs and perhaps several different AC inputs, including the ON and OFF subtypes of starburst GABAergic/cholinergic ACs and other GABAergic ACs.^{89,90} OFF starburst ACs hyperpolarize to light and are driven by OFF cone BCs. ON starburst cells have somas displaced to the GCL, depolarize to light and are driven by ON cone BC inputs. Each class stratifies with and synapses on the dendrites of DS GCs. The precise classes of other γ ACs in DS GC networks are not known, but the functional roles of GABAergic inhibition are emerging. At least one GABAergic AC inhibits the starburst ACs, and others inhibit DS GCs. Thus, as stimuli come from the preferred side, a combination of excitatory glutamatergic BC and cholinergic starburst AC signals converge on the GC in advance of GABAergic inhibition. The excitatory gain is likely enhanced by the BC > starburst AC > GC chain, which should have greater gain than a direct BC > GC transfer. In the null direction, a strong GABA signal reaches the DS GC in advance of the excitatory input and prevents it from reaching spike threshold (Fig. 21.7). GABA receptor antagonists block this strong inhibition and convert DS GCs into non-directional cells.⁸⁶ The inhibition seems so strong (almost like veto synapses in cerebellum) that the BC > starburst AC > GC circuit can't break through. In fact, that may be the *raison d'être* for starburst ACs: to break through any residual inhibition in the preferred direction as GABA inhibition is strong *even in the preferred direction*. This is likely an archetype for all AC circuits, where spatial properties, timing, and convergence of multiple cell classes select for fine grain features such as edges, texture, or flicker.

The synaptology of color – HC surrounds again?

Humans and old-world primates have cone mosaics with sparse blue (B, SWS1) cone arrays⁹¹ surrounded by randomly distributed red cones and green cones (R, LWSR; G, LWSG). Most mammals possess dichromatic vision via B and G cone opponencies. Complete trichromatic vision has two opponent processes:⁹² (1) blue/yellow (B/Y) opponency (where the Y signal is the sum of R and G cones signals);^{93,94} and red/green (R/G) opponency. Both pose conceptual problems. The R and G pigment genes are tandem head-to-tail LSW arrays on the X chromosome.^{21,92} LSW cones can express only one pigment, either LWSR or LWSG, creating either R or G cones^{95,96} and this may be the *only* gene product that discriminates R and G cones. This suggests that the connectivity of R and G systems is probabilistic. Even so, R/G opponency is robust in trichromatic primates.

R/G opponency

In the foveola, each midget BC contacts only one cone and each midget GC contacts only one midget BC. Thus four types of center/surround R/G color opponency emerge (Fig. 21.8).⁹⁷ If the behavior of a single foveal R cone is not confounded by R::G coupling, a midget BC > midget GC chain should manifest a pure R or G center. Thus all midget GCs will be color opponent (Fig. 21.8) since their surrounds, whether derived from HCs or ACs, should be “yellower” than both: always greener than R cones or redder than G

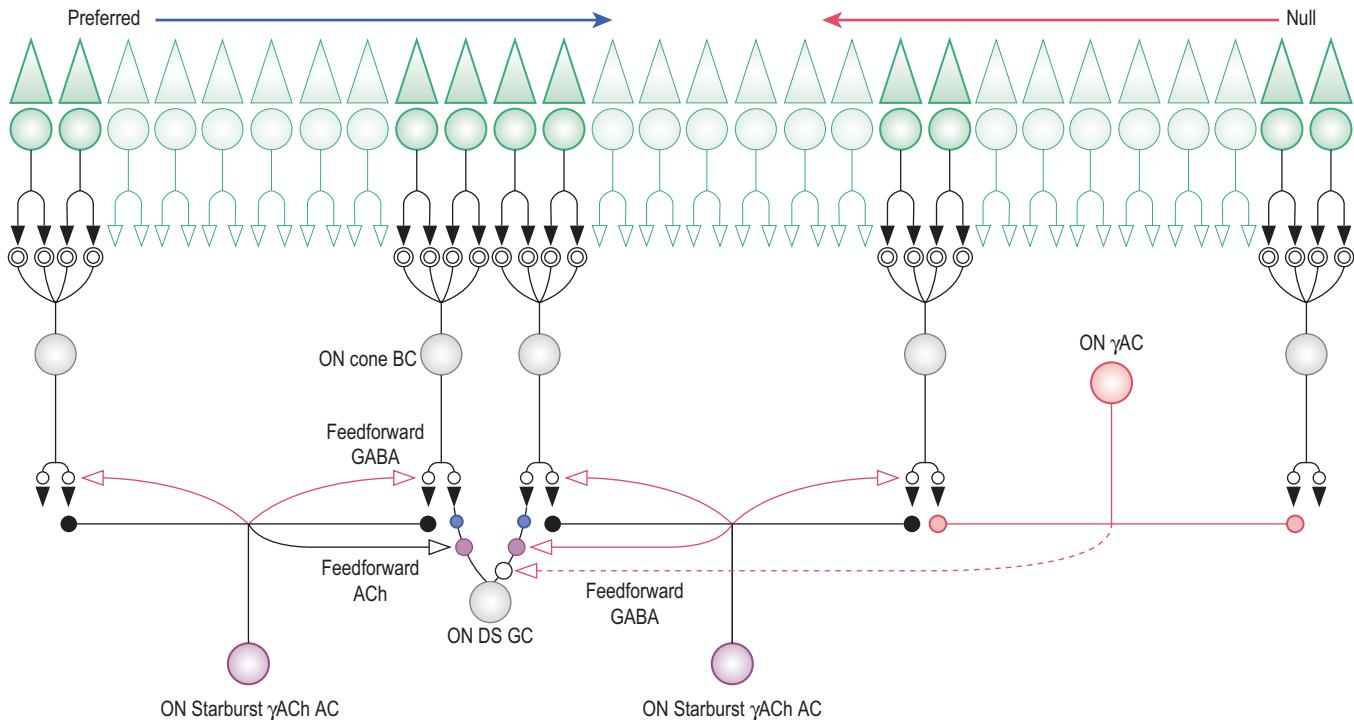

Figure 21.7 One possible synaptology for the mammalian ON-center DS GC network. ON DS GCs collect glutamatergic excitatory signals from ON cone BCs and cholinergic excitatory signals from ON starburst ACs. This amplifies the center response. ON starburst ACs also provide GABAergic feedback onto BCs. However, additional GABAergic inputs exist in the DS strata of the IPL. Such cells may receive inputs in the surround on one side and send axons (dotted) to target distant DS GC dendrites. Thus stimuli approaching from the left will excite and those from the right will inhibit. (Symbols as in Fig. 21.1.)

cones. HCs do not show any spectral selectivity for R or G cones and sum their inputs.⁹⁸ It was once posited that the GC surrounds were pure (pure R versus pure G) via selective contact of opponent BCs by ACs, but electron microscopy shows this is not so,⁹⁹ that the AC driven surrounds of midget GCs encode mixtures of R and G cones. Even so, some midget GCs show nearly pure opponent surrounds,^{100–102} perhaps because of the patchiness of R and G cone distributions¹⁰³ and the small size of midget GC surrounds. Thus there is much more to be understood about midget GC networks. For example, why don't broad yellow-sensitive (Y) HC surrounds dominate midget BCs, as they do for B/Y opponent GCs?

B/Y opponency

GCs that convey blue signals are thought to be of two varieties: large and small bistratified B+/Y- GCs^{93,97} receive B cone ON BCs synapses in sublamina *b* and Y inputs from diffuse OFF BCs in sublamina *a*. Though it was thought that B/Y centers and surrounds overlapped tremendously, recent data suggest that the Y surround comes from HCs via HC > i cone feedback and is much larger.⁵³ Recent anatomical evidence suggests the existence of a midget B cone OFF BC pathway in monkey¹⁰⁴ and a diffuse B cone OFF BC in rabbit.¹⁰⁵ Further, melanopsin GCs are putative B-/Y+ GCs with large receptive fields.¹⁰⁶ Which cells carry "the" blue signal remains uncertain as human patients lacking the mGluR6 receptor (and thus lacking ON BC signaling) apparently have quite excellent photopic sensitivity and apparently no color deficits.

Revising the retinal synaptic networks with disease

It was once thought that retinal networks were laid down once and for all in development by a process independent of sensory experience, but that is clearly incorrect. No less correct is the idea that, during the process of photoreceptor deconstruction and death, the neural retina remains normal. Many studies show that retina behaves much like CNS in response to challenges such as oxidative stress, denervation and trauma by remodeling its synaptic connectivity and reprogramming neural signaling rules. For example, the loss of photoreceptors in retinitis pigmentosa leads to the retraction of BC dendrites and the evolution of new axon-like structures; the generation of abundant new processes from retinal neurons of all kinds; the formation of new synaptic zones in the form of micro-neuromas; the switch from mGluR6 to iGluR expression in former ON rod BCs; and the ultimate death of many neurons.^{12,107,108} These changes challenge many strategies to restore vision by genetic, molecular, cellular, and bionic schemes. But beyond that, they demonstrate two very important concepts. First, synaptic communication is likely never static and that signaling mechanisms are stabilized by active mechanisms. Second, the rules used by any neuron to decide which glutamate (or other) receptors to express are not known. We do not understand which transcriptional regulators make the decision to choose mGluR6 initially, much less choose AMPA or KA receptors in response to reprogramming.

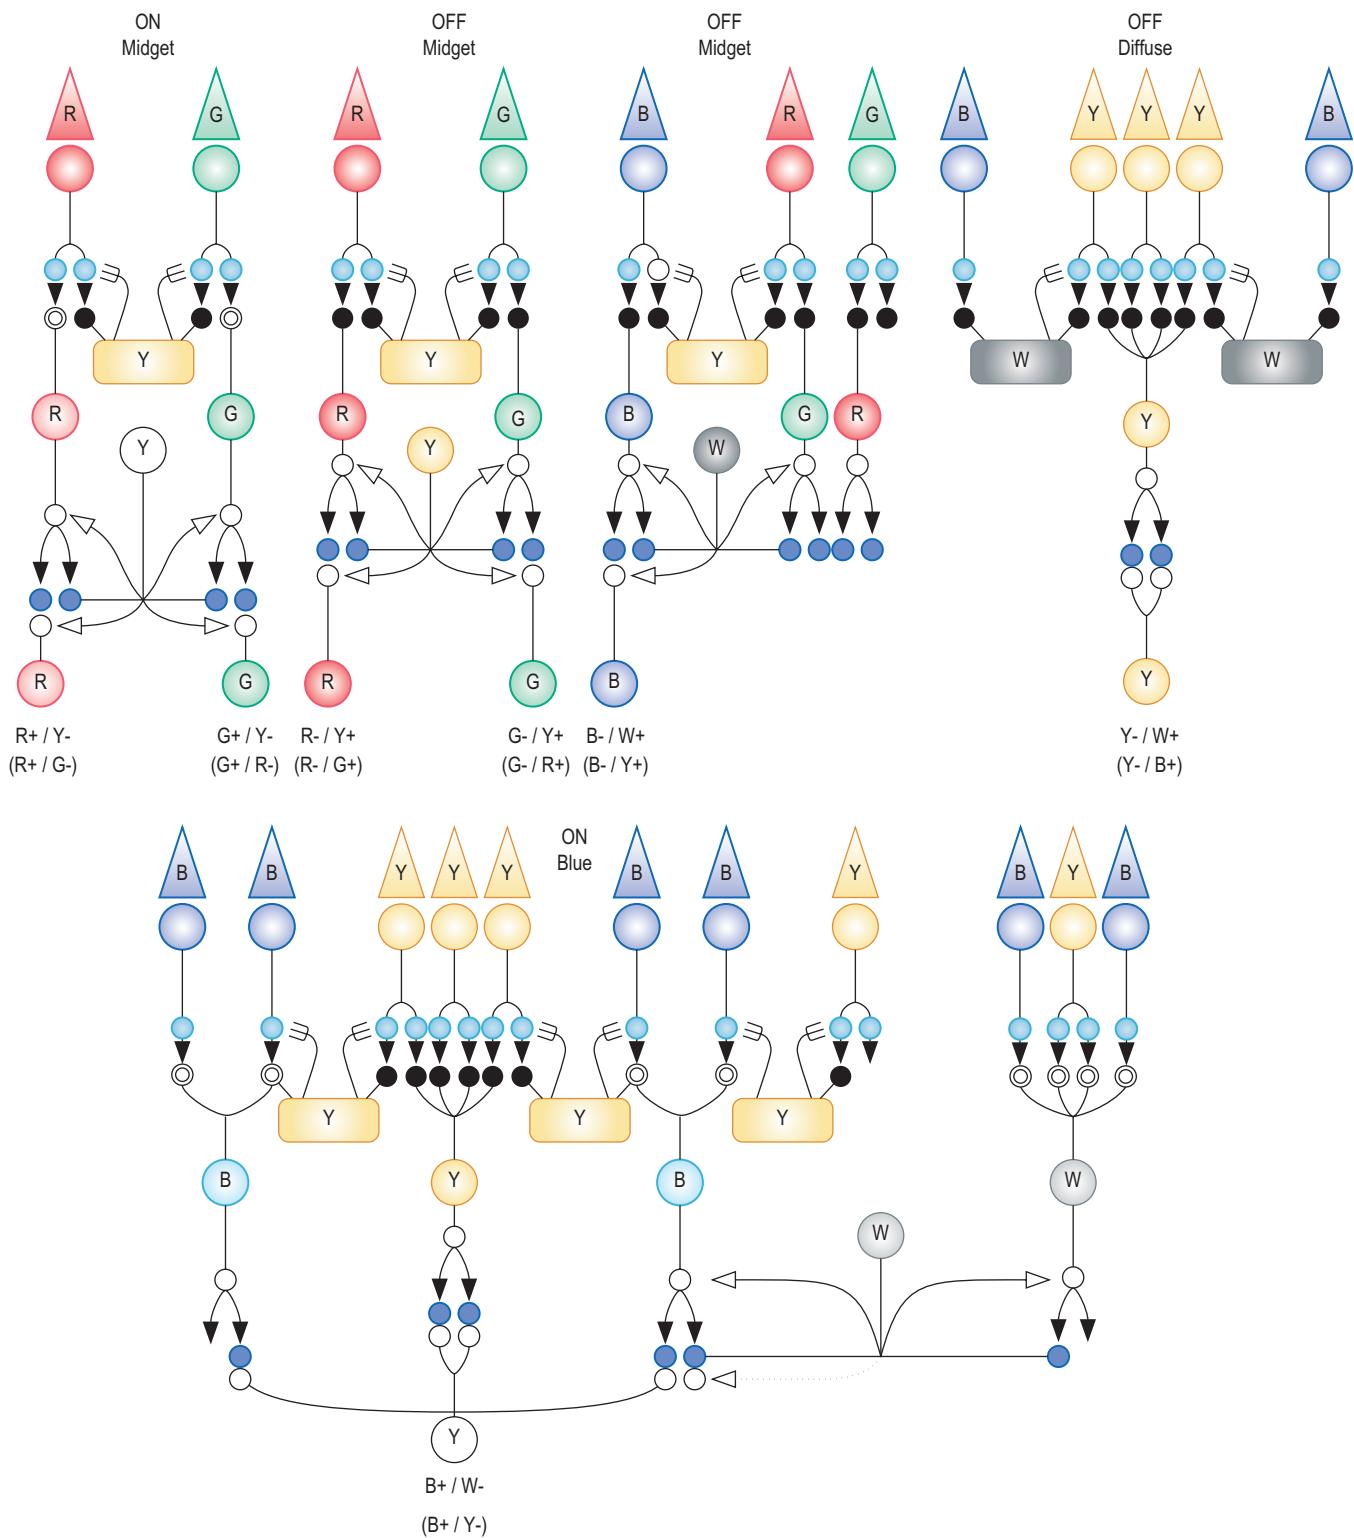

Figure 21.8 Possible color channel synaptologies for the mammalian (primate) retina. Midget pathways arise from midget BCs that contact only one cone and midget GCs that contact only one BC. This creates pure red (R) or green (G) center GCs in both ON and OFF channels. However the surround information from HCs and ACs collect from both R and G channels, generated "yellow" (Y) surrounds. GCs that are R/Y will generate net R/G percepts (shown in parenthesis), with similar outcomes for the three other possible R and G channels. OFF midget blue channels are likely antagonists by "yellow" H1 HCs and either Y or "white" (W) ACs that collect from all classes of cone BCs. GCs that are B/W will generate net B/Y percepts (shown in parenthesis), with similar outcomes for the three other possible R and G channels. It is also possible that diffuse BCs that contact all LWS cones (summarized as Y cones) may have surrounds from "white" H2 HCs (either by feedback as shown or feedforward) that generate Y-W+ fields leading to Y-B+ percepts. Finally, the best known B pathway involves selective for SWS1 B cones. The GCs that collect these signals are small bistratified cells with ON B BC inputs in sublamina b and Y selective OFF BC inputs in sublamina a. There are at least three possible -Y channels: H1 HC feedforward to B cones, direct OFF BC inputs from LWS-selective BCs, and W opponent inputs from non-selective ACs. The inability of GABA antagonists to block Y opponency in these cells suggest that the HC network dominates. (Symbols as in Fig. 21.1.)

Signal Processing in the Outer Retina

Samuel M. Wu

Light-evoked hyperpolarizing signals in rods and cones are transmitted to and processed by neurons in the rest of the retina through a complex, but highly organized network of electrical and chemical synapses.¹⁴ In the outer retina, photoreceptors are electrically coupled to one another,⁵ and rods and cones send output signals to second-order retinal cells, the horizontal cells (HCs) and bipolar cells (BCs), via chemical synapses. HCs make feedback synapses on cones, and send feedforward synaptic signals to BCs.⁵ BCs can be classified into two major types, the on-center (or depolarizing bipolar cells, DBCs) and the off-center (or hyperpolarizing bipolar cells, HBCs).⁷⁸ Additionally, they can be further classified according to their relative rod/cone inputs, color opponency, axonal outputs and other parameters. BCs are the first neurons along the visual pathway that exhibit clear center-surround antagonistic receptive field (CSARF) organization, the basic code for spatial information processing in the visual system,²⁵ and the synaptic circuitry underlying bipolar cell receptive fields will be discussed in this chapter.

Electrical synapses (coupling) between photoreceptors

Electrical coupling between photoreceptors was first discovered in the turtle retina by Baylor et al in 1971.⁵ Electron microscopic studies revealed that gap junctions exist between photoreceptors in many vertebrate species. In the primate retina, anatomical data have shown large gap junctions between cones and smaller junctions between rods and cones, suggesting that cone–cone coupling is stronger than rod–cone coupling.^{59,60} In the turtle and ground squirrel retina, couplings are found between cones of the same spectral sensitivity and between rods;^{5,9,11,63} whereas in amphibians, rods are strongly coupled to each other, but cones are not.^{3,4} Coupling between rods and cones has been observed in turtles, tiger salamander and mammals, but the coupling strength is weaker than that between cones (in turtles) and between rods (in tiger salamander).^{4,62} Recent evidence has shown that gap junctions between photoreceptors are mediated by connexin 35/36 gap junction proteins (Fig. 22.1)^{10,53,94} and double patch recordings have revealed detailed properties of electrical synapses between photoreceptors. For

example, junctional conductance between salamander rods is linear, with an average value of 500 pS (Fig. 22.2A).⁹⁵ In ground-squirrel, green-green cone pairs are coupled with an average conductance of 220 pS, whereas coupling is undetectable in blue-green cone pairs (Fig. 22.2B).³⁹ In the monkey retina, coupling has been found between red-cones, between green-cones and between red- and green-cones (Fig. 22.2C).²²

Although most rods are weakly coupled with cones in the tiger salamander retina, a small fraction of rods (10–15%) are strongly coupled with adjacent cones. Voltage responses of these rods (named rod_{CS}) to current injection into a next-neighbor cone are about three to four times larger than those of the other rods.⁸⁷ Rod_{CS}s behave like hybrids of rods and cones, and one of their functions is to generate off overshoot responses in higher-order retinal neurons under light-adapted conditions.⁸²

Photoreceptor coupling decreases resolution (visual acuity) of the visual system by spatially averaging photoreceptor signals over some lateral distance in the retina. However, the advantage of this arrangement is that it improves the signal-to-noise ratio of the photoreceptor output when the retina is uniformly illuminated. This is especially important for the rods to detect dim images under dark-adapted conditions when the voltage noise is high. It can be shown mathematically, however, that photoreceptor coupling decreases the signal-to-noise ratio of the photoreceptor network if the number of illuminated photoreceptors is less than the square root of the number of photoreceptors that are effectively coupled (Box 22.1).

Rod and cone photoreceptors operate in different ranges of illumination, and they exhibit different spectral sensitivities. Electrical coupling between rods and cones broadens the operating ranges and spectral sensitivity spans of both types of photoreceptor by mixing their light-evoked signals. Additionally, under conditions when the signal in one type of photoreceptor is suppressed (e.g. rod response in the presence of background light), its output synapse can be used to transmit signal from the other type of photoreceptor (e.g. cones). It has been shown that rod–cone coupling in the tiger salamander retina is enhanced by background light.⁸⁸ This allows transmission of cone signals through the rod output synapses. Such “synapse sharing” minimizes the

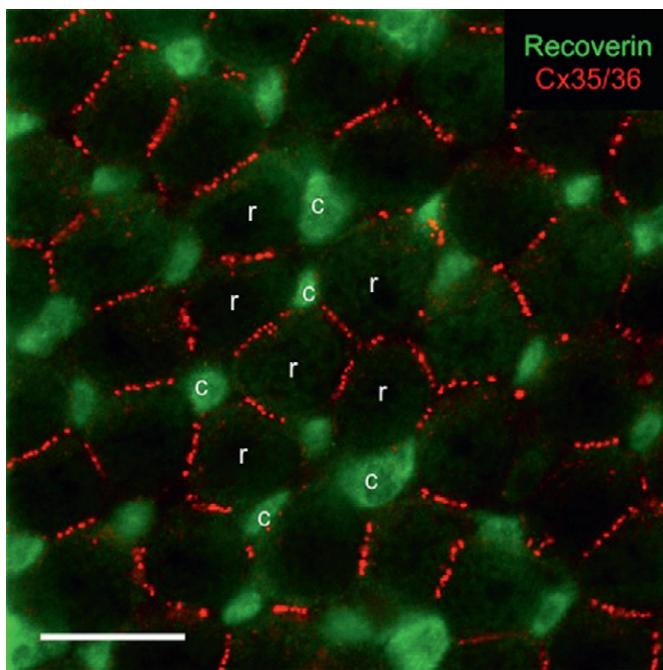

Figure 22.1 Connexin36 in the photoreceptor network. Confocal image of a salamander flatmount retina (with focal plane at the level of the distal region of rod cell bodies) double labeled with anti-Cx35/36 (red) and recoverin (green). Recoverin differentially labeled rods (r, weak green) and cone inner segments (c, strong green). The strong Cx35/36 punctate labeling on membrane contacts outlined the mosaic of the rod network in the field. Scale bar = 20 μ m.

Box 22.1 Photoreceptor Coupling Alters the Signal-to-Noise Ratio of the Photoreceptor Network

If N photoreceptors are coupled and k photoreceptors are uniformly illuminated, then the average (sample) signal is $S = kS_1/N$ (where S_1 is the light-evoked signal in one photoreceptor and σ_1 is the noise, or the standard deviation of S_1 from the mean), and the average (sample) variance:

$$\begin{aligned}\sigma^2 &= \text{var}(S) = \text{var}((1/N)(S_1 + S_2 + \dots)) = (1/(N^2))\text{var}(S_1 + S_2 + \dots) \\ &= (1/(N^2))(\sigma_1^2 + \sigma_2^2 + \dots) = ((\sigma_1^2)/N), \text{ and thus} \\ \sigma &= ((\sigma_1)/\sqrt{N})\end{aligned}$$

The average (sample) signal-to-noise ratio:

$$S/\sigma = (kS_1/N)/(\sigma_1/\sqrt{N}) = (k/\sqrt{N})(S_1/\sigma_1).$$

Therefore when $k > \sqrt{N}$, $S/\sigma > S_1/\sigma_1$, the average signal-to-noise ratio improves, and when $k < \sqrt{N}$, $S/\sigma < S_1/\sigma_1$, the average signal-to-noise ratio worsens.

amount of neural hardware and facilitates cone inputs in second-order retinal cells.⁸⁴

Glutamatergic synapses between photoreceptors and second-order retinal neurons

Vertebrate photoreceptors use glutamate as their neurotransmitter, which is released continuously in darkness as the

photoreceptors are depolarized.⁸ Calcium enters photoreceptor synaptic terminals through voltage-gated calcium channels and triggers exocytosis of glutamatergic vesicles,⁷³ releasing packages of glutamate, each of these packages activates a number of glutamate receptors that initiate transient postsynaptic currents termed spontaneous excitatory postsynaptic currents, or sEPSCs.^{41,55} sEPSCs are seen in most HBCs, but analogous (sign inverted) discrete postsynaptic currents are generally not observed in the DBCs.^{57,85} This probably reflects a difference in the kinetics of the glutamate receptors in DBCs and HBCs.² Postsynaptic responses of the HBCs and horizontal cells (HCs) are mediated primarily by ionotropic glutamate receptors (kainate (KA) or α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors),^{13,40,45,55} and the responses of the DBCs are mediated mainly by metabotropic (mGluR6, or L- α -amino-4-phosphonobutyrate (L-AP4)-sensitive) receptors (Fig. 22.3).^{50,51,64,66} Glutamate released from photoreceptors in darkness binds to the KA/AMPA receptors in HBCs and HCs and opens postsynaptic cation channels. It also binds to the mGluR6 receptors in DBCs, resulting in a G protein-mediated process, which closes cation channels. Light suppresses glutamate release from photoreceptors, closes AMPA/KA-mediated cation channels and results in hyperpolarization in HBCs and HCs, and it opens mGluR-mediated cation channels and results in depolarization in DBCs. In fish, cone transmission to DBCs has been shown to be mediated by a glutamate-activated chloride current (TBOA-sensitive) that is shut down in the light, resulting in membrane depolarization.^{18,80}

It has been shown that the AMPA/KA receptors in HBCs are largely desensitized in darkness, leading to small postsynaptic currents and reduced response dynamic ranges.¹³ In the salamander retina, rod-dominated HBCs have been found to evade postsynaptic receptor desensitization by using synchronized multiquantal release at multiple invaginating ribbon junctions and GluR-4 AMPA receptors as the postsynaptic receptors.⁵⁵ The large multiquantal events have fast decay time so that self-desensitization is avoided and they allow long intervals between events so that mutual desensitization is minimized. Consequently HBC_Rs are not desensitized in darkness, allowing light signals to be encoded by the full operating range of the glutamate-gated postsynaptic currents.

The exact gating mechanism of the mGluR6 receptor-mediated cation channels is unclear.⁶⁷ The mGluR6 receptors generate substantially slower conductance changes compared with the AMPA/KA receptors in HBCs, and thus the sEPSC events in DBCs are heavily filtered.

Detailed descriptions of ionotropic and metabotropic glutamate receptors and glutamate transporters in the retina are also given in Chapter 21.

Horizontal cell responses

Intracellular recordings from the horizontal cells were first made by Svaetichin in the bream retina,⁷² and thus the light responses of these cells were termed S-potentials. In the fish retina, two major types of horizontal cells which receive cone inputs may be distinguished: the L-type (luminosity), which hyperpolarizes to light stimuli of all wavelengths; and the C-type (chromaticity or color), which hyperpolarizes to

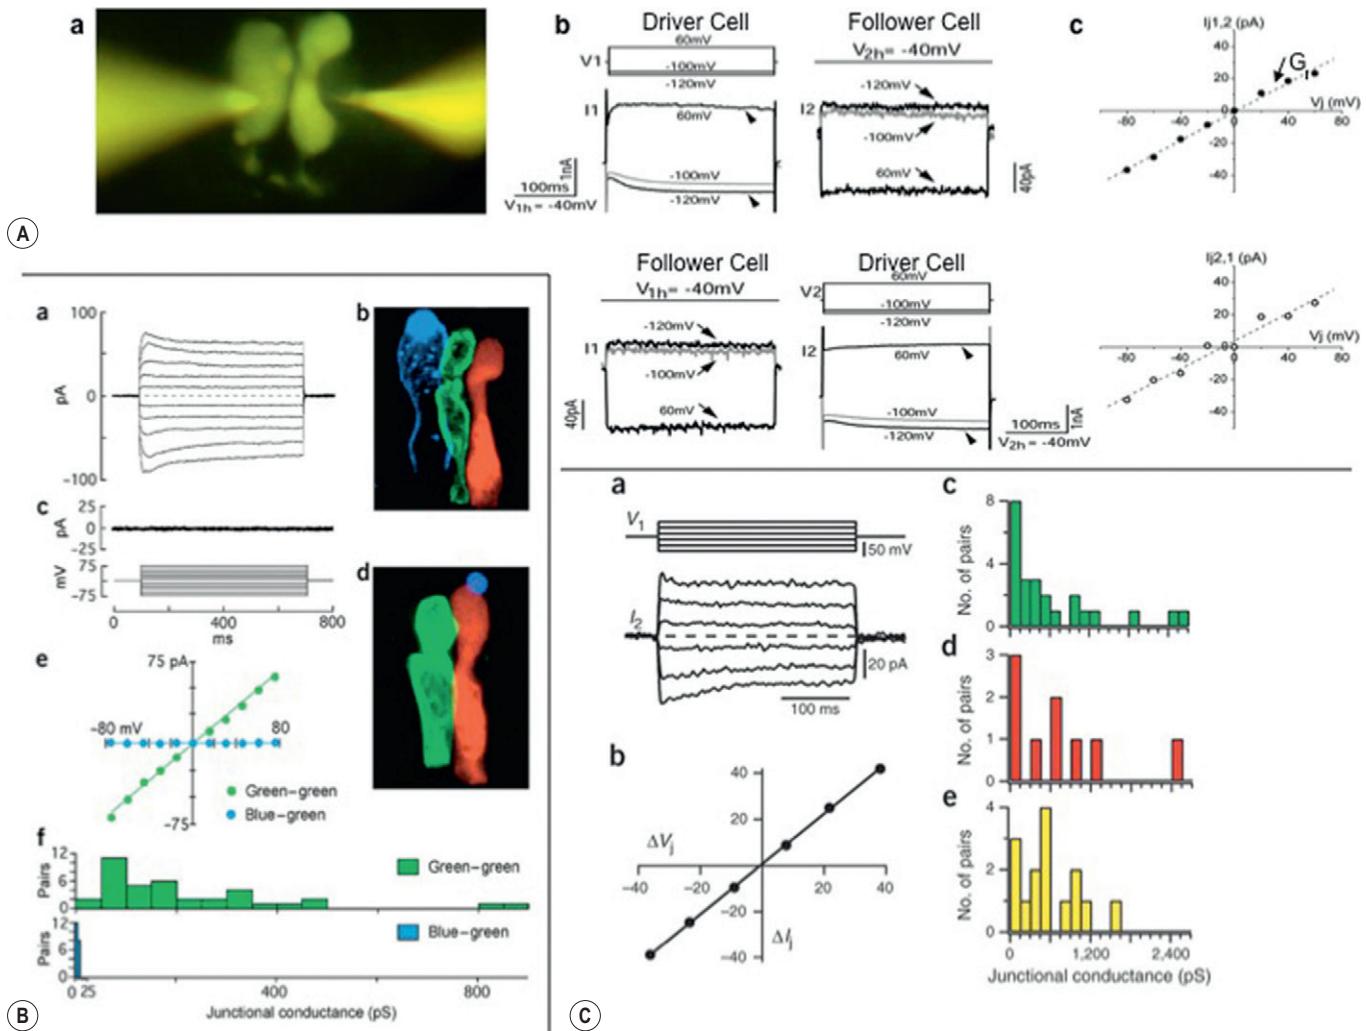

Figure 22.2 Rod-rod coupling in the tiger salamander retina (A), cone-cone coupling in the ground squirrel retina (B), and cone-cone coupling in the monkey retina (C). (A) (a) A pair of rods simultaneously patch clamped and filled with Lucifer yellow through two recoding pipettes. (b) Simultaneous dual whole-cell voltage clamp recordings from a pair of next-neighboring rods. The membrane potential of two rods was held at -40 mV . Upper panel: when a series of voltage step commands (V_1) (from -120mV to 60mV with an increment of 20mV) were applied to cell 1 (driver cell), the voltage activated current responses (I_1) (arrowheads) were recorded in cell 1 (left panel) and the junctional currents of the opposite polarity (I_2) (arrows) were recorded in cell 2 (follower cell, right panel). Lower panel: switching the position of driver/follower cells. (c) Relations of transjunctional current (I_j) and transjunctional voltage (V_j) obtained in upper and lower panels in b. The junctional conductance (G_j) measured in either direction is 500 pS . (From Zhang & Wu 2005.⁹⁵) (B) (a) Junctional currents from a pair of green cones during a series of steps in transjunctional voltage (lower traces in c). (b) The green cones in (a) were labeled with Alexa Fluor 568 (red) and 488 (green). A blue cone (blue) is adjacent to the green cone pair. (c) Junctional currents (upper traces) from a pair of blue and green cones during a series of transjunctional voltage steps (lower traces). (d) The blue cone in (c) was labeled with Alexa Fluor 568 (red) and the green cone was labeled with Alexa Fluor 488 (green) (e) Plot of the steady transjunctional current versus transjunctional voltage for the green-green pair (green) and blue-green pair (blue). (f) Histogram of junctional conductance for 38 green-green and 20 blue-green cone pairs. Bin widths, 50 pS for green-green pairs; 5 pS , blue-green pairs. (From Li & DeVries 2004.³⁹) (C) (a) Change in membrane current in a red cone (I_1) in response to change in membrane potential (V_1) in an adjacent green cone. The red cone was voltage clamped to -55 mV and the green cone voltage was stepped from an initial value of -55 mV . (b) The slope of the relationship between the transjunctional current (I_j) and the transjunctional voltage (V_j) gives a coupling conductance of $1,086\text{ pS}$. (c-e) Histograms of cone junctional conductances for 24 green-green pairs (c), 9 red-red pairs (d) and 15 red-green pairs (e). (From Hornstein et al 2004.²³)

light stimuli within certain ranges of wavelength but depolarizes to light in other wavelength ranges. The C-type horizontal cells may be divided into the biphasic and the triphasic cells. Two kinds of biphasic C-cells have been reported: the green/blue cells, which depolarize to red and green flashes and hyperpolarize to blue light; and the red/green cells which depolarize to red light and hyperpolarize to green and blue lights. The triphasic C-cells, on the other hand, hyperpolarize to both blue and red lights and depolarize to green light.⁴⁸ Horizontal cells which receive input only

from rods are found in many species. The light responses of these cells differ from those of the cone horizontal cells in two ways: Rod S-potentials in the carp are found to have peak spectral sensitivity around 520 nm while the L-type cone S-potentials peak around 600 nm . The sensitivity to light is much higher in rod S-potentials than the L-type S-potentials.³⁴ The receptive fields of horizontal cells are much larger than those of the photoreceptors. Naka & Rushton showed that the amplitude of the L-type horizontal cell response continued to increase up to a light spot

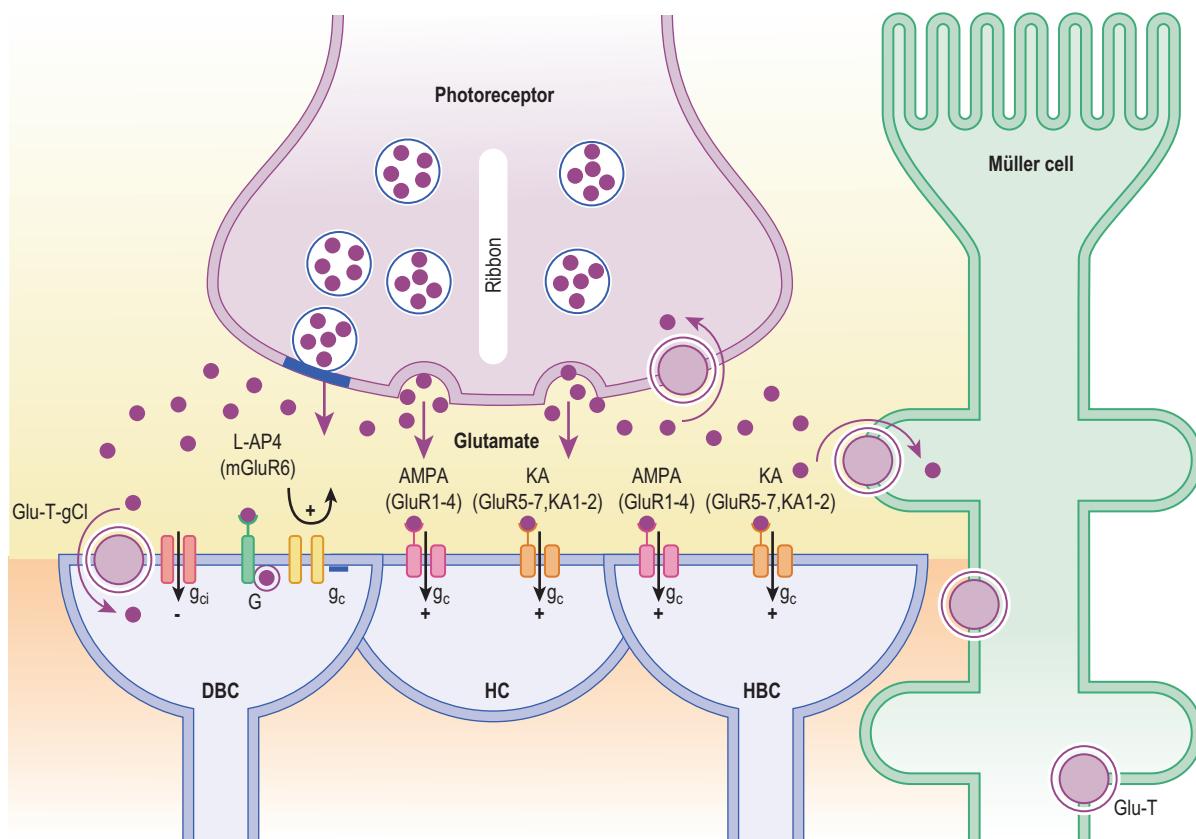

Figure 22.3 Schematic diagram of glutamatergic synapses between photoreceptors and second-order retinal neurons. HC: horizontal cell, DBC: depolarizing bipolar cell, HBC: hyperpolarizing bipolar cell, Glu-T: glutamate transporters, mGluR6: metabotropic glutamate receptor 6, AMPA: α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid receptor, KA: kainate receptor, L-AP4: L- α -amino-4-phosphonobutyrate. g_c: cation channel, g_{Cl}: chloride channel, G: G-protein, Glu-T-g_{Cl}: glutamate transporter coupled chloride channel.

diameter of 1.2 mm.⁴⁹ Very similar results have been obtained in the amphibian and cat horizontal cells.^{69,93}

Horizontal cells in the vertebrate retina are electrically coupled to one another. In fish retina, the electrical (gap) junctions between HCs are very extensive. Gap junctions are observed between HC perikarya or between HC processes, but the couplings are only made between HCs of homologous types. For example, the H1 cone HCs in the fish couple only with other H1 cells, H2s couple only with other H2 cells, and HC axon terminals couple only with other HC axon terminals.^{31,79} In the salamander retina and most mammals, there are two types of HC somas, one not bearing axons (axonless, A-type) and the other has axons (B-type).^{16,38} B-type axon terminals are functionally isolated from the B-type somas and form their own network. All three types of HCs (A-type soma, B-type soma and B-type axon terminals) are electrically coupled with their own kinds. A-type somas are weakly coupled and thus they have narrow receptive fields, whereas B-type soma and B-type axon terminals are strongly coupled (with their own type) and thus they have wide receptive fields (Fig. 22.4).⁹³

Horizontal cell output synapses

Horizontal cells mediate bipolar cell surround responses through a feedback synaptic pathway (HC \rightarrow cone \rightarrow bipolar

cell) and through feedforward synapses (HC \rightarrow bipolar cell). The HC \rightarrow cone sign-inverting feedback synapse was discovered by Baylor et al (the same paper that discovered photoreceptor coupling),⁵ and the HC \rightarrow bipolar cell feed-forward synapses were suggested by anatomical evidence.^{15,37} Injection of hyperpolarizing current into horizontal cells elicits depolarizing responses in cones (Fig. 22.5A-D)⁵ and HBCs and hyperpolarizing responses in DBCs,^{44,47} consistent with the notion that horizontal cells drive the surround responses in these cells. Figure 22.5E shows the depolarizing surround responses in a cone, mediated by the sign-inverting feedback synapse from horizontal cells to the cone.⁶⁵ Three synaptic mechanisms have been proposed for the HC feedback actions on cones. The first is that HCs release an inhibitory neurotransmitter (GABA in several species) in darkness that opens chloride channels in cones, and surround light hyperpolarizes the HCs, suppresses feedback transmitter release, depolarizes the cones, and results in depolarization in HBCs and hyperpolarization in DBCs.^{46,83}

The second mechanism is that surround light hyperpolarizes HCs, resulting in an outward current through hemichannels in their dendrites near the cones, charging the cone membrane and modulating calcium currents in cones, thereby increasing their calcium-dependent glutamate release which depolarizes the HBCs and hyperpolarizes the DBCs.^{28,29}

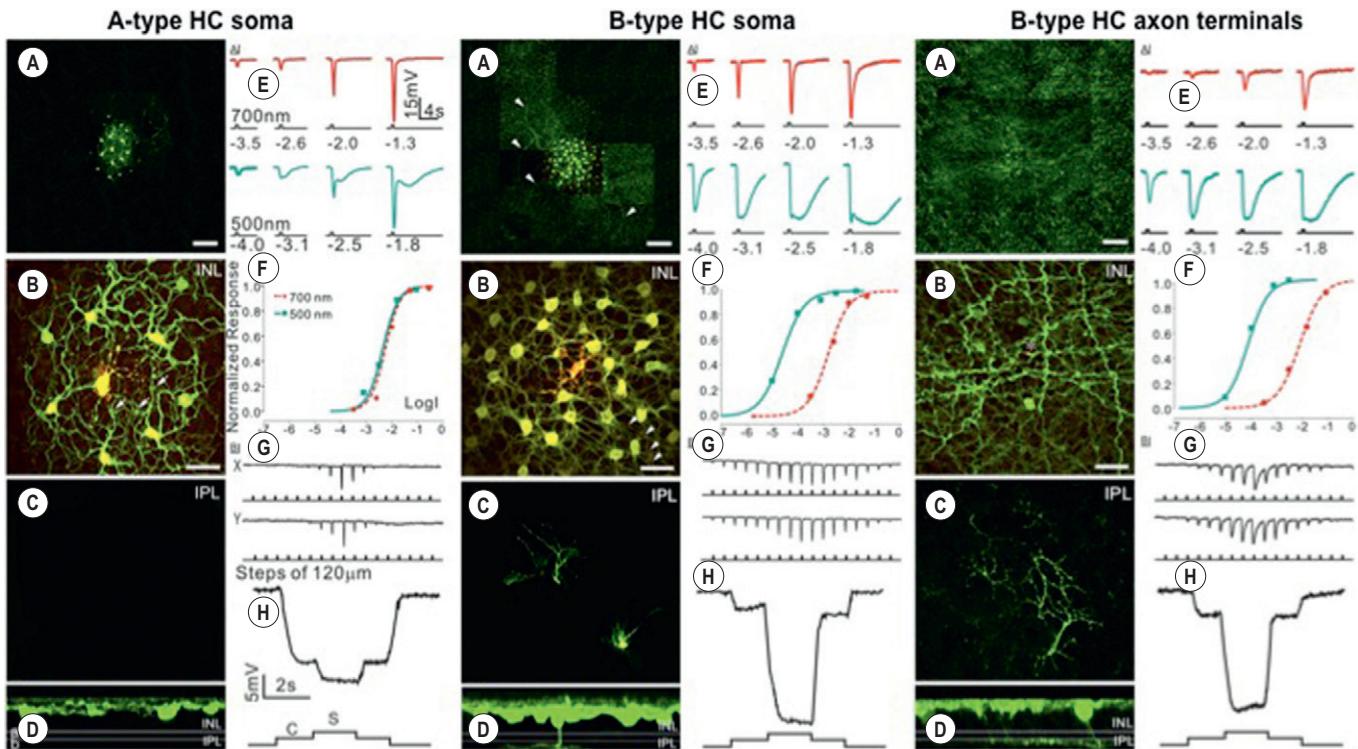

Figure 22.4 Morphology, dye coupling, light responses and receptive field properties of three types of horizontal cells. Confocal fluorescent micrographs (A: low magnification at distal INL, B: high magnification at distal INL, C: at IPL and D: z-axis rotation) stained by injection of Lucifer yellow (red) and neurobiotin (green), voltage responses to 700 nm and 500 nm lights of various intensities (E), the response-intensity relations (F), voltage responses to a stepwise (120- μ m steps) moving light bar (50 μ m wide) in the x- and y-directions (G), and voltage responses to center and surround light stimuli (H) of A-type horizontal cell somas (left panels), B type horizontal cell somas (middle panels) and B type horizontal cell axon terminals (right panels). Scale bar = 200 μ m (A), 50 μ m (B). The spectral difference, ΔS (see definition in Fig. 22.6 legend), was determined by the separation of the two V-Log I curves for a criterion response of 5 mV. (From Zhang et al 2006.⁹³)

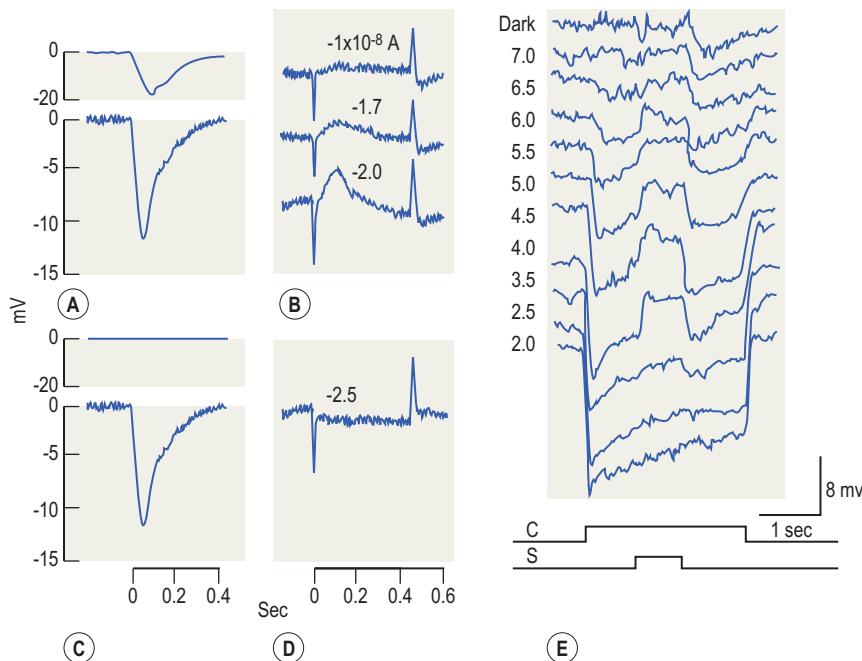

Figure 22.5 Feedback synapse from horizontal cells to cones. (A) Voltage responses of a horizontal cell (H) and a cone (C) to a light flash (600 μ m radius) in the turtle retina. (B) of hyperpolarizing current (-1 to -2×10^{-8} A) in the horizontal cell produced graded depolarization in the cone. (C) light responses after withdrawal of the electrode from the horizontal cell. (D) No depolarization was observed in the cone when hyperpolarizing current was passed through the extracellular electrode (withdrawn from the horizontal cell). (E) Voltage responses of a cone in the tiger salamander retina to a center light spot (300 μ m diameter) of various intensities (numbers on the left indicate log units of light attenuation) and a light annulus (650 μ m inner diameter, 2.5 log unit attenuation). (A–D from Baylor et al 1971,⁵ E from Skrzypek & Werblin 1983.⁶⁵)

The third mechanism is that surround-induced HC hyperpolarization elevates the pH in the HC-cone synaptic cleft, leading to an increase of calcium current in cones and a higher rate of glutamate release which depolarizes the HBCs and hyperpolarizes the DBCs.^{21,75} It is possible that different species under different conditions favor different feedback synaptic mechanisms, and/or different types of HC-cone synapses in the same animal may use one or more of these three HC-cone feedback mechanisms. This idea is supported by a recent study demonstrating that the responses of salamander GCs to dim surround stimuli are sensitive to GABA blockers and those to bright surround stimuli are sensitive to carbenoxolone, a gap junction/hemichannel blocker.²⁷

Properties of the feedforward synapses are less well understood. Results from salamander retina suggest that HC → DBC feedforward synapses may be functional, as application of L-AP4 (which blocks the cone → DBC synapse) converts the DBC depolarizing response to a sustained hyperpolarizing response.^{20,89} However, application of GABA on BC dendrites in Co^{2+} Ringer's does not elicit any response, indicating that if feedforward synapses are chemical, the neurotransmitter is not GABA.⁴² Histochemical evidence suggests that only about 50–60% of the HCs in the salamander retina are GABAergic, and the identity of neurotransmitter(s) in the remaining HCs is unknown (but unlikely to be glycine).^{84,96} Recent studies on the rabbit and salamander retinas have shown that HCs and subpopulations of DBC are dye coupled (see Fig. 22.7 below).^{74,92} This raises the possibility that HC-DBC electrical coupling may mediate the HC-DBC feedforward signal for the DBC surround response.

Rod and cone pathways and bipolar cell output synapses

Rods are responsible for vision under conditions of dim illumination when cones are not responsive. Cones operate under conditions of bright illumination, and they mediate color vision and provide high spatial resolution, features that rods do not handle.⁶¹ In addition to dividing into DBCs and HBCs, BCs are further classified according to their rod/cone inputs. In mammals, rods and cones make synaptic connections with rod and cone BC separately, and one type of rod BC and 9–10 types of cone BCs have been identified.^{7,17} In fish small BCs make synaptic contacts exclusively with cones, and large BCs make contacts with both rods and cones.^{32,70} BCs in amphibian retinas contact both rods and cones, but some are clearly rod-dominated where others are cone-dominated.⁹⁰ Despite these differences between species, BCs in most vertebrate retinas have many common functional and morphological features.

It has been established in many vertebrate species, for example, that axon terminals of DBCs ramify in the proximal half (sublamina B) of the IPL whereas those of the HBCs ramify in the distal half (sublamina A) of the IPL.^{1,52} Axon terminals of rod BCs in mammalian retinas end near the proximal margin of the IPL, and axon terminals of cone BCs ramify in more central regions of the IPL.⁷ This agrees with the patterns of BC axon terminal stratification in the salamander: axon terminals of rod-dominated BCs ramify at the two margins of the IPL whereas those of cone-dominated

BCs ramify at central regions of the IPL.⁸⁶ Additionally, despite the fact that mammalian rod and cone BCs make segregated synaptic contacts with rods and cones, their light responses are somewhat mixed with rod/cone signals like most BCs in lower vertebrates, partially because rods and cones are electrically coupled (see above), and partially because rod BC signals can be transmitted to cone BCs through AII amacrine cells.^{54,56,71} Furthermore, although rod HBCs have not been identified anatomically in mammalian retinas, recent physiological evidence suggests that rod signals may be transmitted by HBC-mediated channels in at least some mammals.^{12,68}

Based on the properties of BCs across vertebrate species, it is reasonable to propose that most vertebrate retinas have 6 major functional types of BCs: the rod (or rod-dominated), cone (or cone-dominated) and mixed (rod/cone) depolarizing and hyperpolarizing bipolar cells (DBC_R , DBC_C , DBC_M , HBC_R , HBC_C and HBC_M). Each carries a characteristic set of light response attributes and projects them to the inner retina through axons that terminate at segregated regions (strata) of the IPL. Such stratum-by-stratum projection of light response attributes is exemplified by a large-scale patch clamp study of the salamander BC responses and morphology (Fig. 22.6).⁵⁷ This study reveals several rules for the function-morphology relationships of retinal bipolar cells:

- (1) Cells with axon terminals in strata 1–5 (sublamina A) are HBCs (generated by outward light-evoked cation currents (ΔI_C)) and those in strata 6–10 (sublamina B) are DBCs (generated by inward ΔI_C). This agrees with the sublamina A/B rule observed in many vertebrate species.
- (2) Cells with axon terminals in strata 1, 2 and 10 are rod-dominated, those in strata 4–8 are cone-dominated, and those in strata 3 and 9 exhibit mixed rod/cone input.
- (3) ΔI_C at light onset in rod-dominated HBCs and DBCs are sustained, that of the cone-dominated HBCs exhibits a smaller sustained outward current followed by a transient inward current at the light offset, and that of the cone-dominated DBCs exhibit a sustained inward current followed by a small transient off outward current.
- (4) ΔI_{Cl} (light-evoked chloride currents) in rod-dominated bipolar cells are sustained ON currents whereas those in cone-dominated bipolar cells are transient ON-OFF currents. ΔI_{Cl} in all BCs are outward, and thus they are synergistic to ΔI_C in HBCs and antagonistic to ΔI_C in DBCs.
- (5) Bipolar cells with axon terminals stratified in multiple strata exhibit combined light response properties of the narrowly monostratified cells in the same strata.
- (6) Bipolar cells with pyramidal branching or globular axons exhibit light response properties very similar to those of narrowly monostratified cells whose axon terminals stratified in the same stratum as the axon terminal endings of the pyramidal branching or globular cells.^{56,57}

Electrical coupling between bipolar cells has been reported in several vertebrate retinas. Electron microscopic studies have revealed that gap junctions are made between bipolar

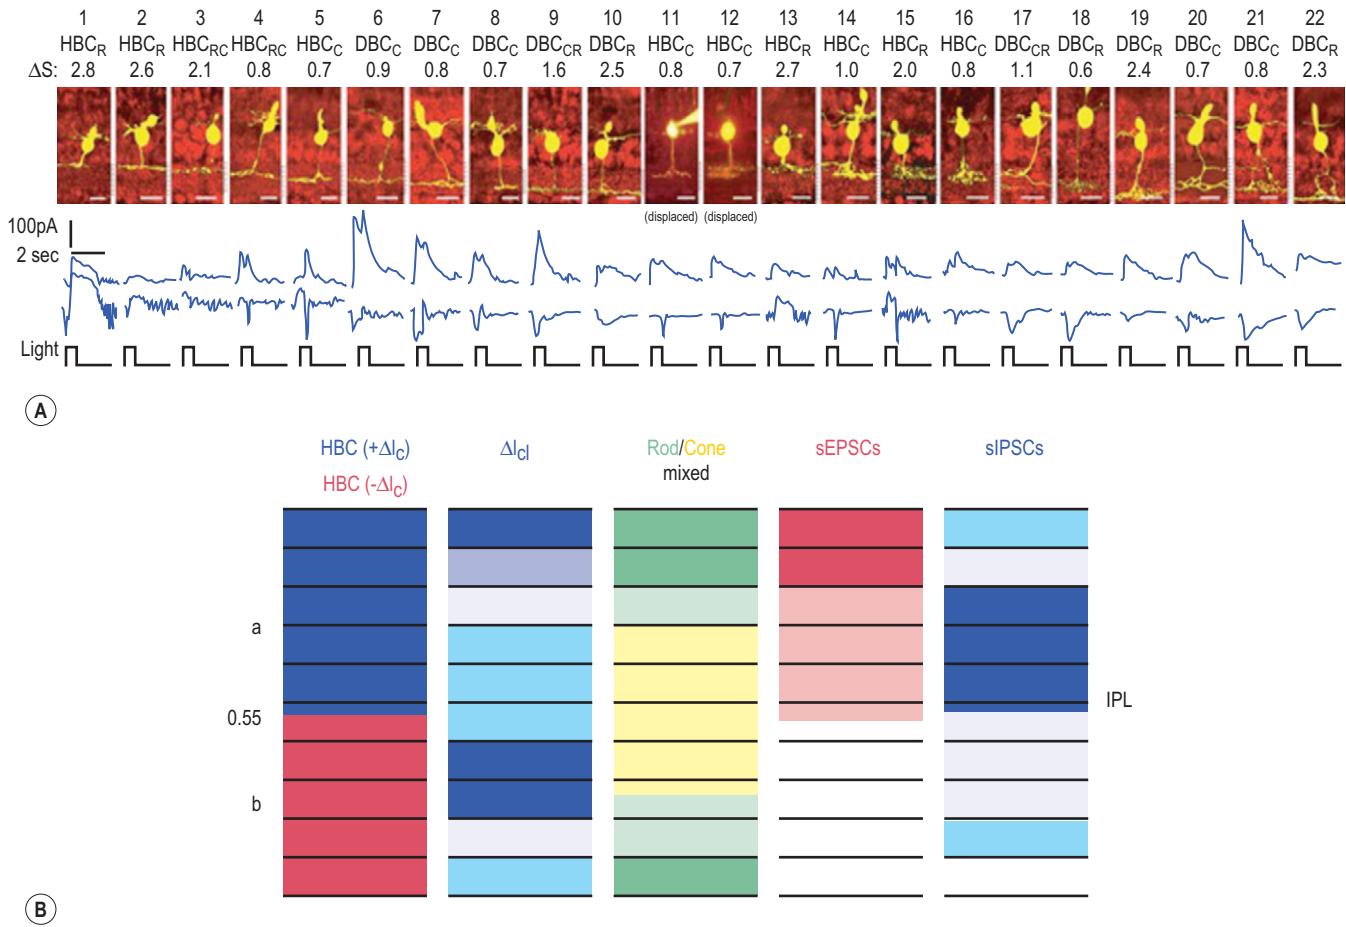

Figure 22.6 Stratum-by-stratum rules for correlating patterns of axon terminal ramification and physiological responses in retinal bipolar cells. (A) 22 morphologically identified (by Lucifer yellow filling) BCs and their light-evoked excitatory cation current (ΔI_c) and inhibitory chloride current (ΔI_{Cl}) recorded from dark-adapted salamander retinal slices. Each cell is named according to their spectral difference (ΔS) and ΔI_c polarity as rod-dominated, cone-dominated, mixed rod/cone hyperpolarizing or depolarizing bipolar cells (HBC_R, HBC_C, HBC_{RC}, DBC_R, DBC_C or DBC_{RC}). BCs with inward ΔI_c are DBCs and with outward ΔI_c are HBCs. The spectral difference, ΔS , is defined as $S_{700} - S_{500}$ (where S_{700} and S_{500} are intensities (in log units) of 700 nm and 500 nm light eliciting responses of the same amplitude). Since ΔS for the salamander rods is about 3.4 and that for the cones is about 0.1, BCs with $\Delta S > 2.0$ are rod-dominated (HBC_R or DBC_R), with $\Delta S < 1.0$ are cone-dominated (HBC_C or DBC_C), and with $1.0 < \Delta S < 2.0$ are mixed rod/cone cells (HBC_{RC} or DBC_{RC}) (also named HBC_M or DBC_M, see Figs 22.7 and 22.8). displaced HBC_C: HBC_Cs with somas displaced in the outer nuclear layer. (Modified from Pang et al 2004;⁵⁶ and Maple et al 1994.⁴¹) (B) Stratum-by-stratum correlation of BC axon terminal ramification in the IPL with physiological function. ΔI_c : light-evoked excitatory cation current, $+ \Delta I_c$: outward ΔI_c , $- \Delta I_c$: inward ΔI_c , ΔI_{Cl} : light-evoked excitatory chloride current, sEPSC: spontaneous excitatory postsynaptic current, sIPSC: spontaneous inhibitory postsynaptic current. More saturated hues indicate stronger response parameters.

cell axon terminals in the inner plexiform layer.^{43,81} Current injection into fish bipolar cells elicits sign-preserving responses in adjacent bipolar cells.³⁶ In the tiger salamander retina, the diameter of the bipolar cell receptive field center is about 10–20 times larger than the diameter of the dendritic arbors of these cells.^{6,19} These results suggest that bipolar cells of the same type are extensively coupled to one another at least in certain species or certain areas of the retina. Recent evidence has shown that bipolar cells of the same types are dye coupled (see Fig. 22.7),⁹² consistent with the notion that bipolar cell receptive field centers are mediated by dendrites from more than one bipolar cell. The primary function of bipolar cell coupling is to increase the receptive field center of these cells. Additionally, bipolar cell coupling also improves the signal-to-noise ratio of the bipolar cell output signals. The disadvantage of bipolar cell coupling, however, is that it reduces the spatial resolution of bipolar cell outputs.

Bipolar cell responses and center-surround antagonistic receptive field (CSARF) organization

Center-surround antagonistic receptive fields (CSARF) are the basic alphabet for encoding spatial information in the visual system.²⁵ CSARF was first discovered by Kuffler in 1953, who demonstrated that light falling on the central region of the receptive field of cat retinal ganglion cells elicited a response of opposite sign as that elicited by light falling on the surround region of the receptive field.³⁵ Later studies showed that such CSARF also exist upstream in retinal bipolar cells⁷⁸ and downstream in cells in the lateral geniculate nucleus and the primary visual cortex.^{24,26} Furthermore, complex receptive fields of neurons in higher visual centers are probably mediated by arrays of upstream neurons that exhibit CSARF organization.

The first neurons along the visual pathway that exhibit ON-center and OFF-center CSARFs are the retinal bipolar cells, first reported by Werblin & Dowling in 1969⁷⁸ and Kaneko in 1970.³⁰ The center input of a bipolar cell is mediated by direct photoreceptor output synapses made on its dendrites (and the dendrites of adjacent bipolar cells electrically coupled). The surround input is mediated by the horizontal cells in the outer plexiform layer and by amacrine cells in the inner plexiform layer.⁷⁶⁻⁷⁸ As mentioned earlier, two major types of bipolar cells are found in all vertebrates, the depolarizing bipolar cells (DBCs) depolarize to central illumination and hyperpolarize to concentric surround illumination (ON-center cells); the hyperpolarizing bipolar cells (HBCs) hyperpolarize to central illumination and depolarize to concentric surround illumination (OFF-center cells). In the mudpuppy and salamander retinas annular illumination does not polarize the bipolar cells unless the centers of their receptive fields are simultaneously illuminated.^{65,78}

The CSARF is also a major vehicle for carrying color information in the visual system. In some species the receptive field of certain bipolar cells and ganglion cells exhibit "double-opponent" organization. For instance, the receptive field center of a bipolar cell is depolarized by red and hyperpolarized by green, while the surround is depolarized by green and hyperpolarized by red.³³ In other species bipolar cells have other color coding configurations that include opponent receptive field centers with non-opponent surround, or vice versa.⁹¹ These types of color-coded CSARF organizations help the visual system to detect stationary and moving color edges.

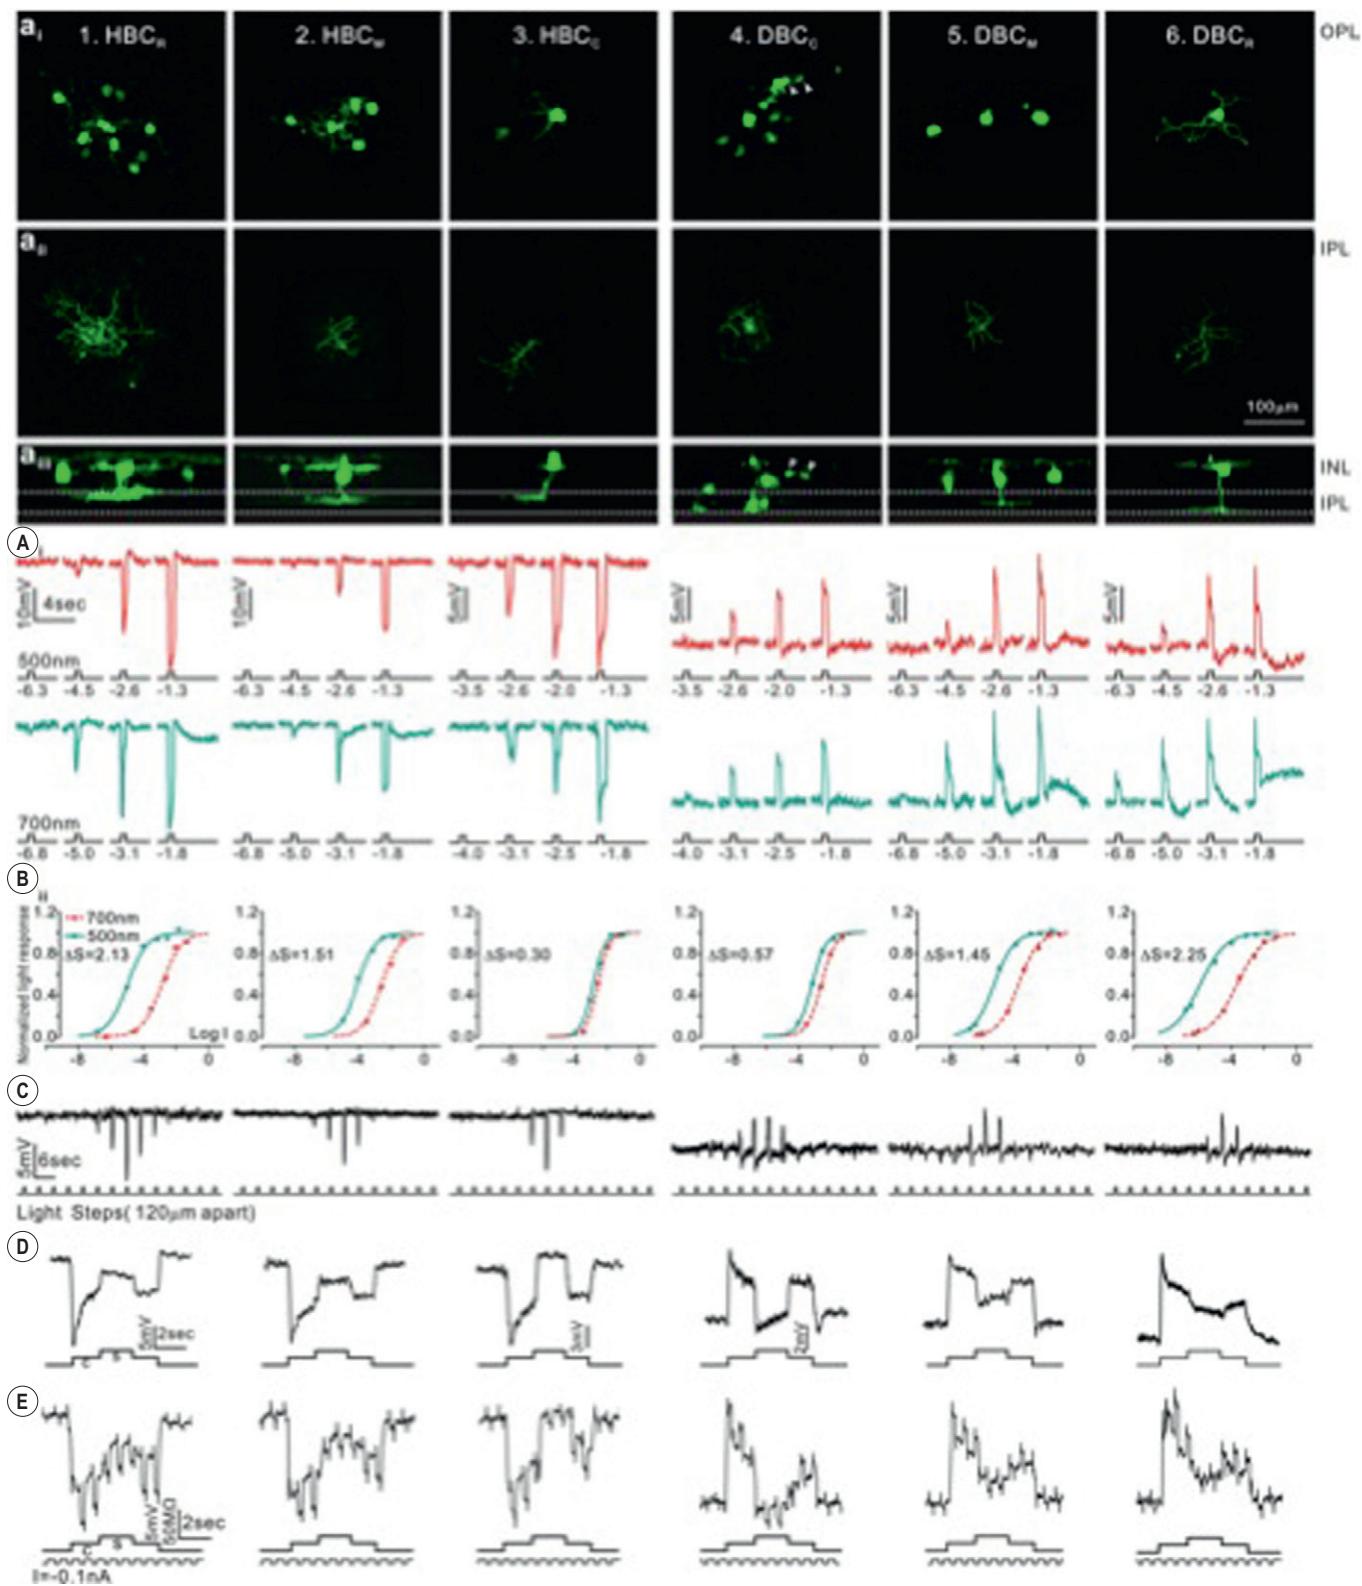

In addition to projecting signals to various strata of the IPL (described in Fig. 22.6), BCs with various light response attributes have different CSARF organizations. Figure 22.7 shows the morphology, patterns of dye coupling, light responses, CSARF properties and membrane resistance changes associated with the center and surround voltage responses of the six functional types of BCs (HBC_R , HBC_M , HBC_C , DBC_C , DBC_M and DBC_R) in the tiger salamander retina.⁹² The BC receptive field center diameters (RFCD) vary with the relative rod/cone input: RFCD is larger in DBCs with stronger cone input, and it is larger in HBCs with stronger rod input. RFCD also correlates with the degree of dye coupling: BCs with larger RFCD are more strongly dye coupled with neighboring cells of the same type, suggesting that BC-BC coupling significantly contributes to the BC receptive field center.

Membrane resistance measurements in Figure 22.7E demonstrate that the center responses of all HBCs are associated with a resistance increase and the center responses of all DBCs are accompanied with a resistance decrease. This is consistent with the notion that glutamate released from rods and cones in darkness opens AMPA/kainate receptor-mediated cation channels in HBCs and closes mGluR6 receptor-mediated cation channels in DBCs. Center light stimuli hyperpolarize rods and cones, suppress glutamate release, and result in a resistance increase (close ion channels) in HBCs and a resistance decrease (open ion channels) in DBCs.

Figure 22.8 is a schematic representation of the possible and unlikely synaptic pathways underlying surround inputs of various types of BCs, based on the surround response polarity and accompanying resistance changes shown in Figure 22.7.⁹² These results suggest that the HC-cone-BC feedback synapses may contribute to the surround responses of all six types of BCs. The negative HC-cone feedback synapses (pathway I in Fig. 22.8) partially "turn off" the center responses by depolarizing the cones, as the membrane resistance changes associated with surround responses of all BCs are opposite to the resistance changes associated with center responses (Fig. 22.6E).

In addition to the common HC-cone-BC feedback pathway, various types of BCs use different HC and AC synaptic pathways to mediate their surround responses. It is unlikely, for example, that HBC surround responses are directly mediated by chemical synaptic inputs from hyperpolarizing lateral neurons such as HCs and AC_{OFF} s because of resistance change mismatch, and thus HBCs may only receive surround inputs from HC-cone-HBC and AC_{ON} -HBC synapses. On the other hand, resistance analysis suggests that DBC surround responses can be mediated by HC-cone-DBC, HC-DBC and AC_{OFF} -DBC chemical synapses, but not the AC_{ON} -DBC synapses. Moreover, dye coupling (Fig. 22.7A) results indicate that DBCs receive additional surround inputs from wide-field HCs through electrical synapses. Despite the heterogeneity, it is interesting to point out that an ON/OFF crossover inhibition rule applies here: cells with OFF (hyperpolarizing) responses (HCs and AC_{OFF} s) mediate surround inhibitory inputs to ON cells (DBCs); and cells with ON (depolarizing) responses (AC_{ON} s) mediate surround inhibitory inputs to OFF cells (HBCs). ON/OFF crossover inhibition from amacrine cells to ganglion cells have been reported in the salamander and mammalian retinas,^{23,58} and the data shown in Figure 22.7 suggest that it

Figure 22.7 Morphology, light responses and receptive fields of six types of bipolar cells in the tiger salamander retina. (A): Fluorescent micrographs of a neurobiotin-filled HBC_R (column 1), a HBC_M (column 2), HBC_C (column 3), a DBC_C (column 4), a DBC_M (column 5), and a DBC_R (column 6) viewed with a confocal microscope at the outer INL/OPL level (ai), the IPL level (aii) and with z-axis rotation (aiii). Calibration bar: 100 μ m. (B) (Bi): BC voltage responses to 500nm and 700nm light steps of various intensities. (Bii): response-intensity (V-Log I) curves of the responses to 500 nm and 700 nm lights. ΔS (spectral difference, defined as $S_{700} - S_{500}$, where S_{700} and S_{500} are intensities of 700 nm and 500 nm light eliciting responses of the same amplitude) of the 6 BCs are 2.13, 1.51, 0.30, 0.57, 1.45 and 2.25. Since ΔS for the rods is about 3.4 and that for the cones is about 0.1 in the salamander retina, BCs with $\Delta S > 2.0$ are rod-dominated BCs, BCs with $\Delta S < 1.0$ are cone-dominated BCs, and BC with $1.0 < \Delta S < 2.0$ are mixed rod/cone BCs. (C): Measurements of BC receptive field center diameters (RFCD) by recording voltage responses to a 100- μ m wide light bar moving stepwise (with 120 μ m step increments) across the receptive field. (D): Voltage responses of the 6 types of BCs elicited by a center light spot (300 μ m) and a surround light annulus (700 μ m inner diameter, 2000 μ m outer diameter). The surround light annulus was of the same intensity (700 nm, -2) for all 6 cells whereas the intensity of the center light spot was adjusted so that it allowed the annulus to produce the maximum response. (E): Voltage responses of the 6 types of BCs elicited by a center light spot and a surround light annulus (same as in D), and by a train of -0.1-nA/200-msec current pulses passed into the cell by the recording microelectrode through a bridge circuit. (From Zhang & Wu 2009.⁹²)

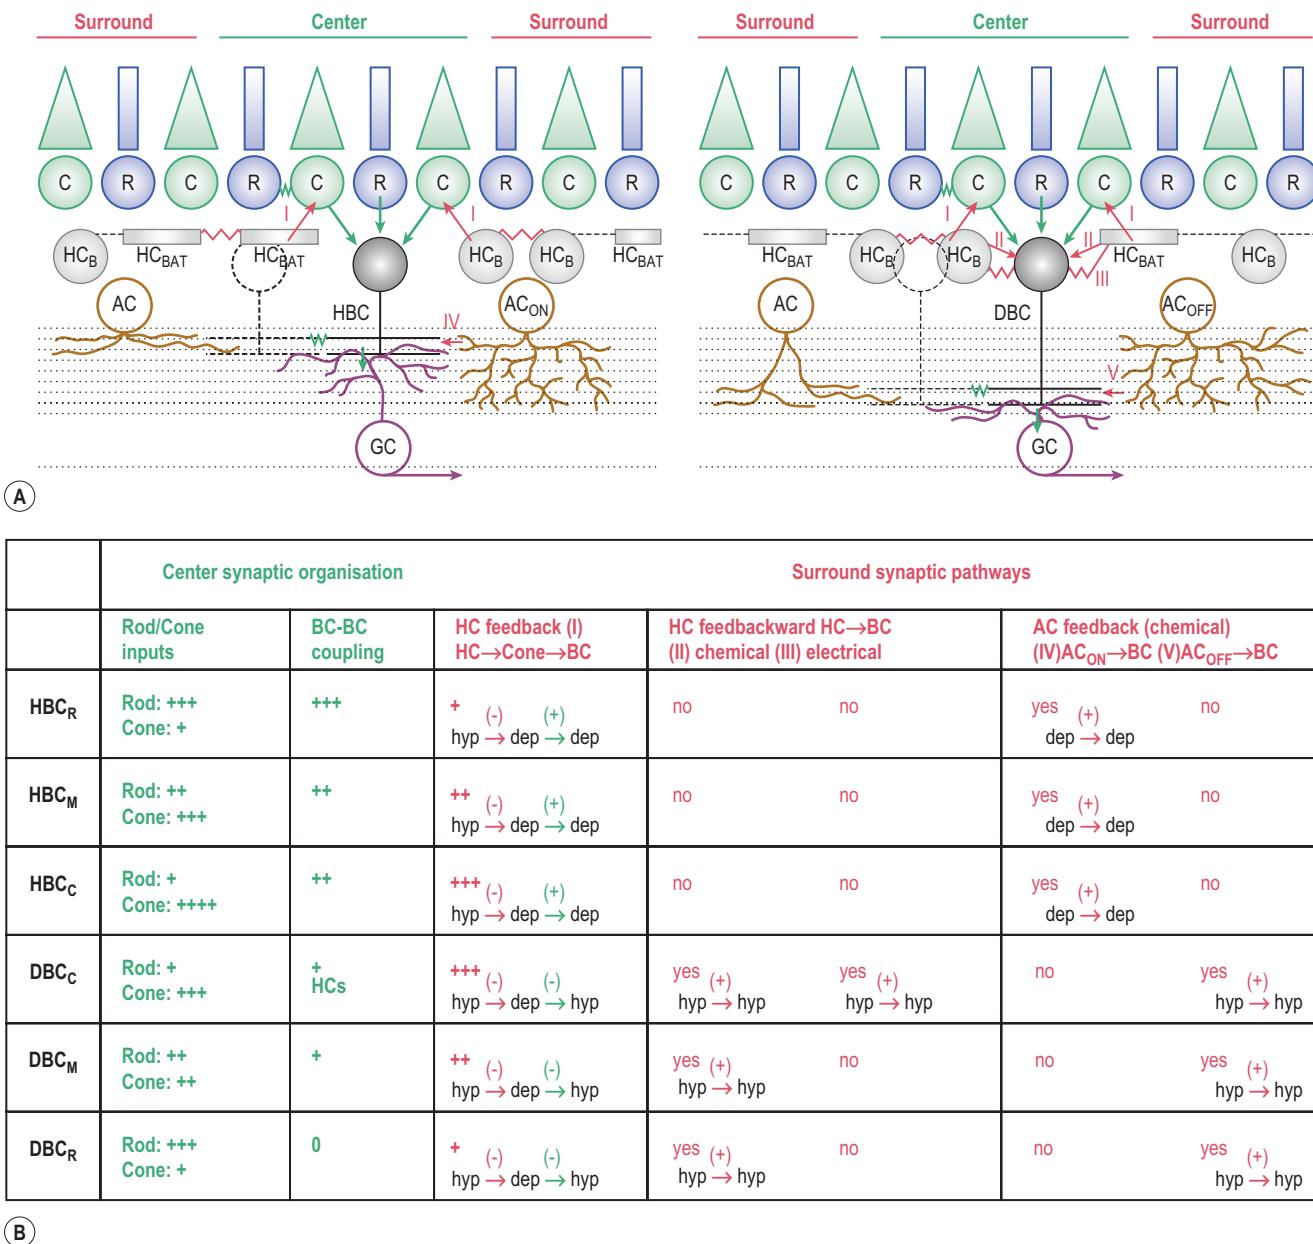

Figure 22.8 Center-surround antagonistic receptive field organization of bipolar cells. (A) Schematic diagrams of center (green) and surround (red) synaptic pathways of HBCs (left) and DBCs (right). R: rod, C: cone, HC_B: B-type HC somas, HC_{BAT}: B-type HC axon terminals, HBC: hyperpolarizing bipolar cell, DBC: depolarizing bipolar cell, AC: amacrine cell, AC_{ON}: ON amacrine cell, AC_{OFF}: OFF amacrine cell, GC: ganglion cell, arrows: chemical synapses, zig-zags: electrical synapses. I-V: five surround synaptic pathways listed in B. (B) Variations in synaptic pathways mediating center (green) and surround (red) responses of the HBC_R, HBC_M, HBC_C, DBC_C, DBC_M and DBC_Rs. +++: strong, ++: intermediate, +: moderate, yes: possible, no: unlikely. For the possible pathways, response polarities (hyp: hyperpolarization, dep: depolarization) in each neuron and the synaptic sign ((+): sign-preserving or (-): sign-inverting) in each synapse in the pathways are indicated [e.g. in the HBC_R HC → cone → BC pathway: (hyperpolarization in HC) via a sign-inverting synapse → (depolarization in cone) via a sign-preserving synapse → (depolarization in BC)]. (From Zhang & Wu 2009.⁹²)

may be a general rule for lateral inhibition in the visual system.

The AC-BC contribution to BC surround responses is mediated by GABAergic or glycinergic synapses, and detailed studies on these synapses are discussed in the next chapter. As illustrated in Figures 22.7 and 22.8, surround responses of different functional types of BCs in the salamander retina are mediated by different combinations of synaptic circuitries: HC → cone → BC (pathway I in Fig. 22.8), HC→BC (chemical/gap junction, pathways II and III in Fig. 22.8) and

AC→BC (GABA/glycine, pathways IV and V in Fig. 22.8). It is conceivable that the surround responses of different BCs/GCs from different animals under different conditions are mediated by different combinations of surround synaptic pathways, and thus they are sensitive to different synaptic blockers. The wide variation of synaptic circuitries underlying surround responses of various functional types of BCs allows for flexibility in function-specific modulation of BC/GC receptive fields. Hence different features of spatial and contrast information, such as rod/cone and ON/OFF signals,

can be differentially modulated by different lighting and adaptation conditions.

Signal Processing in the Inner Retina

Peter D. Lukasiewicz & Erika D. Eggers

The inner plexiform layer (IPL) is the second synaptic layer of the retina (Fig. 23.1) and the final stage for processing visual information before it leaves the eye. Visual signals from rod and cone photoreceptors are first processed in the outer plexiform layer (OPL; Fig. 23.1), where horizontal cells modulate their signaling to bipolar cells. Bipolar cells then transmit these signals to the inner plexiform layer (IPL), where amacrine cells shape bipolar cells signaling to ganglion cells. The visual signals are first separated into separate signaling streams at the bipolar cells. Distinct classes of bipolar cells form parallel pathways that convey information about different aspects of the visual world. Synaptic connections between bipolar cells, amacrine cells and ganglion cells in the IPL produce complex processing of the visual signals. These synaptic interactions in the IPL process spatial, motion, and directional information within the visual scene. The outputs of the IPL are transmitted to distinct ganglion cell types that convey visual signals to different brain regions.

Bipolar cells form parallel pathways and provide excitatory input to the IPL

A variety of bipolar cell types form parallel signaling pathways that relay the processed photoreceptor output to the IPL. Excitatory inputs to the IPL originate from ON bipolar cells and OFF bipolar cells that depolarize in response to increasing or decreasing illumination within their receptive field centers, respectively. These distinct responses are determined by separate classes of dendritic glutamate receptors.^{1,2} ON and OFF bipolar cells respond with opposite polarities because, in darkness, glutamate release from photoreceptors hyperpolarizes ON bipolar cells by activating mGluR6Rs that close cation channels and depolarizes OFF bipolar cells by activating AMPA/KA receptors that open cation channels. The axon terminals of ON and OFF bipolar cells stratify in two distinct sublaminae of the IPL, contacting the dendrites of ON and OFF ganglion cells and amacrine cells. The outer half of the IPL encodes responses to light OFF and the inner half encodes responses to light ON.^{3,4} The ON and OFF sublaminae are further divided into ten bipolar cell types that have axon terminals in different morphological strata (Fig. 23.2), encoding different aspects of the visual scene.⁵

An additional major functional subdivision of both the ON and OFF sublaminae is a stratification of the processes of temporally distinct responses.^{5–7} Retinal neurons generate either transient or sustained responses to continuous visual stimulation that encode the temporal and spatial features of the visual scene, respectively. A transient response can signal the offset and/or onset of a light stimulus, while a sustained response can signal the duration of the light stimulus. Similar to the ON and OFF response separation, sustained and transient responsiveness is first observed at the bipolar cells. Transient and sustained ON and OFF signals recorded in bipolar cells have been attributed to variations in the types of mGluR6 and AMPA/KARs expressed on ON and OFF bipolar cell dendrites, respectively.^{2,6} Transient bipolar cell terminals contact transient amacrine cell and ganglion cell processes in the mid IPL and sustained bipolar cell terminals contact the sustained amacrine cell and ganglion cell processes near the inner and outer margins of the IPL.^{6,8}

These functional divisions in the IPL illustrate a common organizational property of the retina. Distinct retinal neuron types have different morphological classifications. The morphology of retinal neurons determines their functional properties by constraining the IPL strata at which they receive inputs and make outputs. Because neuron morphology is so tightly correlated with neuron physiology in the retina, many studies make use of the morphological properties to help elucidate neuronal function. However, the organization of the IPL may be disrupted by degenerative photoreceptor diseases (Box 23.1).

Synaptic mechanisms shape excitatory signals in the IPL

When ON and OFF bipolar cells are depolarized by increments or decrements of illumination, respectively, they release glutamate, which excites ganglion cells and amacrine cells. Bipolar cells do not spike or fire action potentials, but instead use slow-graded depolarizations to signal.^{9,10} Their transmitter release machinery is optimized for sustained glutamate release (Fig. 23.3A). L-type calcium channels in bipolar cell terminals mediate a sustained calcium influx

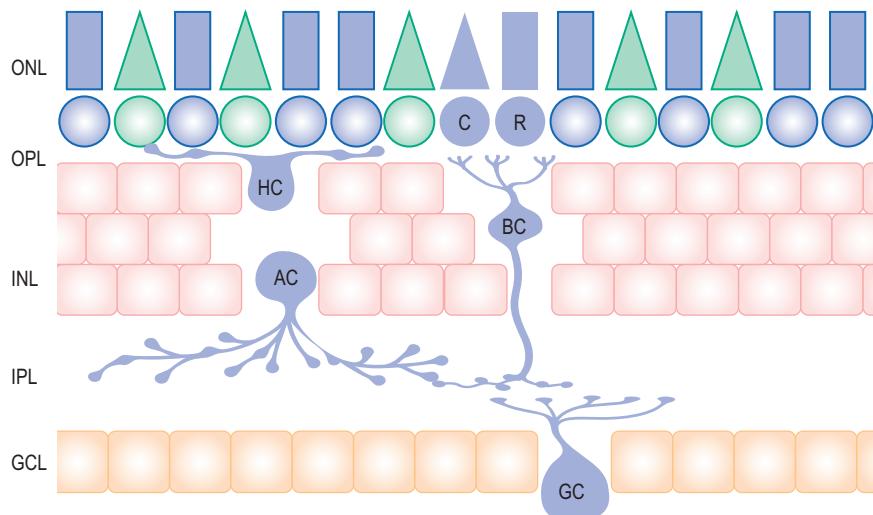

Figure 23.1 Schematic cross-sectional view of retinal layers, showing the vertical and lateral signaling pathways. Vertical signaling pathways are composed of photoreceptors, bipolar cells and ganglion cells. Two lateral pathways, comprised of horizontal cells in the OPL and amacrine cells in the IPL, modulate the flow of information along the vertical pathway. The somata of neurons are located in three cellular layers. Rod (R) and cone (C) photoreceptor somas are located in the outer nuclear layer (ONL); horizontal cell (HC), bipolar cell (BC) and amacrine cell (AC) somas are located in the inner nuclear layer (INL); ganglion cell somas are located in the ganglion cell layer (GCL). Synaptic connections occur in two layers. Synapses between photoreceptors, bipolar cells and horizontal cells are made in the outer plexiform layer (OPL). Synapses between bipolar cells, amacrine cells and ganglion cells are made in the inner plexiform layer (IPL).

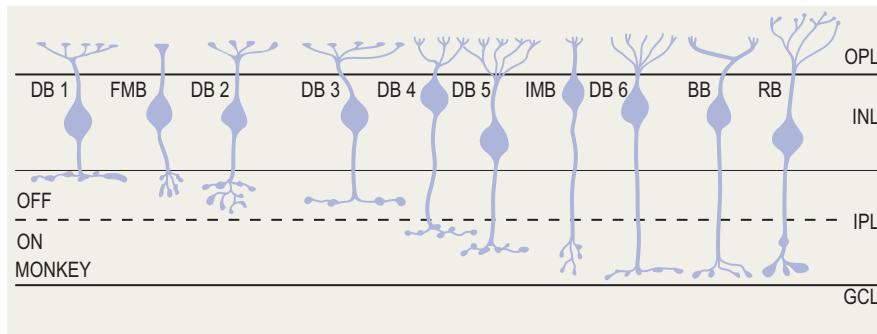

Figure 23.2 Bipolar cells form parallel retinal signaling pathways. Vertical view drawings of Golgi stained bipolar cells from macaque monkey retina illustrate distinct morphological subtypes. The axon terminals stratify at different depths of the IPL. ON bipolar cells have axons that terminate in the inner half of the IPL (ON sublamina) and OFF bipolar cells have axons that terminate in the outer half of the IPL (OFF sublamina). Rod bipolar cell (RB) dendrites exclusively contact rods. The remaining cone bipolar cells (CB) only contact cones. The OFF (FMB) and ON (IMB) midget bipolar cells and the blue bipolar cell (BB) transmit color information. (Reprinted from Ghosh KK, Bujan S, Haverkamp S, Feigenspan A, Wässle H. Types of bipolar cells in the mouse retina. J Comp Neurol 2004; 469:70–82; with permission from Wiley-Blackwell.)

Box 23.1 Degenerative Photoreceptor Diseases Disrupt the Organization of the Inner Plexiform Layer

Many retinal diseases, such as macular degeneration and retinitis pigmentosa, result in the degeneration of photoreceptors. It was long thought that the inner retina was spared in photoreceptor degeneration. Recent studies^{71,72} show that this is clearly not accurate. The inner nuclear layer and IPL of animal models of photoreceptor degeneration show aberrant organization and the formation of inappropriate synaptic contacts, strongly suggesting that the elimination of photoreceptors providing the sensory input to inner retina leads to the profound disorganization of the inner retina. This large-scale structural and presumably functional reorganization of the inner retina points out that caution must be exercised when using approaches to restore vision with photoreceptor transplantation or prosthetic devices.

because they do not desensitize to prolonged depolarization, unlike other subtypes of calcium channels found at conventional CNS synapses. Similar to photoreceptor and hair cell synapses, bipolar cells possess specialized ribbons that are located at release zones, containing large numbers

of tethered, glutamate-filled vesicles that mediate sustained signaling.

The excitatory output of each bipolar cell class is shaped by both pre- and postsynaptic processes (Fig. 23.3B). Response termination at bipolar cell to ganglion cell synapses^{11,12} is attributed to the clearance of glutamate by presynaptic transporters, which limit the amplitude and time course of ganglion cell excitation.¹¹ Blocking glutamate transporters, located in the IPL, increased the amplitude and duration of the excitatory signal from bipolar cells to ganglion cells.^{11,12} This role of transporters is unique to the retina^{11–13} and some other specialized synapses in other parts of the CNS.^{14–16} Elsewhere in the CNS, responses are typically terminated by either the chemical degradation of transmitter or rapid diffusion of transmitter from the synapse.^{17,18} Glutamate transporters may regulate excitatory responses in ganglion cells by limiting signaling attributable to glutamate spillover. Spillover signaling results from released glutamate activating postsynaptic receptors that are distant from the release sites.

Glutamate transporters may affect signaling in the IPL in several ways. Transporters may improve the temporal response properties of some classes of ganglion cells by

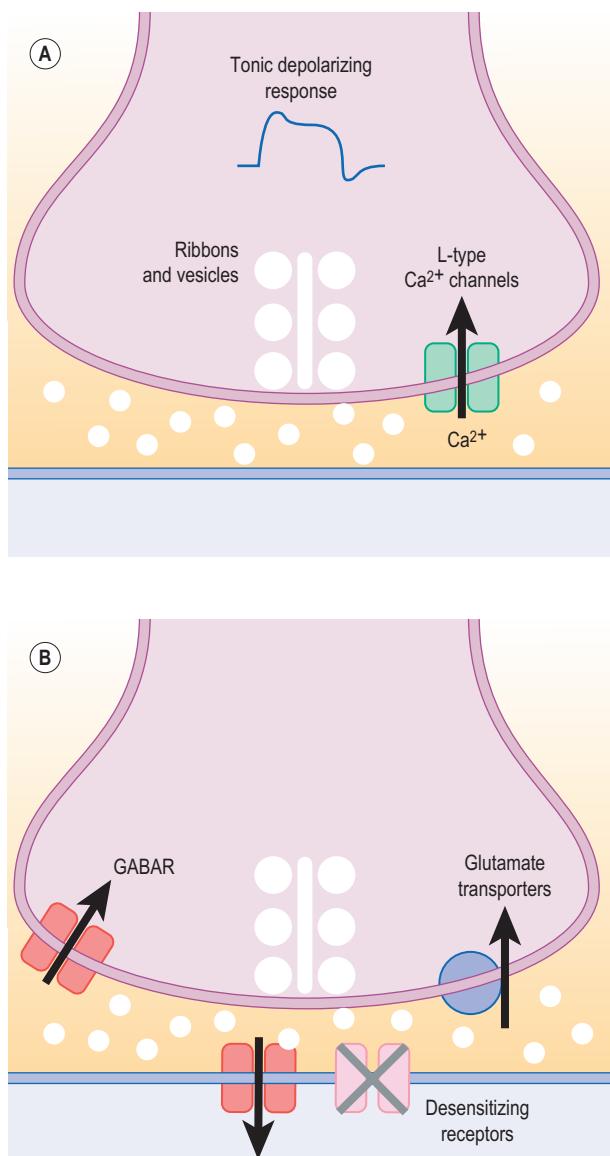

Figure 23.3 (A) Schematic of a bipolar cell terminal showing the processes that contribute to sustained glutamate release. Sustained, graded depolarizations, prolonged calcium influx through L-type calcium channels and a large pool of ribbon-associated vesicles contribute to tonic glutamate release. (B) Schematic illustrating the synaptic mechanisms that shape excitatory signaling from bipolar cells to ganglion cells. Transporters remove glutamate from the synapse, limiting excitatory signaling. Desensitizing glutamate receptors (X) attenuate responses to sustained glutamate release. Glutamate release may be reduced by the activation of presynaptic GABA_A and GABA_C receptors.

speeding the decay of ganglion cell light responses. Another possible role of transporters in the IPL is to limit crosstalk between different sublaminae in the IPL to preserve the functional segregation of distinct layers.^{5,7} The findings that glutamate transporters regulate the spillover activation of glutamate receptors^{11,19,20} suggests that a potential site for controlling IPL signaling is the regulation of glutamate transporters, which control the excitatory signal to ganglion cells.

The desensitizing AMPA receptor (AMPAR), a subtype of postsynaptic glutamate receptor on ganglion cell dendrites,

also shapes ganglion cell responses to glutamate released from bipolar cells. Reducing AMPAR desensitization enhances excitatory light responses in ganglion cells, suggesting that AMPAR desensitization shapes ganglion cell responses.^{11,21} Additionally, glutamate and protons that are released from bipolar cells can restrict glutamate release.^{22–24} Both glutamate and protons are contained in synaptic vesicles and act presynaptically upon metabotropic glutamate receptors and calcium channels, respectively, on bipolar cell terminals to reduce vesicular release.

Amacrine cells mediate inhibition in the IPL

Excitatory signaling in the IPL is also controlled by inhibitory amacrine cell inputs. Amacrine cells receive excitation from bipolar cells and mediate inhibition in the IPL by releasing either GABA or glycine onto ganglion cell dendrites, bipolar cell axon terminals and other amacrine cells (Fig. 23.4). Approximately 50 percent of amacrine cells are GABAergic and 50 percent are glycinergic. Ganglion cells receive mainly amacrine cell input,²⁵ underscoring the importance of inhibition in shaping the retinal output. Bipolar cell terminals are inhibited by presynaptic amacrine cell inputs, limiting excitatory signaling. Amacrine cells also inhibit other amacrine cells, resulting in serial, inhibitory synaptic interactions^{26–28} that shape the timing and spatial sensitivity of inhibition. Using ERG recordings, some of the synaptic processing in the IPL can be assessed non-invasively (Box 23.2).

Presynaptic GABAergic inhibition occurs at the terminals of all classes of bipolar cells and is mediated by GABA receptors (GABARs).^{29,30} The retina is unique because it possesses two types of ionotropic GABA receptors, the GABA_A and GABA_C receptors. Both receptor subtypes gate chloride channels, but they are composed of distinct molecular subunits, have distinct pharmacological profiles and have different biophysical properties. GABA_C receptors are more sensitive to GABA than GABA_A receptors and as a result have much slower activation and decay kinetics in response to GABA application compared to GABA_ARs. These distinct receptor properties shape GABA-mediated synaptic responses in bipolar cells. GABA_AR-mediated light-evoked inhibitory postsynaptic currents (L-IPSCs) rise and decay rapidly and determine the rise time and peak amplitude of bipolar cell inhibition³¹ (Fig. 23.5B). In contrast, GABA_CR-mediated L-IPSCs rise and decay slowly and determine the duration of bipolar cell inhibition (Fig. 23.5B). These two forms of presynaptic inhibition distinctly limit bipolar cell outputs. Slow GABA_CRs limit the extent of glutamate release and the duration of excitatory responses in amacrine and ganglion cells, while fast GABA_ARs limit the initial glutamate release and the initial postsynaptic excitatory responses, as detailed below.

In different bipolar cell classes, the L-IPSC time course depended on distinct contributions of GABA_ARs and GABA_CRs. GABAergic L-IPSCs in rod bipolar cells decay slowly because they are dominated by GABA_CRs, while in OFF cone bipolar cells L-IPSCs decayed rapidly, reflecting a larger GABA_AR contribution (Fig. 23.5C). These different

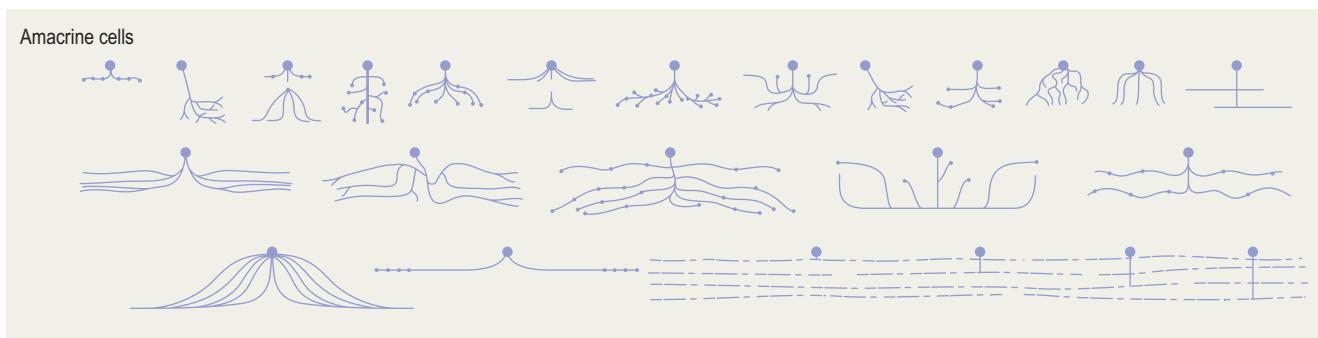

Figure 23.4 The major types of amacrine cells in mammalian retina. Amacrine cells comprise the most diverse class of retinal neurons. This illustrates amacrine cells that were morphologically identified in rabbit retina. Narrow field amacrine cells are shown in the top row and wide field amacrine cells are shown in the lower two rows. (Adapted from Masland RH. Neuronal diversity in the retina. *Curr Opin Neurobiol* 2001; 11:431–436; with permission from Elsevier. Copyright Elsevier 2001.)

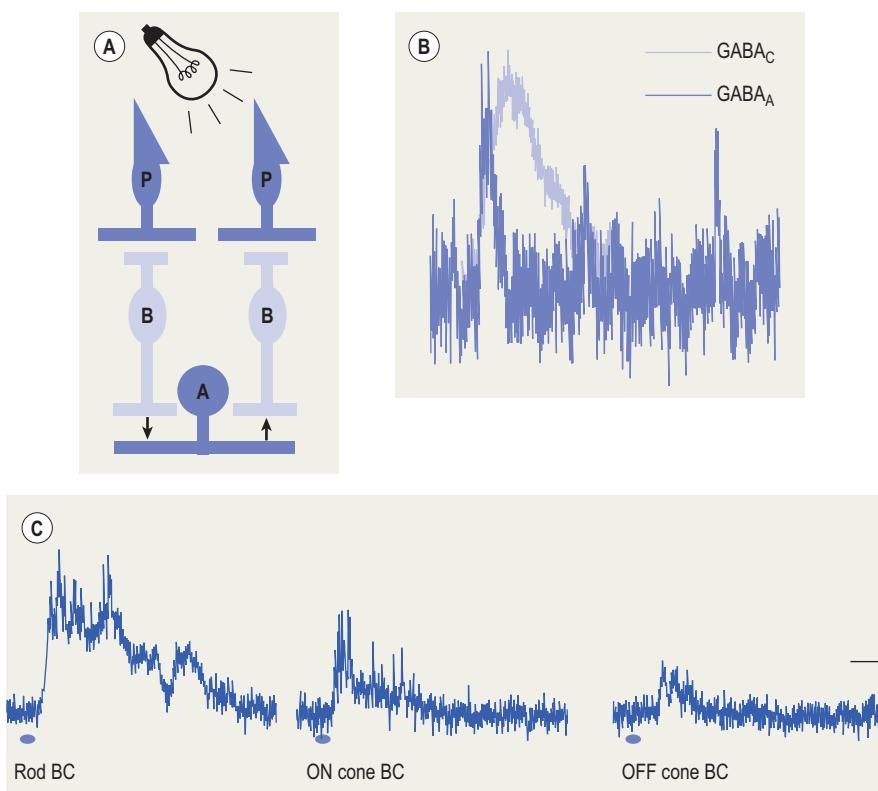

Figure 23.5 GABA_A and GABA_C receptors shape light-evoked inhibition at bipolar cell axon terminals. (A) Diagram illustrating light stimulation and recording procedures for measuring GABAergic L-IPSCs in bipolar cells. **(B)** Pharmacologically isolated GABA_A - and GABA_C -receptor-mediated L-IPSCs recorded from a bipolar cell, scaled to the same peak amplitude to compare response kinetics. The GABA_A -receptor-mediated L-IPSC exhibited fast rise and decay times, while the GABA_C -receptor-mediated L-IPSC exhibited slow rise and decay times. GABA-mediated L-IPSCs were isolated by pharmacologically blocking glycine receptors. The scale bar is 200 ms. (Reprinted with permission from Eggers ED, Lukasiewicz PD. Receptor and transmitter release properties set the time course of retinal inhibition. *J Neurosci* 2006; 26:9413–25.) **(C)** A gradient of GABA_C -receptor-mediated inputs differently shape bipolar cell responses. GABAergic L-IPSCs (isolated with glycine antagonist strychnine) were recorded from the bipolar cell classes. Rod bipolar cells had a large slow L-IPSC, consistent with large GABA_C receptor-mediated input. ON cone bipolar cells had a faster L-IPSC and less GABA_C receptor input. OFF cone bipolar cells had an even faster GABAergic L-IPSC and primarily fast GABA_A receptor input. The scale bar is 5 pA and 200 ms. (Reprinted with permission from Eggers ED, McCall MA, Lukasiewicz PD. Presynaptic inhibition differentially shapes transmission in distinct circuits in the mouse retina. *J Physiol* 2007; 582:569–82.)

Box 23.2 Assessing IPL Function using ERGs

ERG recordings are routinely used clinically and in the laboratory for assessing photoreceptor and bipolar cell function. Retinal function attributed to synaptic interactions in the IPL can also be assessed with ERG recordings (see Chapter 24 for details). Oscillatory potentials (OPs) that are superimposed on the ERG B-wave (attributed to ON bipolar cell responses) reflect synaptic activity in the IPL.⁷³ Photopic negative responses and scotopic negative responses, ERG response components observed when cone and rod pathways, respectively, are activated, are thought to reflect ganglion cell responses to light-elicited inputs.⁷⁴ These more subtle components of the ERG may be helpful in assessing IPL function in the healthy and diseased retina.

contributions influence bipolar cell outputs. Removing $\text{GABA}_\text{C}\text{R}$ -mediated presynaptic inhibition in bipolar cells enhances ON, but not OFF pathway signaling in the IPL,¹⁹ suggesting that presynaptic inhibition is asymmetric (Fig. 23.6). Different complements of $\text{GABA}_\text{A}\text{Rs}$ and $\text{GABA}_\text{C}\text{Rs}$ appear to match the time course of inhibition with the time course of rod and cone photoreceptor input to different bipolar cells.³²

There are two forms of presynaptic inhibition of bipolar cell terminals by amacrine cells. Local presynaptic or feedback inhibition shapes the time course³³ and extent of glutamate release.¹⁹ Lateral inhibition, mediated by long-distance presynaptic inhibitory signaling, contributes to the antagonistic receptive field surround of ganglion cells.^{34–36}

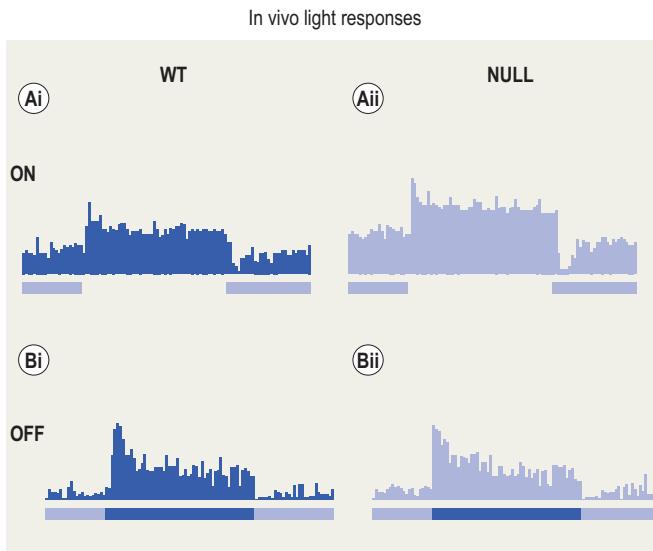

Figure 23.6 Asymmetric presynaptic inhibition differentially affects ON and OFF pathway signaling. Peristimulus time histograms (PSTHs) illustrating spontaneous and light-evoked firing in WT (Ai) and GABA_CR null (Null) (Aii) ON-center ganglion cells (GCs); and WT (Bi) and Null (Bii) OFF GCs. The lower traces in (A) and (B) indicate the duration of the stimuli, a bright, centered spot for ON GCs and a dark, centered spot for OFF GCs, presented on an adapting background. Spontaneous and light-evoked firing rates were significantly increased only in ON GCs in Null mice, compared to WT mice. No difference in spontaneous or light-evoked firing rates was seen between the WT and Null OFF GCs. (Modified from Sagdullaev BT, McCall MA, Lukasiewicz PD. Presynaptic inhibition modulates spillover, creating distinct dynamic response ranges of sensory output. *Neuron* 2006; 50:923–35; with permission from Elsevier. Copyright Elsevier 2006.)

GABAergic feedback inhibition changes the timecourse of bipolar cell signaling

GABA receptors on bipolar cell axon terminals mediate inhibitory feedback from amacrine cells that reduces and shortens bipolar cell transmitter release.³³ In the mouse, these distinct GABA receptors temporally tune inhibitory input to bipolar cells.²⁸ Recordings of light-evoked inhibitory inputs from rod bipolar cells show that slowly responding GABA_C receptors prolong the response decay (Fig. 23.5B) and rapidly activating and decaying GABA_A receptors (Fig. 23.5B) determine the rise time and peak amplitude of the response.³¹ Because bipolar cell light-evoked excitatory responses are slow, GABA_C receptors are thought to be better suited than GABA_A receptors for mediating inhibitory feedback signals. Consistent with this, feedback inhibition to salamander bipolar cells^{33,37} is more sensitive to GABA_C receptor blockade than GABA_A receptor blockade.

The GABA_C receptor-mediated feedback inhibition of bipolar cell release also determines the nature of the excitatory signal to amacrine and ganglion cells.^{19,38} When feedback to bipolar cell terminals is reduced with GABA_C receptor blockers, glutamate release is increased and the NMDA receptor-mediated component of the ganglion cell light responses are enhanced, attributable to the spillover activation of NMDA receptors.^{19,38} So GABA_C receptor-mediated

feedback can control the excitatory ganglion cell response to light by limiting the spillover activation of NMDA receptors.

Both ON and OFF bipolar cells receive presynaptic input at their axon terminals from amacrine cells, suggesting that signaling to ON and OFF ganglion cells is shaped by presynaptic inhibition. However, presynaptic inhibition differentially shapes ON and OFF pathway signaling in the IPL.¹⁹ When GABA_C receptor-mediated presynaptic inhibition was eliminated, ON, but not OFF, ganglion cell responses were augmented, consistent with asymmetric presynaptic inhibition (Fig. 23.6). Electrophysiological measurements showed that presynaptic inhibition alters the response range in ON ganglion cells by limiting glutamate release from ON, but not OFF bipolar cells.

GABAergic inputs to the bipolar cell axon terminals contribute to surround signaling in the retina

While the receptive field surround of ganglion cells is often attributed to lateral interactions in the outer retina,^{39,40} subsequent work demonstrated that inhibitory pathways in the IPL also contribute to surround inhibition measured in amacrine and ganglion cells.^{34,35,41,42} Recordings from amacrine and ganglion cells suggest that GABA_A and GABA_C receptors on bipolar cell terminals, and GABA_A receptors on the dendrites of third-order cells, mediate surround signaling.^{35,41,43} The details of the lateral inhibitory signals that modulate distinct bipolar cell signaling pathways are starting to emerge. Since each bipolar cell class has different proportions of GABA_A and GABA_C receptors, lateral, inhibitory signaling for different bipolar cell pathways may vary.^{30,32}

We do not know the relative roles of lateral inhibition feeding back to bipolar cell terminals versus lateral inhibition feeding forward onto third-order neuron dendrites. Experiments in salamander retina show that dim surround illumination activated GABA_C receptors on bipolar terminals, but did not activate GABA_A receptors on ganglion cell dendrites. GABA_A receptor-mediated IPSCs were recorded in ganglion cells, but only in response to bright surround illumination.³⁶ These differences may be attributable to either the different complements of GABA receptors on bipolar and ganglion cells, or different inhibitory pathways contacting the two cell types.

The contributions of the inner and outer retina to ganglion cell receptive field surround organization

Although there is evidence for lateral inhibition in both the OPL and the IPL, the relative roles of these two pathways in the formation of the ganglion cell surround are not known. The roles of these inner and outer retinal pathways were investigated by measuring the effects of surround illumination on ganglion cell responses after either IPL or OPL signaling was blocked.³⁶ Dim surround illumination reduced the ganglion cell response to center illumination. The dim surround effect was diminished upon GABA_C receptor

blockade, consistent with an IPL signaling role. Brighter surround illumination further reduced ganglion cell center responses, but this effect was insensitive to GABA or glycine receptor blockade, suggesting that it was not mediated by the inner retina. Carbenoxolone or HEPES, both of which decrease horizontal cell feedback to cones,^{44,45} reduced the bright surround effects,^{36,46,47} suggesting they were mediated in the OPL. Thus lateral, inhibitory pathways in the OPL and IPL may affect ganglion cell responses to center illumination in different ways. The effects of bright surround illumination were mediated by horizontal cells in the outer retina, while the effects of dim surround illumination were mediated by GABAergic amacrine cells in the inner retina.

Glycinergic inhibition plays several different roles in the IPL

Presynaptic glycinergic inhibition has different roles than GABAergic inhibition. Rod and OFF cone (but not ON cone) bipolar cells receive input from glycinergic amacrine cells.^{28,32} Glycine signaling plays a prominent role in the rod signaling pathway. In mammals, rod signals flow to ganglion cells by a unique pathway, consisting of rod bipolar cells and AII amacrine cells that both depolarize in response to light. AII amacrine cells then split the rod signal into the ON and OFF pathways within the IPL by contacting ON and OFF bipolar cell terminals via electrical and inhibitory chemical synapses, respectively. Slow rod signals are transmitted to OFF bipolar cell terminals by AII amacrine cells, which in turn contact OFF ganglion cells that send rod signals to the brain. Light-evoked presynaptic inhibition is slow and mediated by glycine, matching the time course of rod signaling. In contrast to GABAergic inhibition, the slow time course of glycinergic inhibition is determined primarily by transmitter release and not receptor properties.⁴⁸

The two inhibitory transmitters GABA and glycine are utilized in the IPL in distinct signaling pathways. In mammalian retina, GABAergic amacrine cells have wide field processes, signal laterally and are confined to the same sublaminae,⁴⁹ where they play a critical role in the processing of spatial information and contribute to the receptive field surround of ganglion cells.^{34,35} Wide field GABAergic amacrine cells synapse onto bipolar cell terminals and ganglion cell dendrites to form two IPL surround signaling pathways. In contrast to wide field GABAergic amacrine cells, glycinergic amacrine cells have narrow field processes that extend vertically within the IPL, mediating signaling between different sublaminae.⁵⁰ Glycinergic inhibition, which is reduced by light, acts in a push–pull manner with increased bipolar cell excitation to enhance light responses in amacrine, bipolar and ganglion cells.^{51–53}

Neuromodulators in the IPL

In addition to inhibitory synaptic transmission that shapes signaling in the IPL, neuromodulators are also prevalent in the retina that shape inner retinal signaling. Dopamine, the best-studied neuromodulator in the retina, is found in a small subset of amacrine cells (reviewed by Witkovsky⁵⁴). Although the population of dopaminergic amacrine cells is

small in number, their processes tile or cover the entire retina. GABA is co-localized with dopamine in this class of amacrine cells. Dopamine can act as a paracrine substance that is released into the extracellular space, affecting both local and distant targets. Dopamine is a mediator of light adaptation in the retina that acts in both the inner and outer retina. Dopamine reduces signaling through rod pathways and enhances signaling through cone pathways. At the IPL, dopamine reduces rod-mediated signaling by uncoupling the electrical synapses between AII amacrine cells. Dopamine may also modulate fast synaptic signaling by GABA_A and GABA_C receptors in the IPL.

Numerous neuroactive peptides are localized to specific populations of amacrine cells with immunocytochemistry.⁵⁵ Throughout the CNS, neuropeptides modulate the actions of fast excitatory and inhibitory transmitters or the activity of voltage-gated channels. The precise mechanisms by which neuropeptides modify visual information processing in the retina remain unknown. Different amacrine cells contain neuroactive peptides, such as neuropeptide Y, somatostatin, vasoactive intestinal polypeptide and enkephalins. Imaging experiments suggest that both neuropeptide Y⁵⁶ and somatostatin⁵⁷ inhibit calcium currents in rod bipolar cell terminals, presumably limiting glutamate release.

Parallel ganglion cell output pathways

Another critical processing mechanism in the inner retina is the separation of visual information into bipolar cell pathways. Parallel bipolar cell signaling pathways relay different aspects of the visual signal to 10–15 morphological types of ganglion cells.^{49,58} Ganglion cells are also divided into two major ON and OFF classes, both possessing antagonistic surrounds⁵⁹ (Fig. 23.7). ON and OFF types can be further divided into X- and Y-cells that respond to illumination in either a sustained (X) or transient (Y) fashion, similar to bipolar cells⁶⁰ and correspond to distinct morphological types, alpha and beta ganglion cells, respectively.⁶¹ The X and Y ganglion cells are similar to the parvo (P) and magno (M) classes of primate ganglion cells, corresponding to the morphological midget and parasol classes, respectively.⁶² P-ganglion cells transmit form and color information, while M-ganglion cells transmit motion and spatial relationship information to the lateral geniculate nucleus.⁶³ Retinal diseases such as diabetic retinopathy and glaucoma can result in structural and functional pathologies in the IPL and in ganglion cells (Boxes 23.3 and 23.4).

Ganglion cells encode color information

Midget ganglion cells transmit color information to the brain – they receive input from midget bipolar cells. Their central, excitatory, response is determined by a strong single red or green cone input, while the inhibitory surround is determined by weak mixed cone inputs, resulting in red–green color opponency. Another ganglion cell that processes color is a bistratified ganglion cell that is excited by blue light, via blue bipolar cells that make contacts at the inner IPL, and inhibited by yellow light, via red and green signaling bipolar cells that make contacts at the outer IPL to process blue–yellow color opponency. These two ganglion

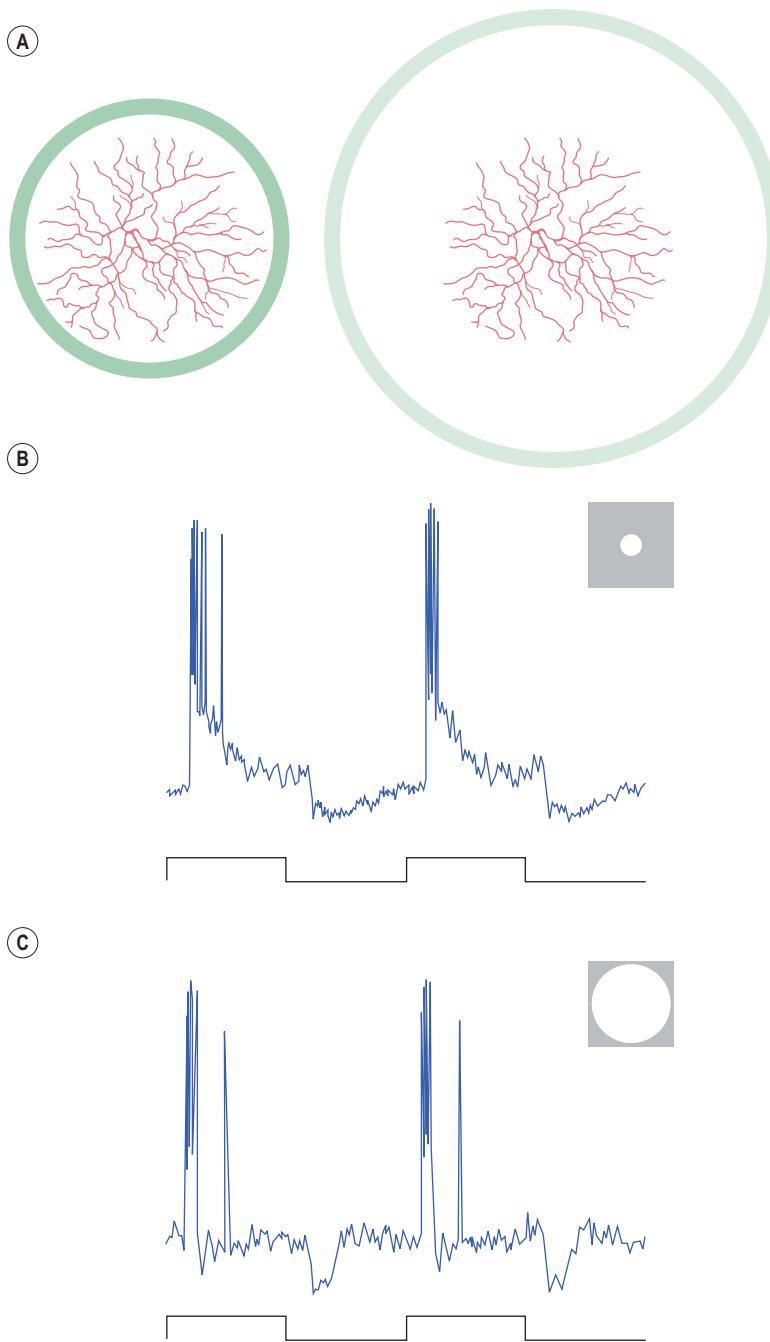

Figure 23.7 (A) Drawing of a parasol ganglion cell dendritic arbor. A stimulus the diameter of the solid dark green line would activate the receptive field center, and a stimulus the diameter of the solid light green line would also activate the receptive field surround. (Reprinted with permission from Diller L, Packer OS, Verweij J et al. L and M cone contributions to the midget and parasol ganglion cell receptive fields of macaque monkey retina. *J Neurosci* 2004; 24:1079–88.) (B) Responses of an ON parasol ganglion cell to a 300- μm -diameter spot (stimulus trace below) square wave stimulus that would activate the receptive field center. (C) Responses of a parasol ganglion cell to a 2000- μm -diameter spot (stimulus trace below) square wave stimulus that would activate both the center and surround. The response is smaller because of the surround antagonism. (Reprinted with permission Davenport CM, Detwiler PB, Dacey DM. Effects of pH buffering on horizontal and ganglion cell light responses in primate retina: evidence for the proton hypothesis of surround formation. *J Neurosci* 2008; 28:456–64.)

cell pathways are the main carriers of color information into the visual cortex.⁶⁴

Directional selective ganglion cells

An additional ganglion cell type – directionally selective (D-S) cells – responds to the movement of images, but only in preferred directions. Image motion in the preferred direction excites D-S cells, but image motion in the null direction elicits no response because inhibition reduces the excitatory input. Although D-S ganglion cells were first described over 40 years ago,⁶⁵ the precise synaptic basis for their behavior remains unknown. One point of agreement between most studies is that a type of amacrine cell called the starburst

amacrine cell is critical for D-S responses in ganglion cells. The genetic ablation of starburst cells, which provide both cholinergic and GABAergic input to D-S cells, results in the elimination D-S responses.⁶⁶

Intrinsically photosensitive ganglion cells

Surprisingly, about 1–3 percent of ganglion cells can directly sense light.⁶⁷ This phenomenon has been attributed to presence of the photopigment melanopsin.⁶⁸ Disrupting rod and cone signaling to these ganglion cells does not eliminate their light responsiveness, consistent with their intrinsic photosensitivity.⁶⁷ Light responses from these ganglion cells are distinct from conventional ganglion cells. These responses

Box 23.3 Ganglion Cell and IPL Pathologies Occur in Diabetic Retinopathy

While diabetic retinopathy is viewed clinically as a disease affecting retinal vasculature, a large body of work shows that it also has neurodegenerative effects in the IPL and in ganglion cells. Diabetic patients and experimental animals have abnormal oscillatory potentials in their ERG responses, consistent with signaling abnormalities in the IPL.⁷⁵ Morphometric measurements show that ganglion cell dendritic trees are smaller and less elaborate in diabetic retinas.⁷⁶ The functional and morphological abnormalities observed in diabetic retinas are often observed before vascular-related pathologies,⁷⁵ suggesting a primary retinal dysfunction before vascular problems arise. These early functional deficits also suggest an avenue of detection of early diabetic retinopathy.

Box 23.4 Glaucoma, a Leading Cause of Blindness, is Attributed to Ganglion Cell Loss

Animal models of glaucoma show that ganglion cell morphology, synaptic connectivity and function is altered in early stages of the disease.^{77–79} These changes are manifested in the IPL and suggest that synaptic inputs to ganglion cells and their ability to process visual information is perturbed. The mechanism of damage to ganglion cells in glaucoma is unclear, but these early changes provide an opportunity for ganglion cell protection, and possibly prevention of their eventual death.

are long-lasting and activated by moderate to bright light intensities. Intrinsically photosensitive ganglion cells also receive input from higher-sensitivity rod and cone synaptic pathways, which elicit lower light intensity responses. Although these ganglion cells are relatively few in number, they have extensive dendritic fields that completely tile the retina, leading to responsivity across the retina. These ganglion cells project to brain areas that control pupillary reflexes and the entrainment of circadian rhythms.

Ganglion cell types form a retinal mosaic

The subtypes of neurons that form the bipolar cell and ganglion cell parallel pathways each sample the entire retina, forming a mosaic of cells through a developmental process called tiling. Each individual cell type is distributed across the surface of the retina, with very little overlap between cells of the same type.⁶⁹ Since each pathway is sampling a different kind of visual information, this allows each cell type to reassemble the entire visual scene and contribute unique information to the downstream visual pathways.⁷⁰ This tiling mechanism occurs through developmental processes that are not yet well understood.

Conclusions

The IPL is a critical stage in visual processing. Distinct bipolar cell types comprise parallel input streams to the IPL. This information is then shaped by synaptic interaction between inhibitory amacrine cells with the bipolar cell inputs and

ganglion cell outputs of the IPL. The ability to detect the direction of movement and certain colors occurs because of processing in the IPL.

Electroretinogram of Human, Monkey and Mouse

Laura J. Frishman & Minhua H. Wang

Introduction

The electroretinogram (ERG) is a useful tool for objective, non-invasive assessment of retinal function both in the clinic and the laboratory. It is a mass electrical potential that represents the summed response of all the cells in the retina to a change in illumination. Recordings can be made *in vivo* under physiological or nearly physiological conditions using electrodes placed on the corneal surface. For standard recordings in the clinic,¹ ERGs such as those illustrated in Figure 24.1 are recorded from alert subjects who are asked not to blink or to move their eyes. Anesthesia, selected for having minimal effects on retinal function, may be required for recordings from some very young human subjects, and is generally used for recordings in animals. The positive and negative waves of the ERG reflect the summed activity of overlapping positive and negative component potentials that originate from different stages of retinal processing. The choice of stimulus conditions and method of analysis will determine which of the various retinal cells and circuits are generating the response. Information about retinal function provided by the ERG is useful for diagnosing and characterizing retinal diseases, as well as for monitoring disease progression, and evaluating the effectiveness of therapeutic interventions.

Much of the basic research on the origins, pathophysiology and treatment of retinal diseases that occur in humans is carried out in animal models. The ERG provides a simple objective approach for assessing retinal function in animals. In recent years it has been of particular benefit in studies of mouse (rat, and other species) models of retinal disease, and it has been valuable for evaluating the retinal drug toxicity.² The ERG also has been useful for characterizing changes in retinal function that occur as a consequence of genetic alterations in mice and other models, which affect the transmission and processing of visual signals in the retina.^{3,4}

This chapter provides information on retinal origins and interpretation of the ERG, with emphasis on advances in our understanding of the ERG that have occurred through pharmacological dissection studies in macaque monkeys whose retinas are similar to those of humans. The similarity of the waveforms of flash ERGs of humans and macaques can be seen in Figure 24.2. The chapter also will examine origins of the mouse ERG, and consider similarities and differences

between mouse and primate ERG. Although the focus of this chapter is on primate and rodent retinas, it is important to note that the ERG is a valuable tool for assessing retinal function of all classes of vertebrates. This includes amphibians and fish in which classical studies of the retina were carried out (for a review, see Dowling⁵) and in which current work continues to improve our understanding of retinal function under normal, genetically altered⁶ and pathological conditions.

This chapter provides useful background information for interpreting the ERG, but does not provide a comprehensive review of the characteristics of ERGs associated with retinal disorders encountered in the clinic. Recent texts by Fishman et al.,⁷ Heckenlively & Arden⁸ and Lam⁹ are recommended resources for learning more about clinical applications.

Generation of the ERG

Radial current flow

The ERG is an extracellular potential that arises from currents that flow through the retina as a result of neuronal signaling, and for some slower ERG waves, potassium (K^+) currents in glial cells. Local changes in the membrane conductance of activated cells give rise to inward or outward ion currents, and cause currents to flow in the extracellular space (ECS) around the cells, creating extracellular potentials. Although all retinal cell types can contribute to ERGs recorded at the cornea, the contribution of a particular type may be large, or hardly noticeable in the recorded waveform, depending upon several factors detailed below.

The orientation of a cell type in the retina is a major factor in determining the extent to which its activity will contribute to the ERG. A schematic drawing of the mammalian retina, with the various cell types labeled, can be found in Chapter 21 (Figs 21.1 & 21.2). When activated synchronously by a change in illumination, retinal neurons that are radially oriented with respect to the cornea, i.e. the photoreceptors, and bipolar cells, make larger contributions to the major waves of the ERG than the more laterally oriented cells and their processes, i.e. the horizontal and amacrine cells. The major waves at light onset are, as marked in Figures 24.1 and 24.2, an initial negative-going a-wave (mainly from photoreceptors),

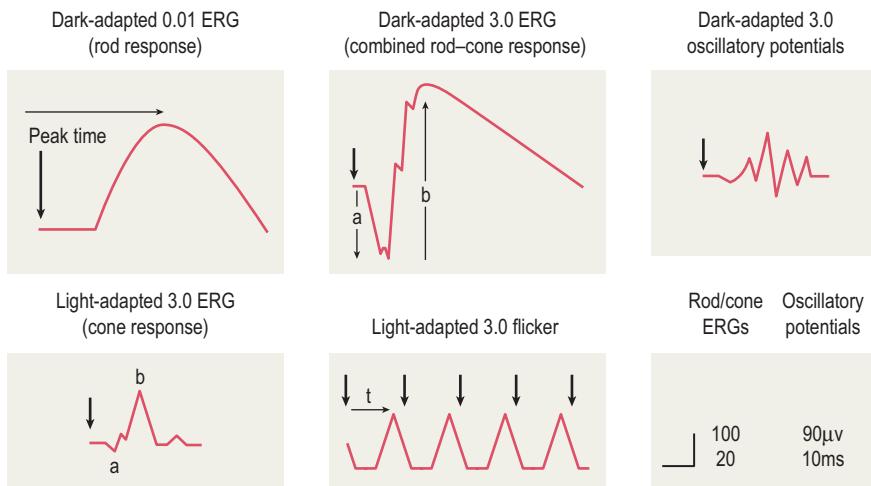

Figure 24.1 Standard tests for full field clinical electrophysiology. The Society for the Clinical Electrophysiology of Vision (ISCEV) has recommended five standard ERG tests with full-field stimulation for use worldwide in clinical electrodiagnostic facilities. This figure, from the 2008 update of “ISCEV Standard for Full-Field Clinical Electroretinography”¹ shows examples, but not norms, of ERGs elicited using the recommended tests in normal humans. Light calibrations in candela seconds per meter squared (cd.s.m^{-2}) for each test appear above the ERGs. Large arrowheads indicate the time at which the stimulus flash occurred. Dotted arrows show common ways to measure time-to-peak (“t”, implicit time), and a- and b-wave amplitudes. For some purposes, e.g. quantitative analyses to separate various ERG components, amplitude measurements at a fixed time after stimulus onset are more appropriate (see Fig. 24.12). (From Marmor MF, Fulton AB, Holder GE, Miyake Y, Brigell M, Bach M. ISCEV Standard for full-field clinical electroretinography (2008 update). Documenta Ophthalmologica 2009;118(1): pp. 69–77, used with permission.)

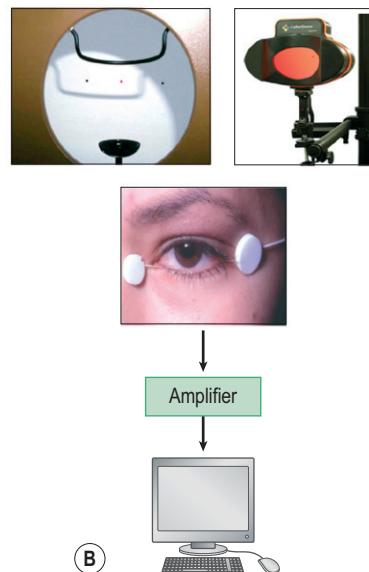

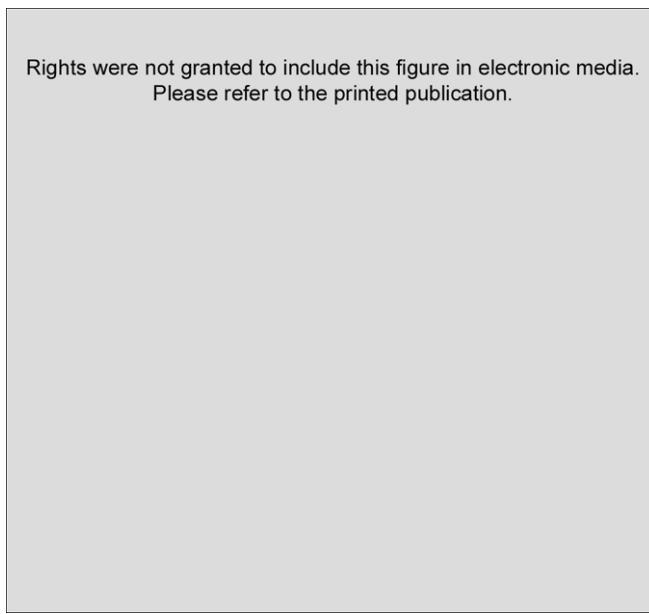

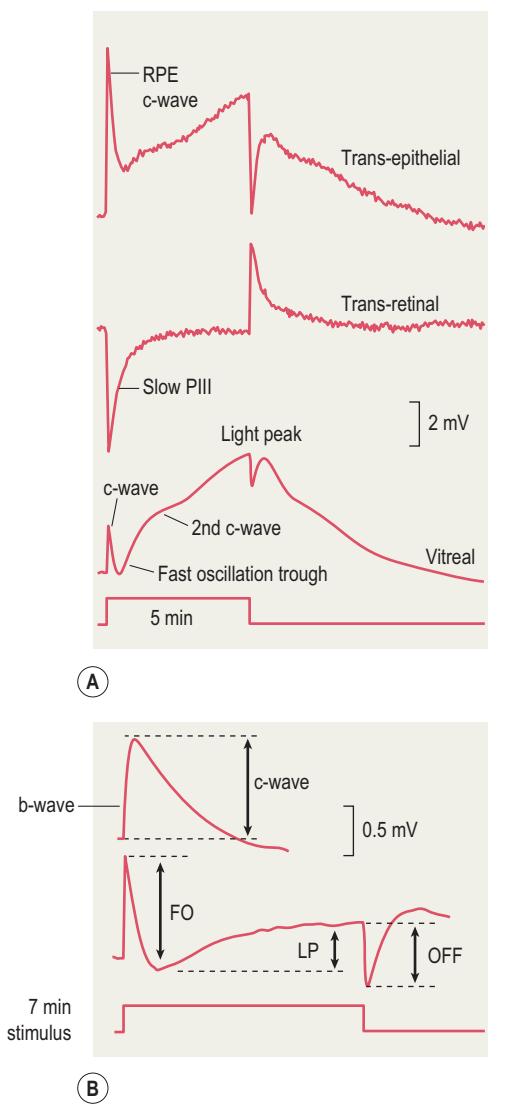

Figure 24.2 Full-field flash electroretinograms (ERGs) of human subjects and macaque monkeys. (A) Top: Dark-adapted ERG responses to brief high energy flashes of ~ 400 scotopic troland seconds (sc td.s) from darkness that occurred at time zero for a normal alert human subject (left) and an anesthetized macaque (right). For macaque ERGs, and ERGs from all animals in subsequent figures, subjects were anesthetized. (Adapted from Robson & Frishman 1998,¹⁶ used with permission.) Bottom: Light-adapted ERGs in response to longer duration flashes (150 or 200 ms). For both subjects, white Ganzfeld flashes of 4.0 log photopic (ph) td were presented on a steady rod-saturating background of 3.3 log sc td. (Adapted from Sieving et al 1994,¹⁷ used with permission.) (B) ERG recording setup: Recordings made using a traditional Ganzfeld bowl (left) or more modern LED-based full-field stimulator. Use of DTL fiber electrodes³² is illustrated. ERG recordings are amplified and sent to a computer for averaging, display and analysis.

which is truncated by a positive-going b-wave, mainly generated by ON (depolarizing) bipolar cells. For longer duration flashes (Fig. 24.2, bottom row), the light-adapted ERG includes another positive-going wave, the d-wave, at light offset, with major contribution from OFF (hyperpolarizing) bipolar cells. Currents that leave retinal cells and enter the ECS at one retinal depth (the current source), will leave the

ECS to re-enter the cells at another (the current sink), creating a current dipole. These retinal currents also travel through the vitreous humor to the cornea, where the ERG can be recorded non-invasively, as well as through the extraocular tissue, sclera, choroid and high resistance of the retinal pigment epithelium (RPE) before returning to the retina. Local ERGs can be recorded near the retinal generators using

intraretinal microelectrodes in animals, while simultaneously recording the global ERG elsewhere in the current path, e.g. from the corneal surface, or using an electrode in the vitreous humor, with a reference electrode behind the eye.^{10,11} Such recordings have provided useful information about the origins of the various waves of the ERG.

Glial currents

The ERG waveform also will be affected by glial cell currents. Retinal glial cells include Müller cells, RPE cells, and radial astrocytes in the optic nerve head. One crucial function of glia is to regulate extracellular K^+ concentration, $[K^+]_o$, to maintain the electrochemical gradients across cell membranes that are necessary for normal neuronal function. Membrane depolarization and spiking in retinal neurons that occur in response to changes in illumination lead to leak of K^+ from the neurons and to K^+ accumulation in the ECS. Membrane hyperpolarization, in contrast, leads to lower $[K^+]_o$ as the membrane leak conductance is reduced, but the $Na^+ K^+$ ATPase in the membrane continues to transport K^+ into the cell.

K^+ currents in Müller cells move excess K^+ from areas of high $[K^+]_o$ to areas of lower $[K^+]_o$ by a process called spatial

buffering.^{12,13} Return currents in the retina are formed by Na^+ and Cl^- . The regional distribution and electrical properties of inward rectifying K^+ (Kir) channels in Müller cells (see Fig. 24.3C) are critical for the spatial buffering capacity of the cells. Studies of Kofuji and co-workers have shown that strongly rectifying Kir2.1 channels in Müller cells are located in 'source' areas, particularly in synaptic regions where $[K^+]_o$ is elevated due to local neuronal activity.^{14,15} In contrast, Kir4.1 channels (weakly rectifying) are densest in Müller cell endfeet, in inner and outer limiting membranes and in processes around blood vessels. K^+ enters Müller cells through Kir2.1 channels that minimize K^+ outflow and K^+ exits the Müller cells via the more bidirectional Kir4.1 channels to enter the extracellular 'sink' areas with low $[K^+]_o$: the vitreous humor, subretinal space (SRS), and blood vessels.¹⁴

ERG waves associated with glial K^+ currents have a slower timecourse than waves related to currents around the neurons whose activity causes the changes in $[K^+]_o$. As $[K^+]_o$ increases or decreases with neuronal activity, the resulting glial K^+ currents will be related to the integral of the K^+ flow rate, e.g. the glial contribution to the b-wave modeled in Figure 24.11.¹⁶ Other waves generated by glial K^+ currents in Müller cells, or

other retina cells with glial function, such as the RPE, include the c-wave and slow PIII (Fig. 24.3A,B), both related to the reduction in $[K^+]$ _o in the SRS that occurs when photoreceptors hyperpolarize in response to a strong flash of light.^{15,17–21} The negative scotopic threshold response (nSTR) and photopic negative response (PhNR), both originating from inner retinal activity, are also thought to be mediated by glial K⁺ currents in retina or optic nerve head.^{22–29}

Stimulus conditions

Aside from structural and functional aspects of the retina, stimulus conditions are of great importance in determining the extent to which particular retinal cell or circuits contribute to the ERG. Signals will be generated in rod pathways, in cone pathways or both depending upon the stimulus energy, wavelength and temporal characteristics, as well as upon the extent of background illumination, with rods responding to, and being desensitized by lower light levels than cones. Fully dark-adapted, ERGs driven by rods only (i.e. scotopic ERGs) are thus useful for assessing rod pathway function (Figs 24.1 and 24.2, top), and light-adapted ERGs driven only by cones (i.e. photopic ERGs), for assessing cone pathway function (Figs 24.1 and 24.2, bottom). Figure 24.1, bottom right, also shows responses to 30 Hz flicker which isolates cone-driven responses because rod circuits do not resolve well such high frequencies. Very bright light flashes elicit small wavelets superimposed on the b-wave called oscillatory potentials (OPs) that are generated by circuits proximal to bipolar cells.^{30,31} OPs can be isolated by band-pass filtering: 75–300 Hz in Figure 24.1, top right.

The spatial extent of the stimulus is an important factor in ERG testing. For standard clinical tests, as illustrated in Figure 24.1, and listed in Box 24.1A, as well as for most testing of animal models, a full-field (Ganzfeld) flash of light is used (Fig. 24.2B). A full-field stimulus generally elicits the largest responses because more retinal cells are activated and the extracellular current is larger than for focal stimuli. It also has the advantage that all regions of retina are evenly illuminated, and with respect to background illumination, evenly adapted. Pupils are generally dilated for full-field stimulation. More spatially localized (focal) stimuli are useful for analysis of function of particular retinal regions, e.g. foveal vs peripheral regions in primates. Multifocal stimulation allows assessment of many small regions simultaneously.

ERG responses illustrated in Figure 24.1 are to a minimum set of stimuli selected by the International Society for the Clinical Electrophysiology of Vision (ISCEV) to efficiently acquire standard, comparable data on rod and cone pathway function from clinics and laboratories around the world.¹ Names of the standard tests are listed in Box 24.1A. Tests using stimuli presented over a fuller range of stimulus conditions to allow more complete or specific evaluation of retinal function, are listed in Box 24.1B, and a few of these tests will be described later in this chapter.

Non-invasive recording of the ERG

ERGs can be recorded from the corneal surface using various types of electrodes. A commonly used electrode, with good

Box 24.1 Standard and More Specialized ERG Tests

A. Standard ERG tests

Described by ISCEV Standard for full-field clinical Electroretinography (2008 update).¹ All numbers are stimulus calibrations in cd.s.m⁻²

- Dark-adapted 0.01 ERG (“rod response”)
- Dark-adapted 3.0 ERG (“maximal or standard combined rod–cone response”)
- Dark-adapted 3.0 oscillatory potentials (“oscillatory potentials”)
- Light-adapted 3.0 ERG (“single-flash cone response”)
- Light-adapted 3.0 flicker ERG (“30 Hz flicker”)
- Recommended additional response: either dark-adapted 10.0 ERG or dark-adapted 30.0 ERG

B. Specialized types of ERG and recording procedures

- Macular or focal ERG
- Multifocal ERG (see published guidelines¹⁶²)
- Pattern ERG (see published standard⁹¹)
- Early receptor potential (ERP)
- Scotopic threshold response (STR), negative and positive
- Photopic negative response (PhNR)
- Direct-current (dc) ERG
- Electro-oculogram (see published standard³⁹)
- Long-duration light-adapted ERG (ON-OFF responses)
- Paired-flash ERG
- Chromatic stimulus ERG (including S-cone ERG)
- Dark and light adaptation of the ERG
- Dark-adapted and light-adapted luminance-response analyses
- Saturated a-wave slope analysis
- Specialized procedures for young and premature infants¹⁶³

signal-to-noise characteristics, is a contact lens with a conductive metal electrode set into it (Burian Allen electrode). It has a lid speculum to reduce effects of blinking and eye closure. In the bipolar form of the electrode, the outer surface of the lid speculum is coated with conductive material that serves as the reference. This type of electrode is best tolerated (in alert subjects) when a topical anesthetic is used. Other types of contact lens electrodes have been used as well, e.g. the jet electrode which is disposable. Some clinicians and researchers use thin mylar fibers impregnated with silver particles, called DTL electrodes,³² as illustrated in Figure 24.2B, or gold foil, or wire loop electrodes (H-K loop) that hook over the lower eyelid. For rodents, metal wires, in loops or other configurations placed in contact with the corneal surface are often used. Some labs use cotton wick electrodes and some use DTL fibers under contact lenses, or another form of contact lens electrode.^{26,33} Corneas are kept hydrated with a lubricating conductive solution in all cases. The reference electrode can be placed under the ey lid, e.g. the speculum of a contact lens electrode, as described above, or remotely, for example on the temple, the forehead, or the cornea of the fellow eye. ERG signals ranging from > microvolt to a millivolt or more, peak to peak, for responses to strong stimuli, are amplified, and digitized for computer averaging and analysis. Filtering is done to remove signals outside the frequency range of retinal responses to stimulation (<1 and >300 Hz), and to remove line frequency noise (e.g. 50 or 60 Hz).

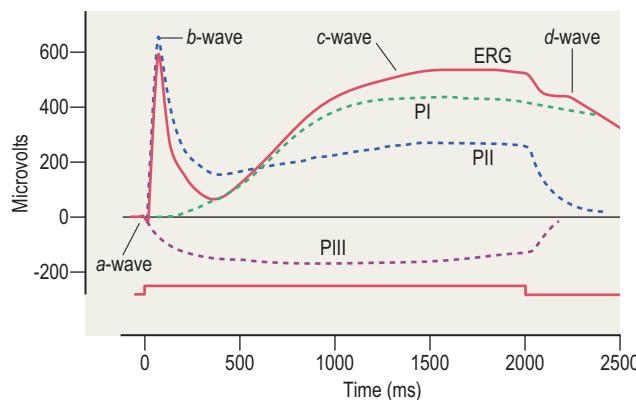

Figure 24.4 Dark-adapted ERG of the cat and its three component processes revealed by induction of ether anesthesia. The solid black line indicates the ERG of the intact cat eye in response to a 2 s flash (14 Lamberts) from darkness. Dashed lines indicate three processes (PI, PII, and PIII), numbered in the order in which they disappeared from the ERG during induction of ether anesthesia. (Modified from Granit 1933,³⁶ used with permission.)

Classical definition of components of the ERG

The origins of the various waves of the ERG have been of longstanding interest to clinicians and researchers. Our current understanding of the cellular origins of the ERG profits from extensive knowledge, as described in previous chapters, of the functional microcircuitry of the retina, and particularly of the physiology and cell biology of the retinal cell types, and the identity and action of retinal neurotransmitters, their receptors, transporters and release mechanisms. However, a classical study, using ether anesthesia, provided the first pharmacological separation of ERG components.

Granit's³⁶ classical pharmacological dissection of the ERG, illustrated in Figure 24.4, provided valuable insights on origins of ERG waves as well as a nomenclature for waves based on their distinct retinal origins. Component "processes" were found to disappear from the ERG during the induction of ether anesthesia in the following order: process (PI), the slow c-wave response that follows the b-wave; generated predominantly by the RPE; PII, the b-wave, generated by bipolar cells; and eventually PIII, the photoreceptor-related responses that remained the longest. PII and PIII are still commonly used terms for ERG components generated by ON bipolar cells and photoreceptors respectively.

Slow PIII, the c-wave and other slow components of the direct current (dc)-ERG

PIII of the ERG can be separated into a fast and a slow portion: fast PIII is the a-wave, which reflects photoreceptor current (see below), and slow PIII results from Müller cell currents induced by photoreceptor-dependent reduction in $[K^+]$ in the SRS (Fig. 24.3C). Negative-going slow PIII and the positive-going pigment epithelial response to the same

reduction in subretinal $[K^+]$ add together to form the c-wave,^{15,17–19,34} which, as shown in Figures 24.3 and 24.4, is positive-going in the dark-adapted ERG of the cat. This is because, as illustrated by the intraretinal recordings from intact cat eye in Figure 24.3A, the positive-going RPE contribution, is larger than the negative-going Müller cell contribution. In mice, the c-wave also is positive-going,³⁵ as shown in Figure 24.3B. In humans and monkeys, slow PIII and the RPE c-wave are more equal in amplitude, and the corneal c-wave is less positive. Two slower potentials that arise from the RPE, the fast oscillation potential (FO) and light peak (LP), are also present in cat and mouse dc-ERG recordings (Fig. 24.3). The mouse LP is much smaller in amplitude than that in the cat. The cellular mechanisms that generate these slow waves were reviewed in more detail in previous reviews of ERG origins.^{37,38}

In alert human subjects it is not possible to obtain stable dc-ERG recordings necessary for recording slow events, e.g. those arising from the RPE, that occur over seconds or minutes, because the eyes move too frequently. Therefore, to measure slow potentials, the electro-oculogram (EOG), an eye-movement-dependent voltage, is recorded. The EOG is a corneo-fundal potential that originates largely from the RPE; its amplitude changes with illumination, being maximal at the peak of the light peak. Use of EOGs to evaluate retinal/RPE function is described in an ISCEV Standard publication on clinical EOG.³⁹

Full-field dark-adapted (Ganzfeld) flash ERG

Figure 24.5 shows full-field dark-adapted ERG responses to a range of stimulus strengths for a human subject (left), a macaque monkey, whose retina and ERG are similar to that of human (middle), and a C57BL/6 mouse (right). The mouse ERG is similar to the primate ERG, but larger in amplitude (see calibrations). For higher stimulus strengths than shown in the figure, the mouse ERG develops larger oscillatory potentials than those generally seen in the primate ERGs (e.g. Fig. 24.6). The ERGs in Figure 24.5 were generated almost entirely, except for responses to the strongest stimuli, by the most sensitive, primary rod circuit. This circuit is described more fully in previous chapters. For all three subjects, the strongest stimuli evoked an a-wave, followed by a b-wave. For stimuli more than two log units weaker than the strongest one, b-waves were still present, but a-waves were no longer visible. B-waves can be seen in responses to weaker stimuli than a-waves partly because of the convergence of many rods (20–40) onto the rod bipolar cells generating the response, which increases their sensitivity,^{40–42} and partly because of the large radial extent of ON bipolar cells in the retina. The slow negative wave in the ERGs of the three subjects in response to the weakest stimuli, called the (negative) scotopic threshold response (nSTR), and the equally sensitive positive (p)STR are related to amacrine and/or ganglion cell activity, as described more fully in a later section.^{22,25–27,43} The high sensitivity of the STRs relative to b-waves (and a-waves) reflects the additional convergence of rod signals in the primary rod circuit in the inner retina proximal to the rod bipolar cells.^{40,44,45}

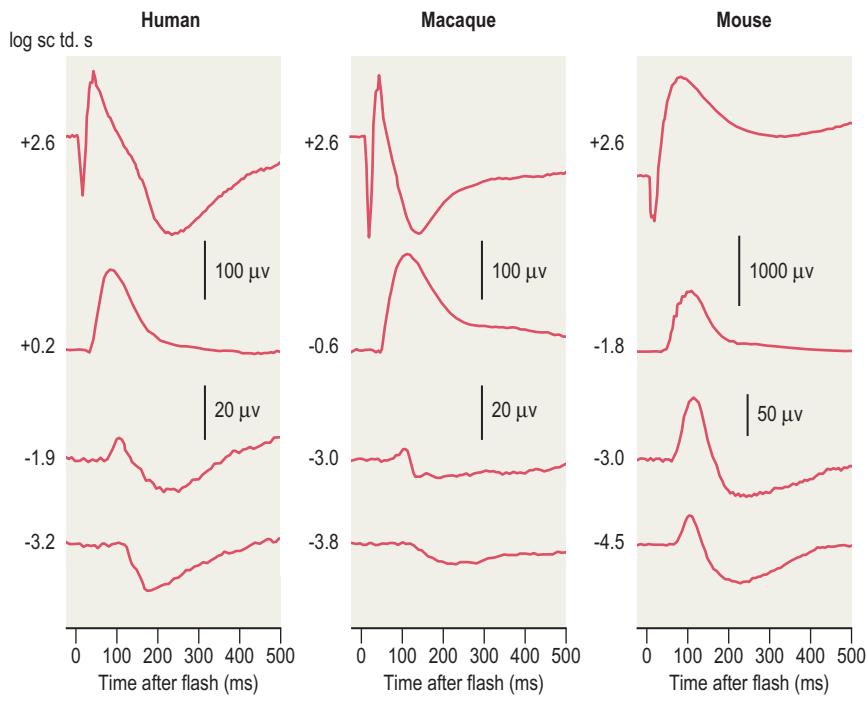

Figure 24.5 Dark-adapted full-field ERG of a human subject, a macaque monkey and a mouse. ERGs of a human, macaque and C57BL/6 mouse, in response to brief (<5 ms) flashes from darkness generated by computer-controlled LEDs. Responses to the weakest stimuli were rod-driven (scotopic), whereas for the strongest stimuli they were driven by both rods and cones. (Adapted from Robson & Frishman 1998,¹⁶ used with permission.)

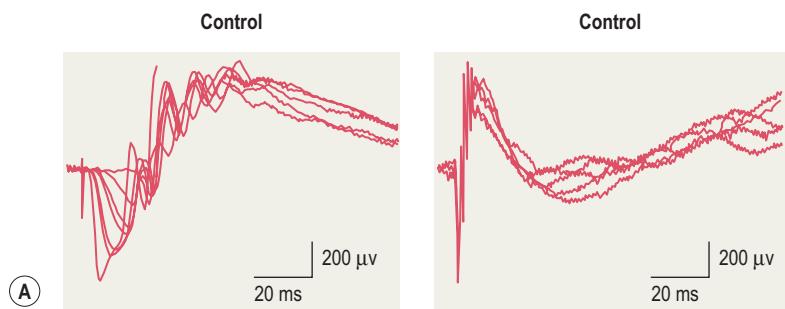

Figure 24.6 Negative ERG of mouse lacking a b-wave. Single-flash responses on short (left) and long (right) time scales from a control C57BL/6 mouse (**A**) and a *Nob1* mouse (**B**). ERGs on the left are responses to flashes of 0.11, 0.98, 2.57, 4.37, 17.4, 27.5, and 348 sc cd.s.m⁻², on the right, to flashes of 40.0, 68.4, 102, 170, and 348 sc cd.s.m⁻². Dark-adapted a-wave

It has long been appreciated that the dark-adapted a-wave primarily reflects the rod receptor photocurrent. The a-wave generator was localized to photoreceptors in classical intra-retinal recording studies in mammalian retinas, some of which included current source density (CSD), or source-sink, analyses.^{10,11,46–48} The most direct demonstration of the a-wave's cellular origin was provided in such experiments by Penn and Hagins^{47,48} in isolated rat retina. These experiments produced evidence that light suppressed the circulating (dark) current of the photoreceptors, and the investigators proposed that this suppression is seen in the ERG as the a-wave.

Negative ERGs

The receptoral origin of the a-wave also was demonstrated in early studies in amphibians using compounds that blocked synaptic transmission, Mg²⁺, Co²⁺, and Na⁺-aspartate, and isolated photoreceptor signals in the ERG, while abolishing responses of postreceptoral neurons.^{49,50} These manipulations also caused the b-wave to disappear, indicating its postreceptoral origin. As our understanding of synaptic pharmacology has improved, it has become more common to use glutamate agonists and antagonists to block transfer of signals from photoreceptors to specific second-order neurons. For example, blocking metabotropic transmission to depolarizing (ON) bipolar cells, with

L-2-amino-4-phosphonobutyric acid (APB or AP4) an mGluR6 receptor agonist,⁵¹ eliminates the b-wave, and produces a negative ERG.^{52,53} Much of the remaining ERG is the rod photoreceptor response, although late negative signals also arise from OFF pathway neurons.^{54,55}

An essentially identical negative ERG to that after APB occurs in mice in which the mGluR6 receptor is genetically deleted,⁵⁶ or when there are mutations in the mGluR6 receptor or other proteins whose function is necessary for normal signal transduction in ON bipolar cells.⁵⁷ For example, Figure 24.6 shows the typical negative ERG of the dark-adapted *Nob1*, i.e. no b-wave, mouse.^{58,59} The *Nob1* mouse has a mutation in the *Nyx* gene that encodes nyctalopin, a protein found in ON bipolar cell dendrites.^{60,61} Mutation of this protein produces a negative ERG in human patients who are diagnosed with X-linked complete congenital stationary night blindness (CNSB-1).^{62,63} Negative ERGs also occur for other forms of CSNB caused by mutations in mGluR6 receptors, and in *Nob3* and *Nob4* mice with such mutations,^{57,64} as well as in *Nob2* mice in which glutamatergic transmission from photoreceptors is compromised.⁶⁵ Although the ERG of the *Nob1*, and other mice lacking b-waves, is almost entirely negative-going, it rises from its trough at the timecourse of the c-wave. Photoreceptor-dependent slow responses such as c-wave and slow PIII are not affected by blockade of postreceptoral responses in neural retina.

Retinal ischemia due to compromised inner retina circulation also isolates the a-wave and eliminates postreceptoral ERG components. This was demonstrated in early experiments in monkeys by occlusion of the central retinal artery.^{66,67} A "negative ERG" in which b-waves are reduced or missing is a common clinical readout of central retinal artery and vein occlusions, as well as other disorders affecting postreceptoral retina such as melanoma-associated retinopathy, X-linked retinoschisis, muscular dystrophy or toxic conditions.^{7,9}

Modeling

The utility of the a-wave in studies of normal and abnormal photoreceptor function was advanced by the development of quantitative models based on single cell physiology that could predict the behavior both of the isolated photoreceptor cells and ERG a-wave in the same or similar species. Hood and Birch^{68,69} demonstrated that the behavior of the leading edge of the dark-adapted a-wave in the human ERG can be predicted by a model of photoreceptor function derived to describe *in vitro* suction electrode recordings of currents around the outer segments of single primate rod photoreceptors.⁷⁰ Lamb and Pugh^{71,72} followed a simplified kinetic model of the leading edge of the photoreceptor response (*in vitro* current recordings initially in amphibians) that took account of the stages of the biochemical phototransduction cascade in vertebrate rods (see Chapter 21). This model was subsequently shown to predict the leading edge of the human dark-adapted a-wave generated by strong stimuli,⁷³ and has been used extensively in clinical studies of retinal disease, and in analyses of photoreceptor function in animal models. A simplified formulation presented by Hood and Birch^{74–76} often is used (see legend to Fig. 24.7), and can be adjusted to application to cone signals as well. Figure 24.7 shows fits of

Hood and Birch's model to the dark-adapted a-wave of a normal human subject and a patient with retinitis pigmentosa (RP).

Photoreceptor models of Hood and Birch,^{74–76} Lamb and Pugh,⁷² and more recent ones, with improved fits,⁵⁵ all provide parameters to represent the maximum amplitude of the a-wave, which is R_{max} in equations of Hood and Birch, and the sensitivity (S) of the response. R_{max} and S vary depending upon the pathology and stimulus conditions (e.g. adaptation level). For example, S is thought to be more affected than R_{max} in eyes whose photoreceptors are hypoxic and more generally for abnormalities in the transduction cascade or increases in retinal illumination, whereas R_{max} is more affected by photoreceptor loss. Both parameters may be affected in RP, but in the case illustrated in Figure 24.7, R_{max} was affected more than S.⁷⁷

Although models of the leading edge of the a-wave yield useful parameters for describing the health of the photoreceptors, simpler approaches, using stronger flashes than those advised by the ISCEV Standard (Fig. 24.1 and Box 24.1)¹ are helpful. Hood and Birch,^{77,78} and other investigators,⁷⁹ have noted that a pair of strong flashes, or even a single flash that nearly or just saturates the rod response can be analyzed without fitting a model, to make a rough estimate of R_{max} and to measure a peak time that is related to S. Such measurements for a single flash⁷⁷ are illustrated in the bottom row of Figure 24.7. The flash strength used was 4.0 log sc td.s which is 63 times (1.8 log units) higher than the current ISCEV standard flash¹ for mixed rod-cone ERG (assuming an 8 mm pupil).

Mixed rod-cone a-wave

For weak to moderate stimuli flashed from darkness, a-waves are dominated by rod signals, but stronger flashes such as those used for responses in the top row of Figure 24.5 elicit mixed rod-cone ERGs. To investigate relative contributions of rod and cone-driven responses to the ERG, it is necessary to separate them. Figure 24.8 shows the ERG (red circles) of a dark-adapted macaque in response to two different flash strengths, and the individual rod- and cone-driven contributions.

Rod-driven responses (blue circles) in Figure 24.8 were extracted by subtracting the isolated cone-driven response to the same stimulus from the full mixed rod-cone response. Isolated cone-driven responses (triangles) were obtained by briefly (1 s) suppressing rod-driven responses with an adapting flash, and then measuring the response to the original test stimulus, presented 300 ms after offset of the rod-suppressing flash. Cone-driven responses in primates recover to full amplitude within about 300 ms, whereas rod-driven responses take at least a second, making it possible to isolate the cone-driven responses. The cone photoreceptor-driven portion of the leading edge of the a-wave represented about 20 percent of the saturated response in Figure 24.8. Model lines for the rod (blue) and cone (purple) photoreceptor responses are modifications of Lamb and Pugh's model.^{55,72} The entire cone-driven a-wave (green line) is larger than the modeled photoreceptor contribution (purple line) because it includes additional negative-going signals from postreceptoral OFF pathway that can be eliminated with ionotropic glutamate receptor antagonists, as described in a later section on light-adapted ERG.

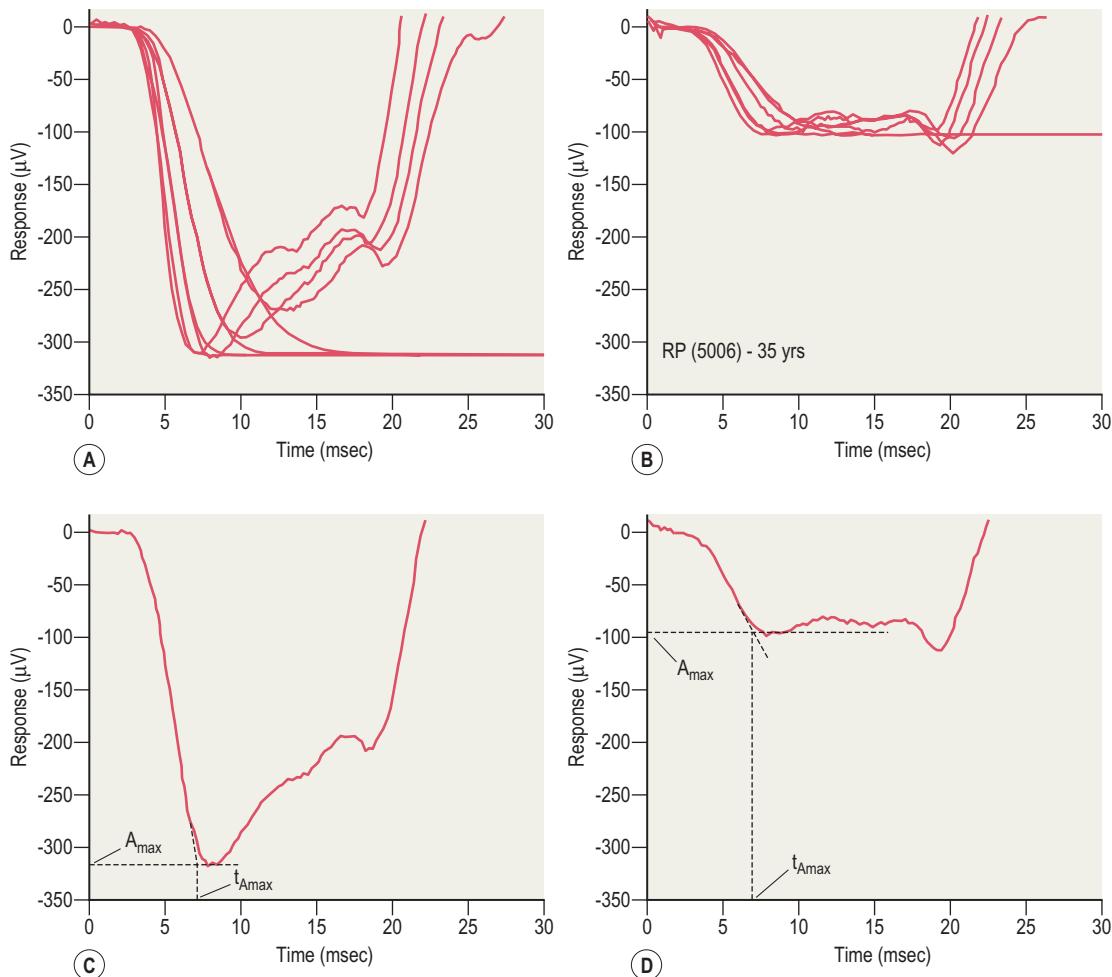

Figure 24.7 Modeling the leading edge of the dark-adapted a-wave. (A) and (B) Rod-isolated ERG of a normal human subject (A), and a retinitis pigmentosa (RP) patient (B) in response to flashes of increasing strengths near a-wave saturation. Responses are fit with the Hood & Birch⁷⁵ adaptation of the Lamb & Pugh⁷² model, expressed in the following equation:

$$R(I, t) = (1 - \exp[-I \cdot S \cdot (t - t_d)^2]) * R_{max} \text{ For } t > t_d$$

where response amplitude, R , is a function of flash strength, I , and the time, t , after the occurrence of brief (impulse) flash of light. S is the sensitivity that scales the stimulus strength, R_{max} is the maximum amplitude, and t_d , a brief delay commonly between 2.4 to 4 ms. (C) and (D) Simple approach for estimating A_{max} and t_{Amax} indicators for model parameters, R_{max} and S for the normal human subject (C) and RP patient. (D). (From Hood & Birch 2006,⁷⁵ used with permission.)

Timecourse of the rod photoreceptor response

The leading edge of the a-wave is the only portion of the photoreceptor response that normally is visible in the brief flash ERG. As shown for the *Nob1* mouse in Figure 24.6, elimination of the major postreceptor contributions to the dark-adapted ERG leaves the c-wave present in the record. For studying photoreceptor responses in isolation from all other ERG components, a paired flash technique was developed by Pepperberg⁸⁰ and colleagues to derive, *in vivo*, the photoreceptor response. The derived photoreceptor responses for a macaque monkey are shown for three different stimulus strengths, all of which saturated the b-wave in Figure 24.9 (top). The time course of the derived response is similar to that of current recordings from individual rod outer segments in the monkey,⁷⁰ although the derived response tends to reach its peak a little earlier *in vivo* in the ERG than *in vitro*. This approach has been used in studies in humans, macaques, and other animals, to study responses of rods and

cones. Note that the (derived) photoreceptor response is quite large at its peak time for the ERG responses to weaker stimuli, when the leading edge of the a-wave is too small to be seen. This nicely illustrates the overlapping nature of ERG components arising from different stages of retinal processing.

Dark-adapted b-wave (PII)

It is well accepted that the dark-adapted b-wave arises primarily from ON bipolar cells. Results of intraretinal recording and CSD analyses were consistent with its originating from bipolar (or Müller cells),^{10,11,66} and as described above, pharmacologic blockade of postreceptoral responses and specifically those of ON bipolar cells was found to eliminate the b-wave,⁵³ as did mutations that prevent signaling by ON bipolar cells (Fig. 24.6).^{57,59}

There also is good evidence that for most of its dynamic range, the dark-adapted b-wave is generated by rod bipolar

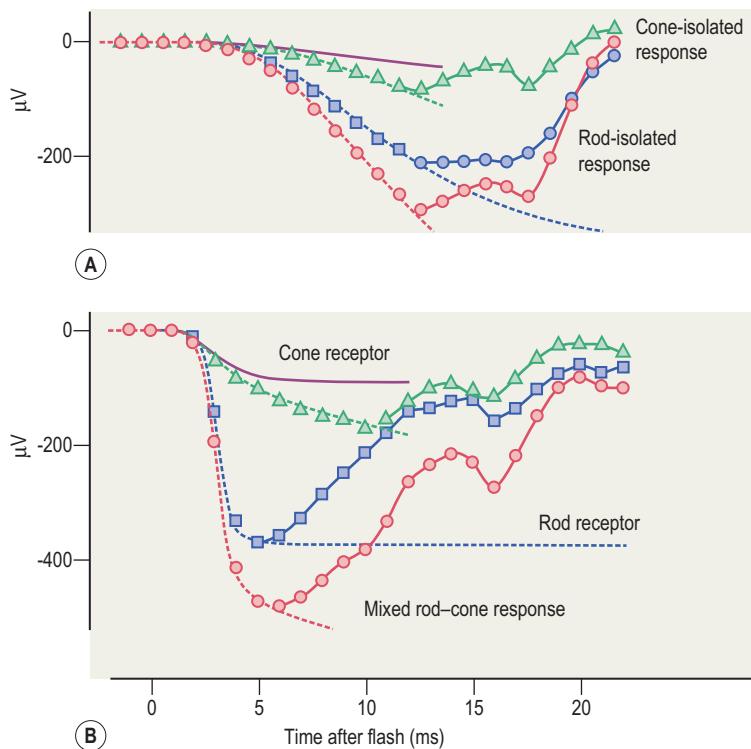

Figure 24.8 Mixed rod-cone dark-adapted ERG of macaque monkey showing separate components. (A) ERG responses of a macaque to a brief blue LED flash of 188 sc td.s (57 ph td.s), and (B) to a xenon-white flash of 59,000 sc td.s (34,000 ph td.s). In both plots, the largest response, (red circles) is the mixed rod-cone a-wave; the red dashed line shows the modeled mixed rod/cone response. The second largest response is the (isolated) rod-driven response (filled blue squares and circles), and the dashed blue line is the modeled rod photoreceptor contribution. The second to smallest response (filled triangles) is the isolated cone-driven response, and the dashed green line shows the modeled response (including postreceptoral portion). The smallest response (purple line) is the modeled cone photoreceptor contribution, based on findings after intravitreal injection of *cis*-piperidine-2,3-dicarboxylic acid (PDA, 5 mM intravitreal concentration, assuming a vitreal volume of 2.1 ml in macaque eye in this and subsequent figures). The stimulus for part A (for 8.5 mm pupil) was 1 ph cd.s.m⁻², i.e. about 3 times weaker (for cones) than the ISCEV standard flash of 3 cd.s.m⁻² whereas for part B it was 200 times stronger than the standard flash. (From Robson et al 2003,⁵⁵ used with permission.)

cells in the primary rod circuit. Only for very strong stimuli, will rod signals pass via gap junctions to cones and then to cone bipolar cells, which also will then contribute to the dark-adapted flash response.^{41,44,81,82} For the dark-adapted, scotopic ERGs it has been possible to isolate Granit's PII from other ERG components and to compare its characteristics with those of rod bipolar cells recorded in retinal slices. One approach is to pharmacologically isolate PII.

Figure 24.10A shows the dark-adapted ERG of a C57BL/6 mouse before and after intravitreal injection of the inhibitory neurotransmitter γ -aminobutyric acid (GABA) to suppress inner retinal activity. GABA receptors are present in bipolar cell terminals, as well as in amacrine and ganglion cells of inner retina, as described in Chapter 23. The figure shows that the most sensitive positive and negative going waves (p- and n-STR) were removed by GABA,^{26,83} leaving a pharmacologically isolated PII, likely generated by rod bipolar cells. Loss of the sensitive STRs was not due to a general loss of retinal sensitivity; a-wave amplitude and kinetics, reflecting photoreceptor function, did not change after GABA injection (Fig. 24.10C).

Figure 24.11B shows PII, isolated by intravitreal GABA from ERGs of four C57BL/6 mice in response to stimuli producing about 1 Rh* per rod. Also included in Figure 24.11A is PII isolated in humans using a weak adapting light to suppress the very sensitive STRs.⁸⁴ Isolated PII has been superimposed on an average of several patch electrode current recordings from rod bipolar cells in a mouse retinal slice preparation, in response to similarly weak stimuli.⁸⁵ The timecourse of PII isolated from the ERG and of single cell currents is remarkably similar, supporting the view that isolated PII reflects rod bipolar cell activity. A primary role for an alternative generator for PII, the Müller cells, is

unlikely in mice because mice with genetically inactivated Kir4.1 channels in their retinas still produce b-waves.¹⁵

Figure 24.11B plots ERG amplitude, measured at a fixed time (110 ms) near the peak the b-wave (and pSTR) before and after GABA injection. After GABA injection, with the pSTR removed, the response rises in proportion to stimulus energy and then saturates in a manner that is adequately described by a simple hyperbolic function (see Fig. 24.10 legend). These findings are consistent with a single mechanism, i.e. one retinal cell type, producing the isolated PII component of the ERG.^{83,86}

Although bipolar cells play a major role in generating b-waves, Müller cells also contribute. The PII component, pharmacologically isolated from macaque ERG (Fig. 24.11B), is similar in its rising phase to PII of the other species illustrated in Figure 24.11A. However PII in macaque (and cat) recovers more slowly to baseline. Macaque PII in Figure 24.11B has been analyzed into a fast component, and a slow component that is a low-pass filtered version of the fast component. In cat, intravitreal injection of Ba²⁺ to block inward rectifying K⁺ channels in Müller cells did not eliminate the b-wave,^{25,87} but did remove a slow portion of isolated PII that is similar in timecourse to a low pass filtered version of the response.³⁸ Although the slow component (in response to a brief flash) is lower in amplitude than the fast component, the area under the two curves is similar in both cat and the macaque. With longer-duration stimuli such as those used in early studies in amphibians,⁸⁸ contributions of neuronal and glial generators of the b-wave could be equal.

Scotopic threshold response (STR)

As illustrated in Figures 24.5 and 24.10, for very weak flashes from darkness, near psychophysical threshold in humans,^{27,89}

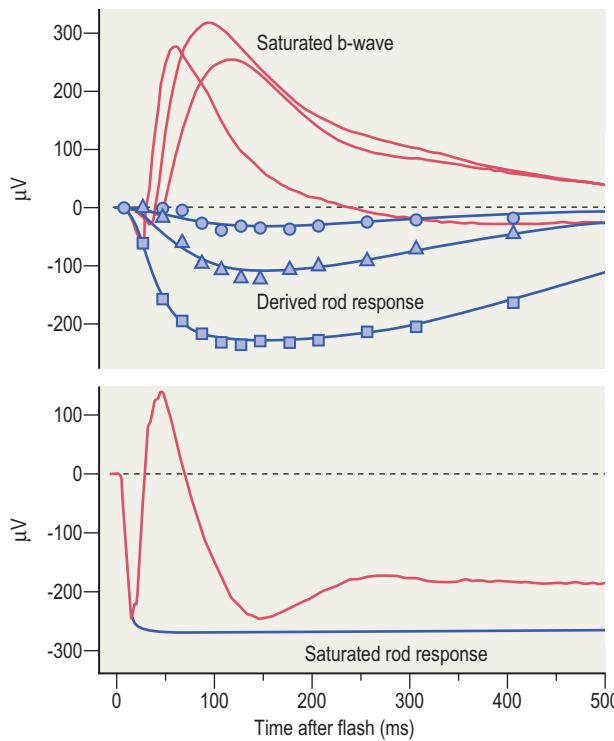

Figure 24.9 Derived rod photoreceptor response from the dark-adapted ERG of a macaque monkey. **Top:** ERG responses of a macaque are shown to three test stimuli (0.28, 1.24, and 6.86 sc td.s). The photoreceptor response was derived using the paired flash technique of Pepperberg et al.⁸⁰ a rod saturating probe flash followed a test flash at fixed intervals after its onset, and the residual response to the probe was subtracted from the probe alone response to derive the rod receptor response at each time point (data points). **Bottom:** ERG response to a stimulus of 2.6 log sc td.s for which the rod photoreceptor response was saturated. Model lines in this and the upper plot were generated using equations modified from Robson et al.⁵⁵

the nSTR and pSTR dominate the ERG of most mammals studied. The nSTR was shown in intraretinal analyses in cat to be generated more proximally in the retina than PII.²⁷ In non-invasive recordings, the p and nSTR can be suppressed and thus separated from PII, using a weak adapting background, inhibitory neurotransmitters (GABA, as illustrated in Figs 24.10 and 24.11, or glycine).⁹⁰ Blockade of inotropic glutamate receptor antagonists (see legend to Fig. 24.11), or use of an agonist for N-methyl-D-aspartate (NMDA) receptors present on inner retinal neurons, also remove the STRs.^{86,91} The effects of GABA on the pSTR in mouse (measured at 110 ms after the flash), and the nSTR (measured at 200 ms) are shown in Figure 24.10B and D respectively. In both cases, after GABA injection the remaining responses can be modeled as the PII component alone.

The plots in Figure 24.10B and D include a linear model of the dark-adapted ERG that takes into account contributions not only from PII, but also from the pSTR, nSTR (and PIII) components of the mouse ERG. These components add together to form the ERG response (blue solid line) at a particular time after the stimulus flash. The model assumes that each ERG component (dashed and red lines) initially rises in proportion to stimulus strength, and then saturates in a

characteristic manner, as has been demonstrated in single cell recordings in mammalian retinas^{70,92} as well as for a- and b-waves in numerous other studies. To isolate PII at higher stimulus strengths when the photoreceptor contribution to the ERG is significant (see Fig. 24.9), the PIII (photoreceptor) component must be removed. A model line for PIII is shown in Figure 24.10B and D for the higher stimulus strengths.²⁶

The neuronal origins of the nSTR and pSTR are species-dependent. In macaques, the nSTR may originate predominantly from ganglion cells; it was eliminated in severe experimental glaucoma with selective ganglion cell death, whereas the pSTR remained.⁴³ In contrast, in rodents the pSTR was eliminated in mice and rats by removing ganglion cells (optic nerve crush (ONC) or transection and subsequent degeneration) and in mice in which ganglion cells were deleted genetically, whereas the nSTR was only partially removed in rat, and of normal amplitude in mice.^{22,93–95} In cat (and human) the nSTR also survives ganglion cell loss,⁹⁶ and in cat, it has been demonstrated that nSTR generation involves K⁺ currents in Müller cells.²⁴

Mice lacking connexin 36 gap junction proteins (Cx36) provide additional insights to the neuronal origins of the STR. Cx36 is expressed in the electrical synapses (gap junctions) between All amacrine cells, All amacrine cells and ON cone bipolar cells as well as between the rod and cone terminals.^{82,97} In the scotopic ERG of mice with Cx36 genetically deleted, pSTR remains, whereas the nSTR is absent.⁴⁴ Because Cx36 is essential for transmission of ON pathway signals to ganglion cells in the primary rod pathway,⁸² preservation of the pSTR in Cx36(−/−) mice suggests that the pSTR, shown to be ganglion cell related in rodents, must depend upon activity of OFF, rather than ON ganglion cells. The nSTR, in contrast, depends on the syncytium of All amacrine cells and their electrical synapses with ON cone bipolar cells, no longer functional in Cx36-deficient mice. Figure 24.11A includes an example of PII isolated from the scotopic ERG of a Cx36(−/−) mouse (already lacking the nSTR) but also lacking the pSTR, due to a ganglion cell lesion subsequent to ONC. This isolated PII is very similar to PII isolated pharmacologically or by light adaptation, as well as to the rod bipolar cell recordings from the retinal slice.

Because of their specific inner retinal origins, the n- and pSTRs are of particular interest in animal models of diseases that affect the inner retina, such as glaucoma. They provide non-invasive readouts of pathologic changes in function, and can be used to document effects of neuroprotective agents.^{22,43,98}

Light-adapted, cone-driven ERGs

Isolating cone-driven responses

To study the cone-driven (photopic) flash ERG, rods must be suppressed, or unable to respond due to characteristics of the stimuli selected. Typically for recording photopic ERGs, rods are rendered unresponsive by imposing a steady background light sufficient to saturate their responses (i.e. >25 cd.m⁻²). Another approach is to briefly saturate rod responses, and to wait for cones to recover. Cones recover more quickly than rods: in primates, in about 300 ms

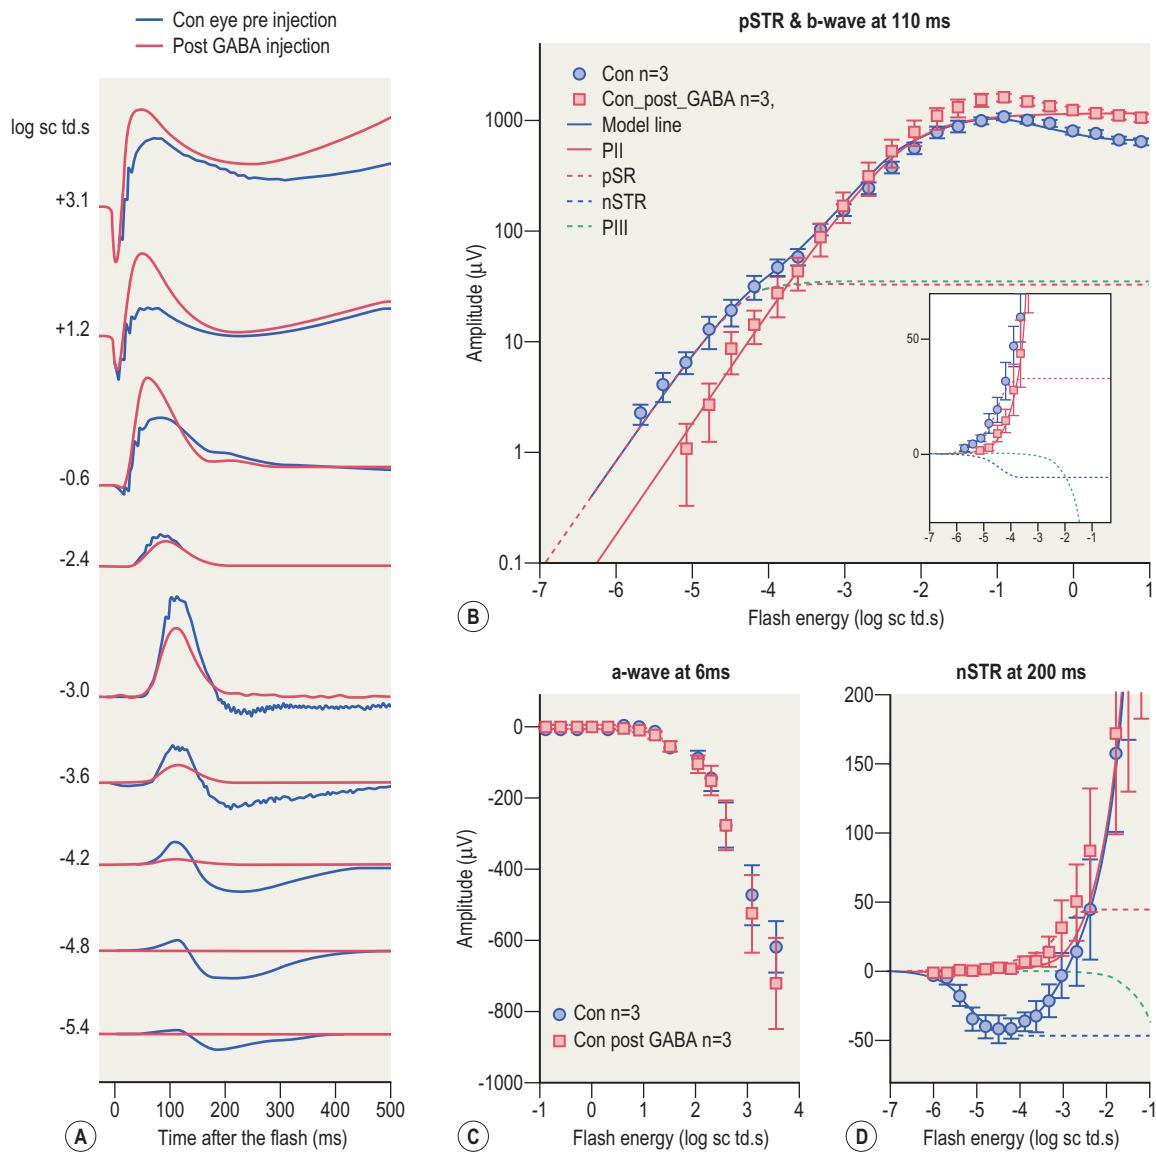

Figure 24.10 Dark-adapted mouse ERG before and after intravitreal injection of GABA: analysis of ERG components. (A) ERG of a C57BL/6 mouse in response to brief flashes of increasing stimulus strength recorded before and after intravitreal injection of GABA (30 mM intravitreal concentration assuming for this and subsequent panels, a 20 μl vitreal volume in mouse). (B) ERGs of three mice measured at 110 ms (mean \pm SEM) after a brief flash, at the peak of the pSTR and b-wave. The modeled full ERG (blue line) includes four components: PII, pSTR, nSTR and PIII. All components are assumed to increase in proportion to stimulus strength before saturating. Explicitly, the exponential saturation of the pSTR, nSTR and PIII is defined by:

$$V = V_{\max} (1 - \exp(-I/I_o))$$

where V_{\max} is the maximum saturated amplitude, and I_o , the stimulus strength for an amplitude of $(1 - 1/e)V_{\max}$.

The hyperbolic relation used for PII is described by the function:

$$V = V_{\max} I / (I + I_o)$$

where V_{\max} has the same meaning as for the exponential function but I_o is the stimulus strength at which the amplitude is $V_{\max}/2$.²⁶

(C) ERGs measured at 6 ms after a brief flash, to measure a-wave amplitude on its leading edge. (D) ERGs measured at 200 ms to measure nSTR amplitude. Model lines for the full response and for component parts are as described for panel B.

as described above for results in Figure 24.8.⁵⁵ In mice and rats, the recovery time of cone signals is longer, about a second.^{93,99}

Rod and cone signals also can be separated by selection of appropriate stimulus wavelength. In trichromatic primates, L-cones can be isolated using red light, at wavelengths greater than 630 nm, and excluding wavelengths much lower. However mice and rats do not have L-cones, and the

spectral sensitivity of their medium wave-length M-cones peaks near 515 and 510 nm respectively^{99,100} and overlaps with that of rods, which peaks around 500 nm. Scotopic stimulus calibrations are thus adequate, and more appropriate than photopic calibrations (based on human spectral sensitivity) for the rodent M-cone responses. However, for any subject, spectral separation of responses of individual cone types is possible using ERG flicker photometry.¹⁰¹ In

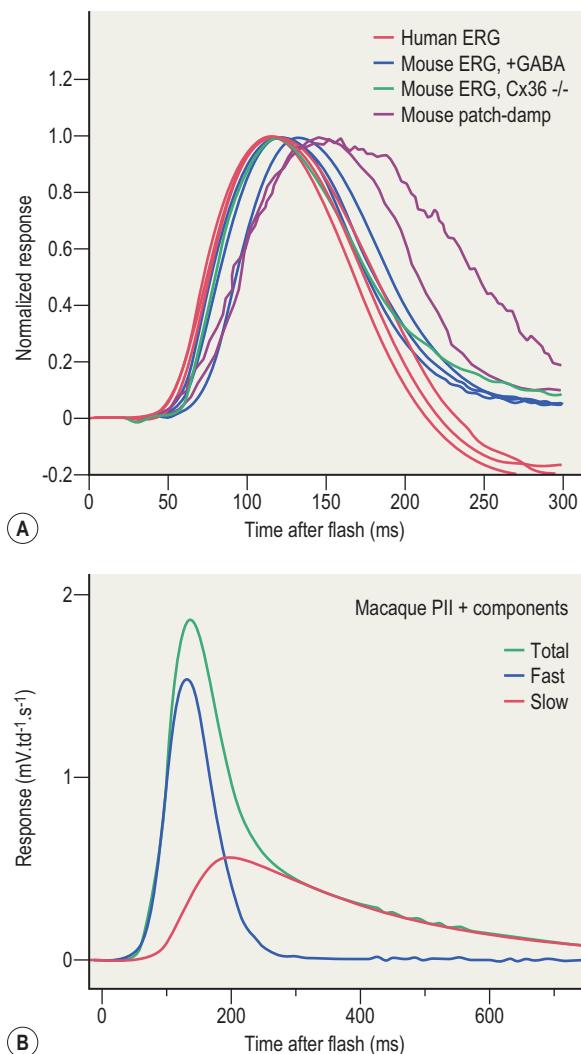

Figure 24.11 Rod bipolar cell component, PII, of the dark-adapted ERG of a human subject, macaque monkey and mouse.

(A) Comparison of rod bipolar cell current from patch recordings in mouse retinal slice (Field & Rieke, 2002) with isolated PII (by weak light adaptation) from humans, isolated PII from ERGs of six C57BL/6 mice by intravitreal injection of GABA (32–46 mM) and from a Cx36(−/−) mouse lacking ganglion cells. (From Cameron et al 2006,⁸⁴ which was modified from Robson et al 2004,⁸³ used with permission.) (B) PII of macaque, isolated by pharmacologic blockade [6,7-dinitroquinoxaline-2,3-dione (DNQX), 0.1 mM; N-methyl-D-aspartic acid (NMDA, 3 mM)] of inner retinal responses. PII has been analyzed into a fast component, proposed to be a direct reflection of the post-synaptic current, and a slow component that is a low-pass filtered version of the faster component, believed to be the Müller-cell contribution. (From Robson & Frishman 1998,¹⁶ and unpublished observations.)

mice and rats such studies have isolated short-wavelength UV (S-) cones that peak around 358 or 359 nm.^{100,102}

Separation of rod and cone signals in mice can also be achieved using genetically manipulated models in which either rods or cones have been inactivated. Examples of such models include: Rho(−/−) (rod opsin knockout) mice which have cone function only, but also eventual cone degeneration¹⁰³, Tra(−/−) (transducin α knockout) with cone function only¹⁰⁴, Cnga3(−/−) (cone cyclic nucleotide channel deficient) mice⁴ or GNAT 2^{cpfl3} (G_T protein) mutant mice with rod function only.¹⁰⁵ Mice with inactivated or degenerated

rods and cones, i.e. rodless, coneless mice,¹⁰⁶ can be used to study function of a more recently identified photoreceptor pigment, melanopsin, found in a small population of retinal ganglion cells. Contributions to ERGs from melanopsin-driven responses are thought to be minimal.¹⁰⁷

Figure 24.12 shows photopic ERG responses to brief stimulus flashes on a rod-saturating background for human, macaque monkey, and mouse. As shown above for the dark-adapted ERG, the responses to brief flashes are similar in man and macaque. In mice, however, the b-wave rises more slowly to its peak, does not return to baseline as early, and OPs are more prominent. Very strong stimuli produce more prolongation of responses in mice, and produce larger OPs (inset on the right of Fig. 24.12) than in primates. For macaques, a second peak after the b-wave, probably an OFF pathway response (i-wave),¹⁰⁸ emerges, and in some cases (not shown) more of the response is below the baseline level.

Light-adapted a-wave

The a-waves in the photopic ERG are smaller than those in the scotopic ERG, reflecting the large difference in retinal densities of cones vs rods. In human and macaque about 5 percent of the photoreceptors are cones, and only up to 3 percent in mice, and fewer in rats are cones. In addition, use of glutamate analogs has shown that much of cone-driven a-wave is postreceptoral in origin. Results of using glutamate analogs in macaques^{109,110} are illustrated in Figure 24.13. The a-wave was reduced in amplitude by the ionotropic glutamate receptor antagonist PDA (*cis*-2,3-piperidine-dicarboxylic acid) (and kynurenic acid, KYN, not shown) that block kainate and AMPA receptors of OFF bipolar and horizontal cells as well as cells of inner retina. In contrast, APB, which eliminates the b-wave, did not reduce the amplitude of the leading edge of the a-wave. Figure 24.13 also shows that PDA had a similar effect to that of aspartate, used to block all glutamatergic transmission, or to cobalt (Co²⁺), used to block voltage-gated Ca²⁺ channels that are essential for vesicular release of the neurotransmitter glutamate, for signal transmission to postreceptoral neurons.

PDA-sensitive postreceptoral neurons, rather than cones, or APB-sensitive ON bipolar cells (and more proximal cells receiving ON signals), were found to generate the leading edge of the a-wave for the first 1.5 log units of increasing flash strength that elicited a cone-driven a-wave in macaque, reaching an amplitude of 10–15 µV in experiments of the studies illustrated in Figure 24.13.¹⁰⁹ Postreceptoral cells continued to contribute 25–50 percent of the leading edge of the a-wave for higher stimulus strengths when cone photoreceptor contributions also were present. The relative sizes of the postreceptor and receptor-driven portions of the photopic a-wave were modeled in Figure 24.8 for cone-isolated responses in the macaque dark-adapted ERG-based results after PDA. Responses up to ~5 ms after the flash in Figure 24.8 were cone photoreceptor responses, as indicated by the blue model line.⁵⁵

Experiments in mouse to investigate the origins of the photopic a-wave yielded similar results to those in macaque. PDA-sensitive responses dominated the leading edge of the a-wave for the initial 1.5 log units, and at least half of the response to stronger stimuli. Photoreceptor

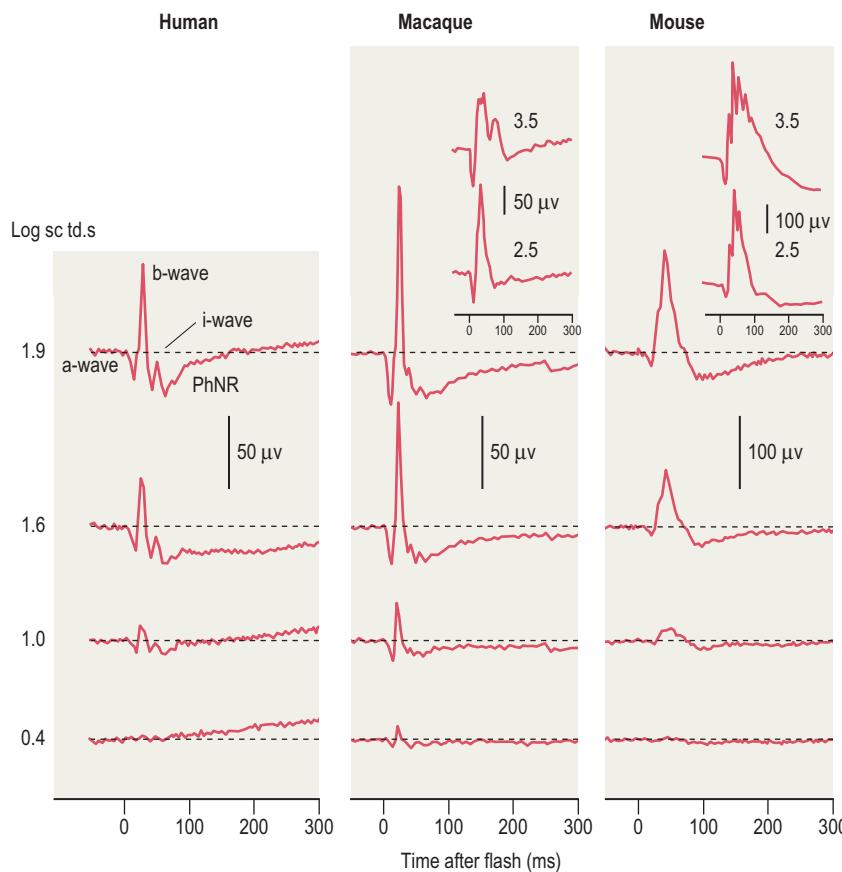

Figure 24.12 Light-adapted full-field ERG of a human subject, macaque monkey and mouse.

ERGs measured in response to brief (<5 ms) white LED flashes for primates, green for mouse, except for insets for the macaque and mouse showing responses from different subjects to white xenon- flashes. Steady background was 100 sc cd.m⁻² for primates, 63 sc cd.m⁻² for mice. (Unpublished observations.)

signals were present in response to strong flashes up to 8 ms after the flash. A significant portion of the a-wave also was removed by NMDA, which suppresses responses of inner retinal neurons, indicating contributions to the leading edge of the a-wave from more proximal neurons in the OFF pathway (unpublished observations, Maeda, Kaneko, and Frishman).

Light-adapted b-wave

Intraretinal recording studies described above for studying origins of the dark-adapted ERG, indicated a bipolar cell origin for light-adapted b-waves, but ON cone bipolar cells, rather than rod bipolar cells were implicated.^{46,111} Origins of the photopic b-wave also were studied in the same series of experiments in macaques as those illustrated in Figure 24.13. Figure 24.14A, top right, shows the macaque photopic ERG response to long-duration flashes, before and after intravitreal injection of APB (eye 1, left).¹¹⁰ APB removed the transient b-wave, supporting a role for ON bipolar cells in generating the response (although the possibility of glial mediation was not eliminated in these studies). In contrast, when PDA was injected first (Eye 2, right), to remove OFF pathway and inner retinal influences (and horizontal cell inhibitory feedback), the b-wave was larger in amplitude and the maximum amplitude was sustained for the duration of the stimulus. These findings indicate that cone-driven b-waves in primates are normally transient because they are truncated by (PDA-sensitive) OFF pathway contribution of opposite polarity to the ON bipolar cell contribution (a

push-pull effect^{109,110}), or by inhibitory feedback via cones from horizontal cells.^{110,112} Only an isolated photoreceptor response of slow onset, but more rapid offset, remained after all postreceptor activity was eliminated, either by APB followed by PDA, or PDA followed by APB.

The outcome in mouse of parallel experiment to that in Figure 24.14A to determine origins of the photopic b-wave is shown in Figure 24.16B. The figure shows that the control response to a 200 ms stimulus in a C57BL/6 mouse is different from that in primates, and in fact, the b-wave looks similar to the response in macaque after PDA. APB removed the b-wave in the mouse, but did not reveal a d-wave, only a tiny positive intrusion was present.^{113,114} Similar results have been observed in rat.¹¹⁵ PDA injection in mouse produced only a small increase in b-wave amplitude; but it removed OPs, and the small positive intrusion. APB combined with PDA left a negative ERG of slower onset than in the normal ERG due to removal of the leading edge of the a-wave. The slow recovery of the isolated photoreceptor-related response, compared to that of the macaque, was due to the presence, in mouse, of slow PIII in the ERG.¹¹⁶

Recent studies in mice and rats found that TTX significantly reduced the amplitude of the light-adapted b-wave.^{93,116} This finding is consistent with presence of TTX-sensitive voltage-gated sodium channels in cone bipolar cells (in rats).¹¹⁷ In macaques, in contrast, the light-adapted b-wave amplitude increased, rather than decreased after TTX, probably due to removal of the negative-going photopic negative response (PhNR) which originates from spiking neurons in inner retina.^{28,108,112}

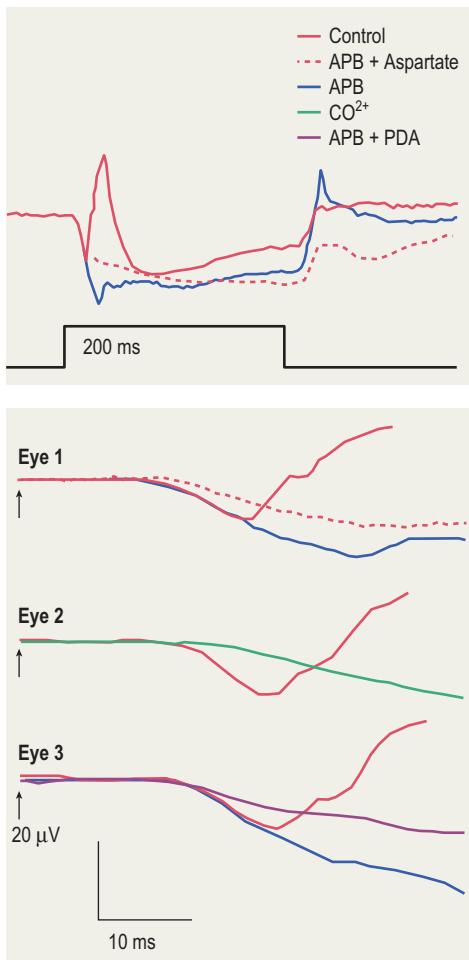

Figure 24.13 Postreceptoral contributions to the a-wave of the macaque monkey ERG. Comparison of effects of intravitreally injected L-2-amino-4-phosphonobutyric acid (APB, 1mM) and APB+PDA (5 mM) with effects of aspartate (ASP, 0.05 M) and cobalt (Co^{2+} , 1 mM); on photopic a-waves of three different eyes of two macaques. The inset at the top shows the control response of eye #1 to the 200 ms stimulus of $3.76 \log \text{td}$ (100 cd.m^{-2}) on a steady background of $3.3 \log \text{td}$ (35.5 cd.m^{-2}). The a-waves are shown below on an expanded time scale. For the stimulus used, the a-wave leading edge ($10 \mu\text{V}$) was mostly postreceptoral in origin.

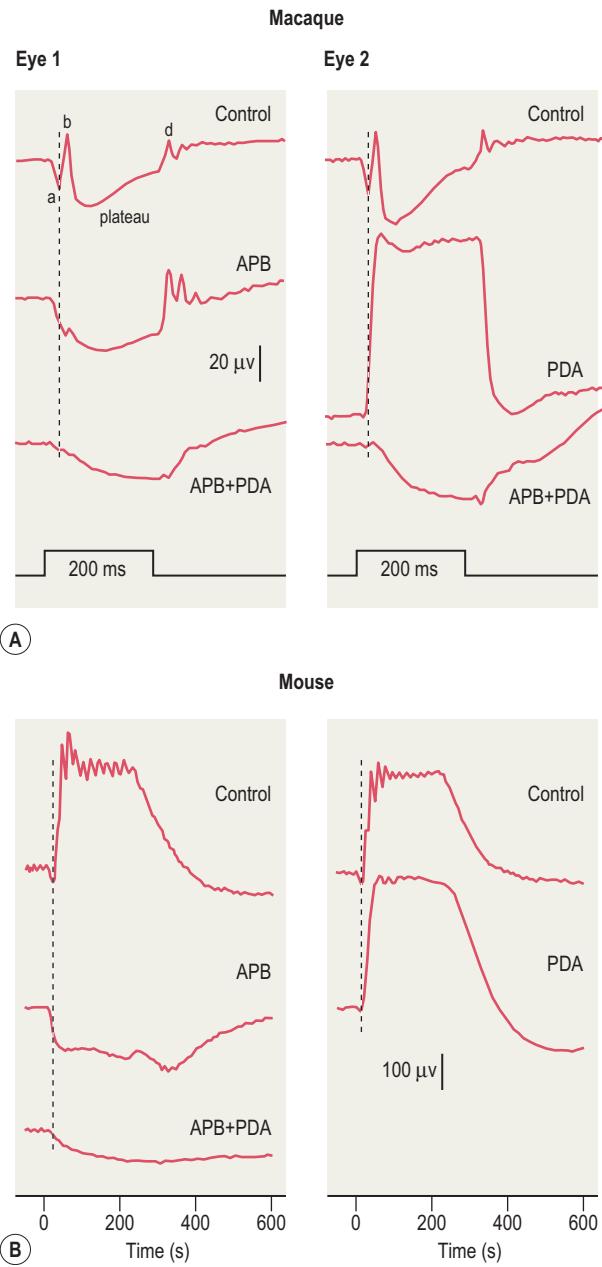

Figure 24.14 Effects of APB and PDA on the light-adapted ERG of macaque monkey and mouse. (A) Macaque: Intravitreal injections were given in two different eyes sequentially: APB followed by PDA for eye 1, and PDA followed by APB for eye 2. The vertical line shows the time of the a-wave trough in the control response. The 200 ms stimulus and drug concentrations were the same as reported for Fig. 24.15. (From Bush & Sieving 1994,¹⁰⁹ used with permission from Association for Research in Vision and Ophthalmology.) (B) Mouse: Control ERG and response after intravitreal injection of APB (1 mM) and PDA (0.5 mM)+ APB in a C57BL/6 mouse. The 200 ms stimulus was $4.6 \log \text{sc td}$ ($3.9 \log \text{cd.m}^{-2}$) on a steady background of $2.6 \log \text{sc td}$ (63 cd.m^{-2}). (From Shirato & Frishman, unpublished.)

Light-adapted d-wave

The d-wave is a positive-going wave at light offset that is a characteristic of the photopic ERG. The d-wave is prominent in all-cone retinas, but also can be seen in the photopic ERG of the mixed rod–cone retina of man and macaque monkey for stimulus durations of 150 or 200 ms, as shown in Figures 24.2A and 24.14A. As described above, the mouse (and rat) photopic ERG does not include a d-wave in response to offset of light flashes of only a few hundred ms in duration.^{114–116}

Intraretinal analysis in monkey retina initially indicated that d-waves represent a combination of a rapid positive-going offset of cone receptors followed by the negative-going offset of the b-wave.^{66,67,118} However intravitreal injection of glutamate analogs in macaques revealed a prominent role, at light offset, for OFF cone bipolar cells as well, in generating d-waves (see Fig. 24.14).^{110,119} The relatively

slower offset of cone photoreceptor responses in rodents may explain, in part, the lack of d-waves for stimuli that elicit them in primates. The lack of d-waves in rodents is not due to differences in relative numbers of ON and OFF cone bipolar cells in rodents and primates, the proportions are similar.¹²⁰

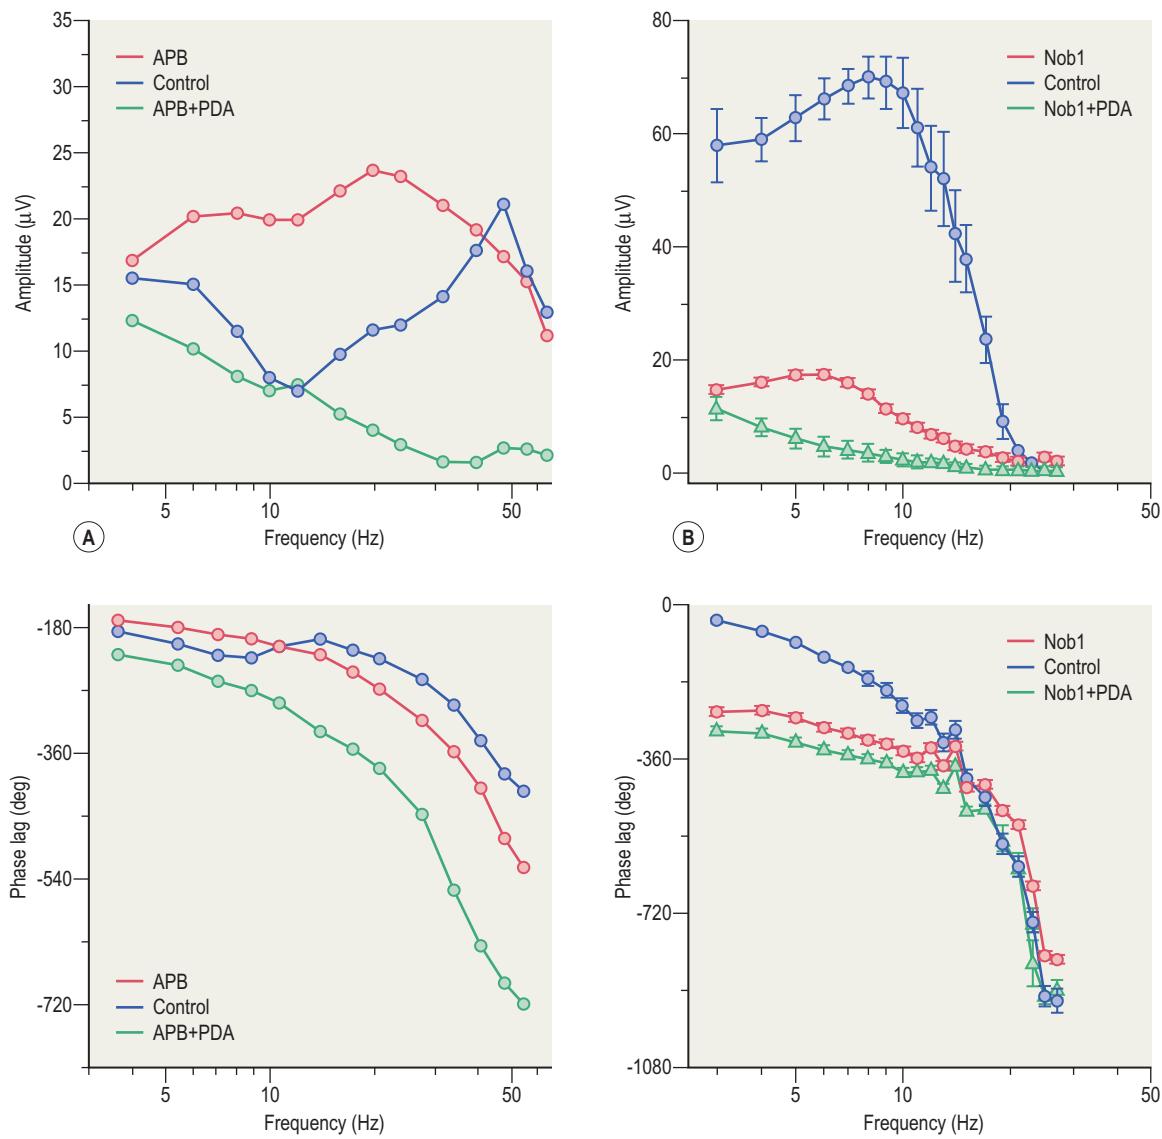

Figure 24.15 Amplitude and phase of the temporal frequency response of the light-adapted ERG in macaque monkey and mouse.

(A) Flicker ERG response of three macaques (mean \pm SEM) to sinusoidal stimulation before and after pharmacological separation of ON and OFF pathway components of the fundamental response. Flicker mean luminance was 457 cd.m^{-2} ; 80 percent contrast, on a 40 cd.m^{-2} white background. Blue circles: control; red circles: after APB (1mM); green circles: after APB + PDA, 5mM. (From Kondo 2001,¹²³ used with permission.) (B) Flicker ERG responses of three C57BL/6 mice (mean \pm SEM) and three *Nob1* mice to sinusoidal stimulation. Mean luminance was 63 cd.m^{-2} , 100 percent contrast. Blue circles: fundamental response of control; red circles: *Nob1* mice; triangles: *Nob1* mice after intravitreal injection of PDA (5.2–6.2 mM). (From Shirato et al 2008,¹¹³ used with permission from Association for Research in Vision and Ophthalmology.)

Flicker ERG

The fast flicker ERG (nominally 30 Hz flicker) is used to assess the health of cone-driven responses in humans because rod-driven responses do not respond to such fast flicker, resolving up to about 20 Hz. It is a particularly valuable test for monitoring residual cone function in degenerative diseases, such as retinitis pigmentosa. Studies using APB and PDA in macaques have shown that most of the fast flicker response (e.g. Fig. 24.1) is generated by postreceptorial cells in ON and OFF pathways.^{121,122} Intravitreal injection of APB, to block the b-wave, left a delayed peak that was practically eliminated by addition of PDA to block OFF pathway responses.

The interactions of ON and OFF pathways in flicker ERGs have been examined in macaque over a wide range of temporal frequencies.¹²³ The typical temporal frequency response function of the photopic ERG of the macaque, illustrated in Figure 24.15A, is similar to that seen in humans.¹²⁴ Response amplitude dips at frequencies around 10–12 Hz before rising to a maximum amplitude around 50 Hz. Injections of APB and PDA revealed that the dip is due to cancellation of contributions to the response at different phases from ON and OFF pathways. Other experiments demonstrated small more proximal retinal contributions to the flicker responses, at the fundamental frequency of stimulation, and prominent TTX-sensitive contributions to the second harmonic component of the response that peaked around 8 Hz.¹²²

Flicker ERGs in mice differ from those in primates in several ways. The frequency response for the primary rod pathway in mice extends up to 30 Hz and secondary rod pathway responses up to 50 Hz.⁸¹ These ranges overlap substantially with the range for cone pathway responses shown in Figure 24.15B for a control C57BL/6 mouse.^{81,113,124} The overlap of rod- and cone-driven frequency responses means that flicker cannot easily be used in rodents to selectively stimulate cone-driven responses. The lower photopic frequency response of mice relative to primates is due at least in part to the slower recovery of cone photoreceptors in mice.¹¹³ Figure 24.17B also shows the frequency response of *Nob1* mice that lack ON pathway responses. The low amplitude of responses in *Nob1* mice indicates that OFF pathway contributions to the light-adapted frequency response are smaller in mice than in primates. The figure also shows that ON and OFF pathway responses do not interact to cancel responses at midrange frequencies in mice. Similar to macaques, however, the photoreceptors, whose contribution was isolated by injection of PDA, contributed only a small signal.¹¹³ Second harmonic responses in C57BL/6 mice, that peak around 17 Hz, were found to be greatly reduced either by loss of ON pathway responses,¹¹³ or injection of TTX.

Oscillatory potentials

Oscillatory potentials (OPs) in flash ERG responses to strong stimuli consist of a series of high-frequency, low-amplitude wavelets superimposed on the b-wave. OPs are present under dark- and light-adapted conditions. The mixed rod-cone flash ERG of a human (Fig. 24.1 top): includes at least four OPs that can be extracted by filtering the response to remove frequencies lower than ~75 Hz signals. The number of wavelets varies between four and ten depending upon stimulus conditions; the temporal characteristics of OPs vary as well. As an example, a recent study described dark-adapted OPs in humans as ranging in frequency from 100 Hz or less to more than 200 Hz, with a peak around 150 Hz for moderate stimulus strengths, but closer to 100 Hz for the strongest stimuli.¹²⁵ Light-adapted OPs also can include a high-frequency band peaking around 150 Hz, but have a lower-frequency band peaking that peaks around 75 Hz and extends to frequencies of about 50 Hz, below the low-frequency cutoff (75 Hz) for isolating OPs recommended by ISCEV.

There is consensus, from experiments in amphibians and mammals, that OPs are generated by inner retinal neurons,³⁰ making them useful for evaluating inner retinal function. However the discrete origins of different OPs, numbered in order from the first to occur, and mechanisms of their generation, are not well understood. Intraretinal studies using stimuli that elicited responses from both rod and cone systems in macaques localized OPs, as a group, to inner retina.³¹ For a brief light flash, the major OPs in the photopic ERG were found to be APB-sensitive, indicating an origin in the ON pathway, but later OPs in the brief flash response, and at light offset for longer duration stimuli were found to originate from OFF pathway.^{126,127} TTX reduced amplitudes of later OPs more than early ones in rabbits, but this finding has not been consistent across species.^{127,128} Inhibitory neurotransmitters glycine and GABA suppress OPs in monkeys and other mammals, as do ionotropic glutamate receptor antagonists that block transmission of signals from bipolar

cells to amacrine and ganglion cells. Consistent with this, PDA removed OPs from the mouse light-adapted ERG illustrated in Figure 24.16B. GABAergic involvement is limited to specific receptor types; genetic deletion of GABA_C receptors in mice enhanced amplitudes of the OPs,¹²⁹ whereas blockade of GABA_A receptors removed OPs in C57BL/6 mice (unpublished observations).

Although the observations described above indicate involvement of amacrine or retinal ganglion cells in generating OPs, the role of ganglion cells has been controversial. Loss of OPs after ganglion cell death has not been observed consistently across species, making amacrine cells more likely generators. Reductions in OPs have been reported in conditions such as diabetic retinopathy that compromise inner retinal circulation, but not ganglion cell function selectively. However, in Ogden's studies in macaques, optic nerve section and subsequent ganglion cell degeneration lead to disappearance of the OPs.¹³⁰ Further, in the macaque photopic "flash" ERG studies of macular regions (using a multifocal stimulus), both severe experimental glaucoma and TTX removed a high-frequency band of OPs (centered at 143 Hz), while a lower-frequency band (at 77 Hz) remained intact.^{128,131} In contrast, OPs were still present in full-field dark-adapted ERGs.⁴³

The mechanisms for generating OPs are likely to involve both intrinsic membrane properties of cells and neuronal interactions/feedback circuits. Oscillatory activity has been observed most frequently in amacrine cells (ACs). For example, GABAergic wide-field ACs (WFAC) isolated from white bass retina generated high-frequency (>100 Hz) oscillatory membrane potentials (OMPs) in response to extrinsic depolarization.¹³² These OMPs were shown to arise from "a complex interplay between voltage-dependent Ca²⁺ currents and voltage- and Ca²⁺-dependent K⁺ currents".¹³²

A feedback mechanism is consistent with effects on OPs of GABA and glycine, both of which participate widely in feedback circuits in inner retina, e.g. between amacrine cells and bipolar cells or other amacrine cells (see Chapter 23). A feedback model has been proposed to account for high-frequency oscillatory (or "rhythmic") activity seen in some mammalian ganglion cell recordings from whole retina that involves electrical synapses, indicated by tracer coupling patterns, as well as inhibitory feedback circuits between amacrine and ganglion cells.¹³³

OPs are more prominent in mice than in primates or rats. Peak temporal frequencies of OPs, in dark-adapted C57BL/6J mice range from 100 to 120 Hz or higher, as in humans, whereas they are about 70–85 Hz in light-adapted mice.¹³⁴ In rats where OPs are much smaller overall, two frequency bands of OPs have been reported for dark-adapted ERG, one peaking around 70 Hz and the other, more like other species, around 120–130 Hz. In the light-adapted ERG, only the lower-frequency band is present, similar to the findings in mice.¹³⁵ In mice and rats, OPs under dark- and light-adapted conditions are present at frequencies lower than common in primates, i.e. down to 50 Hz, and in mice small OPs can occur at frequencies as low as 30–40 Hz.¹³⁴

Photopic negative response

A slow negative wave after the b-wave, called the photopic negative response (PhNR) can be seen in the light-adapted

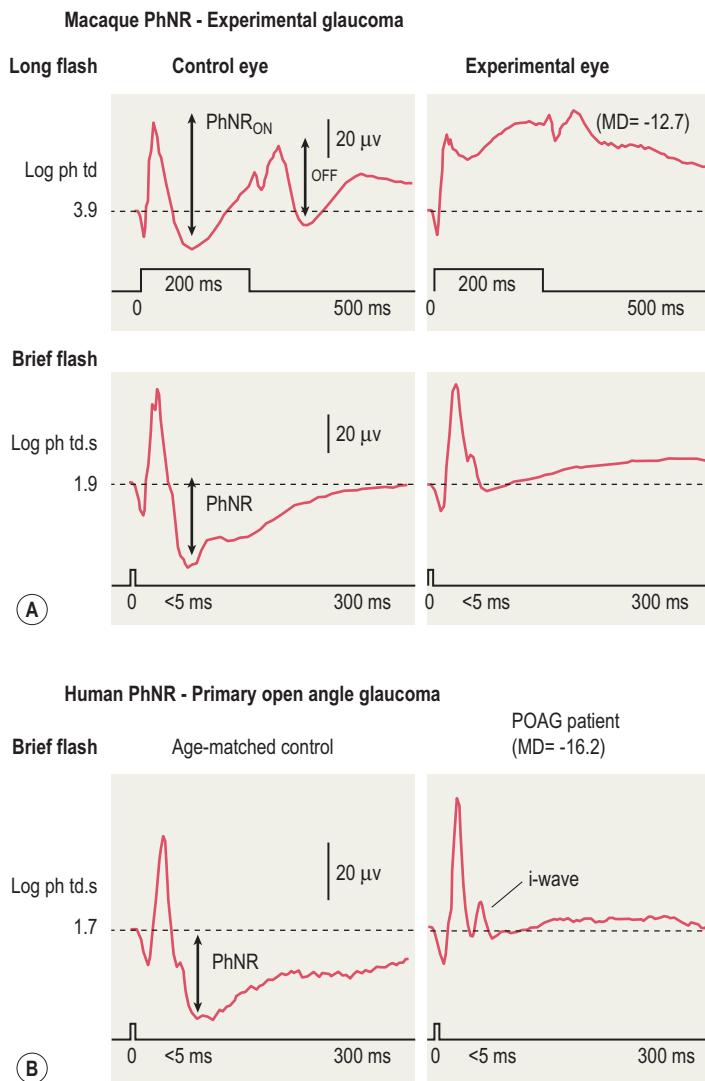

Figure 24.16 Photopic negative response (PhNR) in macaque monkey and human in normal and glaucomatous eyes.

(A) Full-field flash ERG showing the PhNR of a macaque in response to long (top) and brief (middle) red LED flashes on a rod saturating blue background (3.7 log sc td) from the control (left) and “experimental” (middle) fellow eye with laser-induced glaucoma, and the difference between control and experimental records (right). Arrows mark the amplitude of the PhNR. (Adapted from Viswanathan et al 1999,²⁸ used with permission from Association for Research in Vision and Ophthalmology.)

(B) Full-field flash ERGs of an age-matched 63-year-old normal human subject and a patient with POAG under similar stimulus conditions to those used above for monkeys. (Adapted from Viswanathan et al 2001,²⁹ used with permission from Association for Research in Vision and Ophthalmology.)

ERG, more prominently in primates than in mice and rats. In humans and monkeys the PhNR is thought to reflect spiking activity of retinal ganglion cells.^{28,29,122} As shown in Figure 24.16, the PhNR is reduced in macaque eyes with experimental glaucoma (or after TTX injection),²⁸ and in humans with primary open angle glaucoma (POAG).²⁹ It also is reduced in several other disorders affecting the optic nerve head and inner retina. The slow timecourse of the PhNR suggests glial involvement, perhaps via K⁺ currents in astrocytes in the optic nerve head set up by increased [K⁺]_o due to spiking of ganglion cells. PhNRs can be evoked using white flashes on a white background, if the flash is very bright. However a red LED flash on a blue background, as was used for responses in Figure 24.16, elicits PhNRs over a wider range of stimulus strengths. The red flash may minimize spectral opponency that would reduce ganglion cell responses, and use of a blue background suppresses rods while minimizing light adaptation of L-cone signals.¹¹² The PhNR can be exaggerated relative to other major ERG components using slowed focal stimuli confined to the macula.¹³⁶

In rodents, with relatively fewer ganglion cells than in primates, the PhNR is small, and probably originates mainly

from amacrine cells. It is reduced in amplitude by TTX, PDA blockade of block transmission to inner retina in rats and mice, NMDA to suppress inner retinal activity,¹³⁷ but not by loss of ganglion cells in mice, as shown in the inset to Fig. 24.17,¹¹⁶ or rat.⁹³ Glial involvement in generation of the PhNR in rodents is likely. In Royal College of Surgeons rats, a large photopic ERG negative response develops in the degenerating retina,¹³⁷ due at least in part to increased density of Kir4.1 channels in Müller cell endfeet. These channels are critical for producing glial currents that contribute to the ERG.^{14,15}

Pattern ERG

A common technique for assessing ganglion cell function is to record a pattern ERG (PERG). The stimulus is usually a contrast-reversing checkerboard or grating pattern for which changes in local luminance occur with each reversal, but the mean luminance remains constant. This causes the linear signals that produce a- and b-waves to cancel, leaving only the non-linear signals in the ERG. Non-linear signals that compose the PERG are known to depend upon

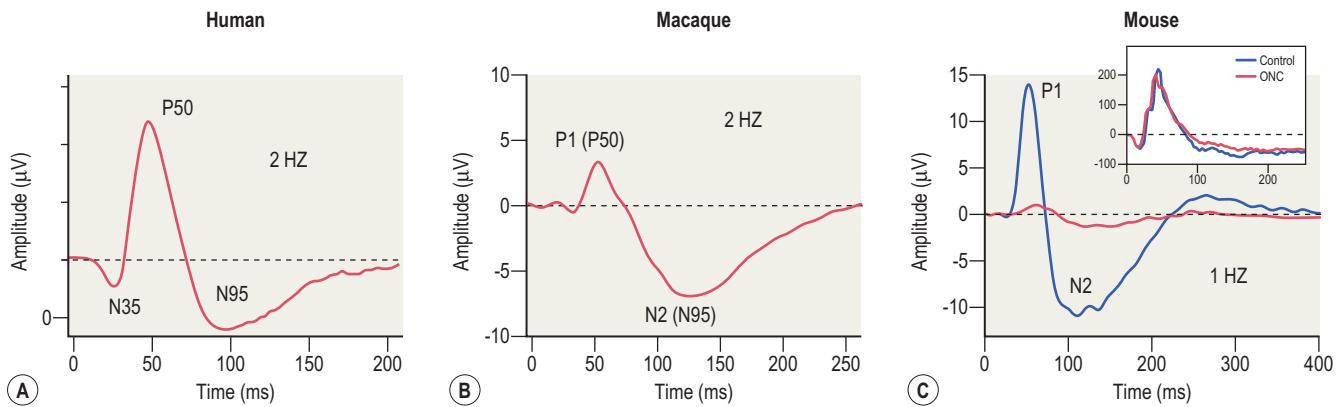

Figure 24.17 Transient pattern electroretinogram (PERG) of human, macaque monkey and mouse. (A) Representative transient PERG of a normal human subject, elicited with a contrast-reversing checkerboard pattern (0.8 deg checks), mean luminance $>80 \text{ cd.m}^{-2}$, modulated at 2 Hz, 100 percent contrast. Amplitude for normal humans ranges from 2 to 8 μV , according to the "ISCEV standard for clinical pattern Electroretinography 2007 update" from which the figure was adapted. (From Holder et al 2007,⁹¹ used with permission.) (B) Transient PERG of a macaque, elicited with a checkerboard (0.5 deg checks), mean luminance of 55 cd.m^{-2} modulated at 2 Hz, 84 percent contrast. (Unpublished, Luo & Fishman.) (C) PERG of a C57BL/6 mouse before (blue line) and 40 days after (red line) unilateral optic nerve crush (ONC) when ganglion cells had degenerated. The pattern was a 0.05 c/deg horizontal bar grating, mean luminance 45 sc cd.m^{-2} , contrast-reversed at 1 Hz, 90 percent contrast. Inset shows brief flash ERGs for the same eye: 57 cd.s.m^{-2} flash on a 63 sc cd.m^{-2} background before (black line) and 40 days after (red line) ONC. (From Miura et al 2009,¹¹⁶ used with permission.)

the functional integrity of retinal ganglion cells. PERGs are eliminated, while a- and b-waves of the flash ERG are still present (e.g. see Fig. 24.17), following optic nerve section or crush that causes degeneration of ganglion cell axons and subsequently, their cell bodies in several mammals. Initial studies done in cat¹³⁸, were extended to monkey¹³⁹, rodents^{116,140–143} and a human with accidental nerve transection¹⁴⁴.

The PERG has been used widely in clinical studies assessing ganglion cell function in eyes with glaucoma and other diseases that affect inner retina (see reviews by Holder¹⁴⁵ and Bach and Hoffman).¹⁴⁶ The PERG can be a sensitive test in early glaucoma when visual field deficits are minimal.^{146–148} It shares this attribute with the PhNR which has similar retinal origins to the PERG in macaque.¹²²

The PERG is also useful for study of rodent models of glaucoma. The DBA/2J mouse model of inherited glaucoma has normal ganglion cell numbers at 2 months of age, and progresses to massive retinal ganglion cell degeneration by 12–14 months.¹⁴⁹ This is reflected in the PERG which is of normal amplitude in young DBA/2J mice, whereas it is practically eliminated in older mice.¹⁴³ Because the PERG is a non-invasive measure it can be used in these mice and other rodent models of glaucoma to track progression of ganglion cell loss as well as to document effects of therapies to slow progression and protect neurons.

PERGs can be recorded as transient responses to low reversal frequencies, 1–2 Hz, or as steady state responses to higher frequencies, e.g. 8 Hz. The transient PERG has prominent early positive and later negative waves, named respectively, P50 and N95 (see Fig. 24.17) in humans, denoting the timing of the peak and trough following each pattern reversal.⁹¹ Both waves reflect ganglion cell activity, although P50 may include some non-spiking input.¹⁵⁰ The early positive (P1) and later negative (N2) component (Fig. 24.17) in the mouse transient PERG, different in exact timing, but have similar general appearance to P50 and N95 in primates.^{116,143}

Multifocal ERG

The multifocal ERG (mfERG) provides a technique for simultaneously recording local ERG responses from many small retinal regions, typically 60 or 103, over 35–40 degrees of the visual field. Focal ERGs from individual regions are recorded in some clinics and labs,¹⁵¹ but sampling more than a couple of regions is time consuming. Figure 24.18A illustrates the stimulus and mfERG records from a normal human subject. The individual hexagons of the stimulus were reversed in contrast following a pseudorandom (m-) sequence which is shifted in time uniquely for each sector to enable extraction via correlation of individual responses.^{152,153} The reversal rate was locked to the frame rate of the visual stimulator, 75 Hz for CRTs, 60 Hz for LCD. Each hexagon had a 50 percent chance of reversing contrast on each frame change. The test is usually done under light-adapted conditions, for which the foveal response is large, allowing changes in function, such as occur in Stargardt's disease, or other macular dystrophies to be easily seen. The scotopic mfERG, rarely attempted, was found to be more susceptible than light-adapted recordings, to effects of scattered light.¹⁵⁴ Dark-adapted recordings in rodents required use of large focal regions,¹⁵⁵ and although difficult, some light-adapted recordings in rodents have been possible.¹⁵⁶

Studies using glutamate analogs have shown that despite different methods of generation and response timing of the mfERG, the cellular origins of the major positive and negative waves are essentially the same as the light-adapted flash ERG; see Figure 24.18B.¹⁵⁷ This was the case for the standard fast mfERG, as well as when the stimulus presentation was slowed by interleaving blank frames between m-steps, to allow the full ERG to form.¹⁵⁸

A small optic nerve head component from axons of retinal ganglion cells may also be observed in the mfERG, especially when stimuli are arranged to optimize the response.^{159,160}

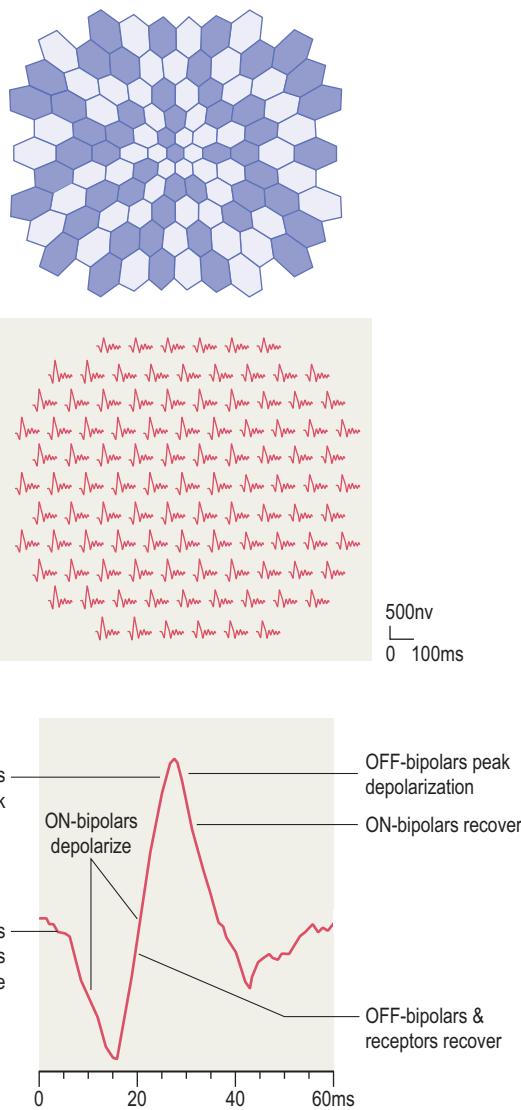

Figure 24.18 Multifocal electroretinogram (mfERG) and its major components. (A) mfERG trace array (field view) using 103 hexagons scaled with eccentricity and covering about 35 deg of visual angle, as illustrated above the traces. (From Hood et al 2008,¹⁶² used with permission.) (B) Model for the retinal contributions to the human mfERG based on results from the macular region of a macaque after pharmacological separation of components. (From Hood et al 2002,¹⁵⁷ used with permission from Association for Research in Vision and Ophthalmology.)

The optic nerve head component is the likely generator of high-frequency oscillatory potentials in the slow sequence mfERG that are reduced in experimental glaucoma in macaques.^{128,131}

Closing comments

The ERG provides a means for non-invasive evaluation of normal and abnormal retinal function in humans and in animal models. Its value as a test has increased as we have better understood the retinal circuits involved and mechanisms of generation for each wave. Our current understanding of the origins of the ERGs recording in standard testing, and in more specialized testing, as reviewed in this chapter, are summarized in Boxes 24.2 and 24.3 respectively.

Box 24.2 Retinal Cells Contributing to the Flash and Flicker ERG in Standard Clinical Testing

a-wave	Photoreceptors Dark-adapted a-wave: rods Light-adapted: cones Late postreceptoral contributions from OFF cone (hyperpolarizing): HCB bipolar cells and more proximal cells in the OFF pathway
b-wave	Bipolar cells Dark-adapted b-wave, rod bipolar cells (RBC) Light-adapted b-wave, ON cone (depolarizing: DCB), OFF cone bipolar cells, and horizontal (Hz) cell feedback via the cones
d-wave	Bipolar cells Mainly a light-adapted response: OFF cone bipolar cells, offset of cone photoreceptors, and offset of ON cone bipolar cells The d-wave is not present in mice and rats
Oscillatory potentials (OPs)	Amacrine and ganglion cells, bipolar cell terminals?
'30 Hz' fast flicker	Bipolar cells ON and OFF cone bipolar cells, and a small cone photoreceptor contribution

Box 24.3 Retinal Cells Contributing to the ERG in Specialized Testing

Scotopic threshold response	Inner retinal neurons
pSTR	Amacrine cells (monkey) Retinal ganglion cells (rodents)
nSTR	Retinal ganglion cells (monkey) Partially retinal ganglion cells (rats, human?) Amacrine cells (All) (mice) Partially amacrine cells (rats, human)
Photopic negative response (PhNR)	Glia currents Retinal ganglion cells (human, monkey) Amacrine cells (rodents) Glia currents
Pattern ERG (PERG)	Retinal ganglion cells (human, monkey, rodent) Glia currents (transient PERG: N95, N2?)
Multifocal ERG	Initial negative and positive waves have similar origins to a- and b-waves in photopic ERG (monkey, and presumably human)

Regulation of Light through the Pupil

Randy Kardon

The pupillary opening appears to occupy a central location, but if carefully measured, it is actually situated slightly inferior and nasal to the center of the cornea. Thus, the pupil center may not correspond exactly to the optical axis defined by a target viewed in the distance and the fovea. The major functions of the pupil are outlined in [Figure 25.1](#) and are summarized as follows.

First, pupil movement in response to changing light intensity aids in optimizing retinal illumination to maximize visual perception. In dim light, dilation of the pupil provides an immediate means for maximizing the number of photons reaching the retina, which in turn supplements the slower dark adaptive mechanisms involving retinal gain control at the photoreceptor and bipolar cell level. With exposure to bright light, pupil constriction can reduce retinal illumination by up to 1.5 log units within 0.5 seconds. Although this reduction in retinal illumination is only a portion of the 12 log unit range of light sensitivity of the retina, it provides an important and immediate means for light adaptation.⁴⁷ Patients with a fixed immobile pupil are usually symptomatic during an abrupt change in illumination; they may be photophobic when they are subjected to sudden increases in light, and they may not be able to discern objects in their environment when they first enter dim lighting conditions. These symptoms are described by patients with an immobile pupil because compensatory retinal photoreceptor adaptation is not fast enough. This emphasizes the important role of the pupil in optimizing visual perception in a timely fashion over a wide range of lighting conditions of the environment.

Second, the diameter of the pupil can also contribute to improving (up to a point) the image quality of the retina when the steady-state pupil diameter is small. A small pupil reduces the degree of chromatic and spherical aberration.^{10,57} Part of the reason is that a smaller aperture size limits the light rays entering the optical system to the central cornea and lens, avoiding more peripheral portions of the cornea and lens, where aberrations are greater ([Box 25.1](#)).

Third, a small pupil increases the depth of focus of the eye's optical system, similar to the known pinhole effect of camera lenses used for photography.⁹ When a subject views objects at near, not only the accommodation power of the eye changes but the near response of pupil contraction helps

bring objects into better focus by increasing the depth of focus afforded by the smaller aperture size.

Besides the physiologic functions of the pupil explained earlier and outlined in [Figure 25.1](#), the pupil diameter and its movement under different conditions also provide an important indicator used for clinical assessment of a patient. The clinical aspects of pupil function ([Fig. 25.2](#)) ([Box 25.2](#)) consist of (1) pupil movement as an objective indicator of afferent input, (2) pupil diameter as an indicator of wakefulness, (3) pupil inequality as a reflection of autonomic nerve output to each iris, (4) the influence of pupil diameter on the optical properties of the eye, and (5) the pupil response to drugs as a means of monitoring pharmacologic effects.

Inequality of the pupils, termed *anisocoria*, is another important clinical state of the pupils because it may represent autonomic nerve interruption to the iris from the sympathetic or parasympathetic nervous system, direct damage to the iris sphincter or dilator muscle, or pharmacologic exposure of the iris to mydriatic or miotic drugs. The clinical significance of anisocoria and the various causes of it are covered in more detail later in this chapter.

Large pupils may produce clinically significant visual symptoms in the form of aberrations in form and color of images, particularly at night or after dilating drops, when pupil diameter is largest. A large immobile pupil resulting from scarring, dilating drops, or damage to the iris sphincter muscle or its nerve supply may produce extreme sensitivity to light. This is because the normal function of the pupil in controlling retinal illumination is impaired.

The pupil may be used clinically as a pharmacologic indicator of peripheral or central drug effects. With topical delivery of drugs into each eye with eye drops, the sensitivity of the iris sphincter or dilator muscle can be compared between the two eyes because, under normal conditions, the two eyes should be matched in their response. Dilute concentrations of cholinergic or adrenergic drops, which normally cause little, if any, pupil response, may produce asymmetric exaggerated mydriasis (adrenergic, sympathomimetic drugs) or constriction (cholinergic, parasympathetic drugs) if the iris has been deprived of its nerve innervation for as little as a few days. In cases of unilateral oculosympathetic nerve damage, topical drugs such as cocaine or apraclonidine may be used to confirm the diagnosis. Once the diagnosis of an

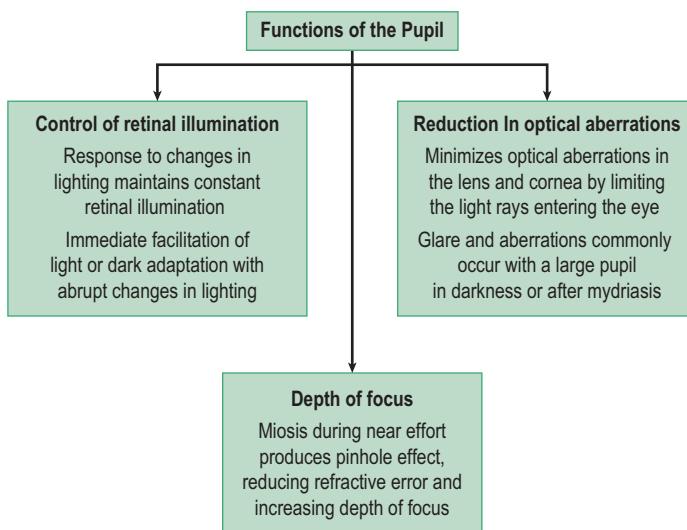

Figure 25.1 Functions of the pupil include control of retinal illumination, reduction in optical aberrations, and improved depth of focus.

Box 25.1 Optics and the pupil

After refractive surgery, younger patients, who usually have larger pupils in dim light compared with older individuals, often experience bothersome symptoms of glare and image degradation, especially at night, as a result of optical aberrations.

The area of the pupil is large enough in these patients to exceed the corneal optical zone of refractive surgery. Most refractive surgeons attempt to address this problem by carefully measuring the pupil diameter in dim lighting conditions preoperatively and then adjusting the optical zone of corneal refractive surgery according to pupil diameter.

Topical drops that produce miosis may reduce pupil diameter enough in dim lighting conditions (without affecting accommodation) to alleviate the symptoms of aberration.

There is a limit to the beneficial optical effects of a small pupil because constriction beyond a certain diameter results in image degradation as a result of increased diffraction and reduction of retinal illumination below an optimal level.¹¹ Therefore there exists an optimal range of pupil diameter for vision, and this size may vary somewhat, depending on the individual optical characteristics of a person's eye.

oculosympathetic lesion is confirmed, hydroxyamphetamine drops may be used a few days later to localize the lesion to the preganglionic or the postganglionic site along the sympathetic nervous system chain (covered in more detail later in this chapter). The pupil response to topical inhibitors of narcotics (naloxone) has also been used to study the effect of narcotic tolerance in addicted individuals. Pupillary responses to psychosensory stimuli has also been used in a laboratory setting to aid in the diagnosis and monitoring of treatment in psychiatric disorders such as depression and schizophrenia and as an objective indicator of cognitive function.

In this chapter the physiology of the normal pupil is discussed, and examples of abnormalities of pupil function are also shown to apply knowledge of normal pupil physiology to understanding various pathologic states. The reader who

is interested in pursuing these subjects in much greater detail is advised to consult the excellent book by Loewenfeld.⁴²

The neuronal pathway of the pupil light reflex and near pupil response

To understand the major factors that can affect the diameter and movement of the pupil to various stimuli, it is important to know the basic neuronal pathway for the pupil light reflex and near response. This is schematically depicted in Figure 25.3. The pupil light reflex consists of three major divisions of neurons that integrate the light stimulus to produce a pupil contraction: (1) an afferent division, (2) an interneuron division, and (3) an efferent division.

The afferent division consists of retinal input from photoreceptors, bipolar neurons, and ganglion cells. Axons of retinal ganglion cells from each eye provide light input information that is conveyed by synapses to interneurons located in the pretectal olfactory nucleus of the midbrain. In turn, these interneurons distribute pupil light input to neurons in the right and left Edinger-Westphal nuclei through crossed (decussating) and uncrossed (non-decussating) connections. From here, the neurons of the Edinger-Westphal nucleus send their preganglionic parasympathetic axons along the oculomotor nerve to synapse at the ciliary ganglion in each orbit. The neurons in the ciliary ganglion give rise to postganglionic parasympathetic axons that travel in the short ciliary nerves to the globe (suprachoroidal space), where they synapse with the iris sphincter muscle.

The pupil constriction to a near stimulus involves activation of neurons in the rostral brainstem that relay their signal to the same Edinger-Westphal neurons that are activated in the light reflex. Therefore the efferent pathway for the near pupil constriction is the same as for the light reflex, but the input pathway to the Edinger-Westphal nucleus differs.

The integration of the pupil light reflex and pupil near response, including the anatomy of the involved neurons, their receptive field properties, and their response to various attributes of light stimuli, has been recently reviewed.²⁸

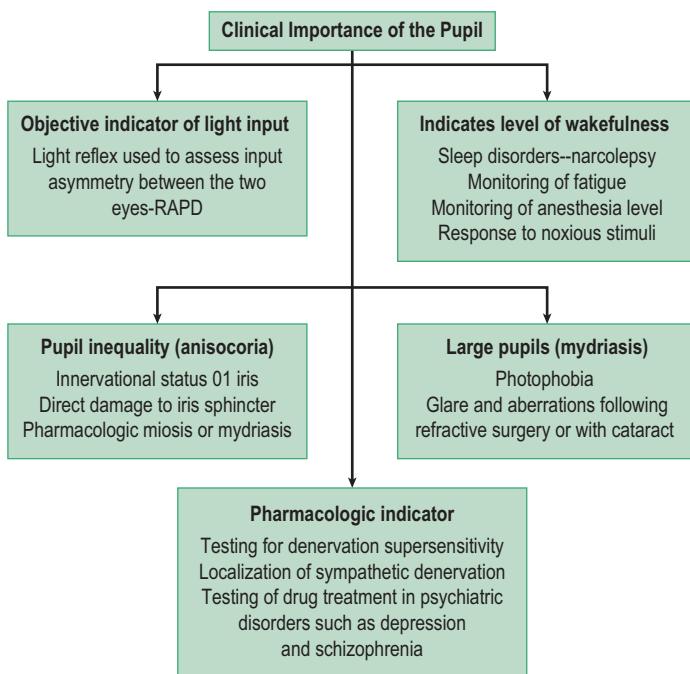

Figure 25.2 Clinical importance of the pupil. RAPD, Relative afferent pupillary defect.

Box 25.2 Diagnosis and the relative afferent pupillary defect

The amount of transient pupil contraction to a light stimulus or the steady-state diameter of the pupil under constant illumination can reflect the health of the retina and optic nerve and may be used to detect disease.

The most common clinical test for assessing input asymmetry between the two eyes is the alternating light test, commonly referred to as the swinging flashlight test. As a light is alternated back and forth between the right and left eyes, the clinician observes the pupil movements in response to the light.

If the two eyes are matched with respect to retinal and optic nerve input, the pupil movements appear similar when either eye is stimulated. However, if one eye's input has been diminished because of disease affecting the retina or optic nerve, the pupil responses to light shown in that eye become noticeably less during the alternating light test.

When this input asymmetry is observed during the alternating light test, it is called a relative afferent pupillary defect (RAPD); RAPDs are discussed in greater length in a subsequent portion of this chapter.

Pupil diameter can also be used to determine the extent of midbrain supranuclear inhibition, which is also related to an individual's state of wakefulness.

An excited, aroused person will have larger-diameter pupils because of the increase in central inhibition of the parasympathetic nerves innervating the iris sphincter, which originate in the midbrain, and the increase in sympathetic tone to the dilator muscle.

Conversely, a sleepy individual, a fatigued individual, or one under the influence of general anesthesia or narcotics will have smaller pupils as a result of central disinhibition at the level of the midbrain. Careful monitoring of the diameter of the pupil in this setting may be clinically useful for ascertaining the presence of sleep disorders such as narcolepsy, the level of anesthesia, or the presence of narcotics.

The extent of pupil dilation to sensory stimuli such as pain or sound may also serve as an objective indicator of how intact the sensory input is.

In the following sections, these neuronal pathways are summarized.

Afferent arm of the pupil light reflex

The neural integration of the pupil light reflex begins with the afferent pathway in the retina, consisting of the photoreceptors, bipolar cells, and ganglion cells. For many years, it was disputed whether it was the rods or cones that contribute to the pupil light reflex and whether these were the same photoreceptors as those contributing to visual perception. Extensive experimental and psychophysical work has shown that the neuronal pathways mediating the pupil light reflex and visual perception share the same photoreceptors. Until

recently, it was thought that all photoreceptor input was shared by both conscious perception of light and the pupil light reflex. In previous studies, almost all changes in light input producing a change in visual perception also produced a comparable change in pupil size. In fact, in almost every way measured, the pupil responses to light parallel those of visual perception. For example, the wavelength-sensitivity profile of pupil threshold for a small transient contraction as the color of light is changed from blue to red exactly parallels the same wavelength-sensitivity profile of visual perception. The shift in sensitivity is also the same as the eye is changed from a condition of light adaptation to dark adaptation (Purkinje shift), providing further evidence that the same photoreceptors are used for both pupil and vision.

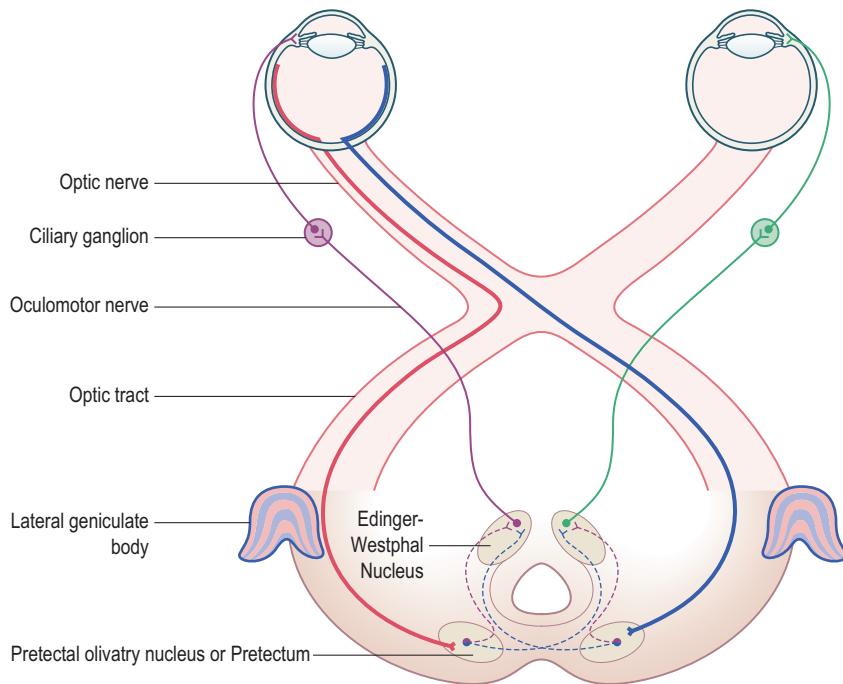

Figure 25.3 Diagram of the nerve pathways involved in the pupil light reflex. Afferent input from the nasal retina crosses to the contralateral side, and the pupil input from retinal ganglion cell axons exits the optic tract in the brachium of the superior colliculus to synapse at the pretectal olfactory nucleus. The temporal retinal input from the same eye follows a similar course on the ipsilateral side. The neurons in the pretectal olfactory nucleus send crossed and uncrossed fibers by way of the posterior commissure to the Edinger-Westphal nucleus on each side. From here, the preganglionic parasympathetic fibers travel with the oculomotor nerve and then synapse at the ciliary ganglion. The postganglionic parasympathetic neurons pass from the ciliary ganglion by way of the short ciliary nerves to the iris sphincter muscle.

Patients with various abnormalities of rods and cones can be shown to have the same deficits in color vision or lack of appropriate sensitivity change during dark adaptation when the results of visual threshold are compared with pupil threshold for small contractions to light stimuli.⁵⁰ Both rods and cones contribute to the pupil light reflex, but to a different extent depending on the lighting conditions.

Under conditions of dark adaptation and in response to low-intensity lights, the pupil light reflex becomes a sensitive light meter and is mediated primarily by rods, giving rise to low-amplitude pupil contractions. However, with brighter light stimuli and under conditions of greater light adaptation, the cones dominate most of the transient pupil light contractions. Therefore the rods are primarily responsible for the pupil's ability to give rise to small contractions in response to low-intensity lights under conditions of dark adaptation – they provide a high sensitivity to the pupil light reflex at low light levels, just as they do for visual perception. The cones provide the input responsible for the larger transient pupil contractions that are easily observed under direct clinical observation, occurring at suprathreshold levels of light, mainly under photopic conditions. Loewenfeld³⁷ has summarized the extensive literature on this subject and her text should be consulted by the reader desiring a more complete discussion of this topic. It is also believed that the bipolar cells, which receive input from the photoreceptors, are the same neurons providing input to the pupil light reflex as those mediating visual perception.

Although it appears that the pupil and visual systems share rod and cone photoreceptor input, a number of interesting observations in recent years has revealed a previously unrecognized and important new aspect of light transduction through the pupil pathway.

New evidence in the last few years has shown that the rod and cone input to the pupil light reflex is mediated by a

special class of retinal ganglion cells containing the primitive visual pigment melanopsin found in the retina of lower animals.^{60–71} Besides being activated by rod and cone input causing a transient pupil response, the melanopsin retinal ganglion cell is also directly sensitive to light, providing a sustained steady-state pupil constriction to light. This intrinsic, direct activation pathway of the melanopsin-containing retinal ganglion cells causes the cell to discharge in a sustained way and is directly proportional to steady-state light input, similar to a DC light meter, which does not show classical light adaptation properties. In genetically altered mice that completely lack functional rods and cones, it was discovered that a rather robust pupil light reflex was still present. This unexpected finding was followed by a series of studies to identify what retinal element could be contributing to the pupil light reflex in the absence of rod and cone input. Through clever labeling experiments, a specific ganglion cell was identified containing melanopsin, which was itself photosensitive, with a broad spectral peak centering on about 490 nm, which is blue light. These melanopsin ganglion cells have been found to project both to the suprachiasmatic nucleus in the hypothalamus and also to the pretectal nucleus (the site of the first midbrain interneuron synapse for the pupil light reflex pathway (Box 25.3)).

Elegant electrophysiologic recordings coupled with the study of response properties of these ganglion cells have revealed that the melanopsin-containing retinal ganglion cells provide the midbrain pathway for the pupil light reflex and also provide light sensing information for the diurnal regulating areas of the hypothalamus that modulate the circadian rhythm. These melanopsin ganglion cells also receive rod and cone input to the pupil light reflex, but are also capable of transduction of light directly (under photopic conditions), without photoreceptor input, and may be responsible for providing more of steady-state light input to

Box 25.3 Melanopsin-containing retinal ganglion cells and the pupil

Activation properties of the melanopsin retinal ganglion cells via input from rods, cones or intrinsic light stimulus can be assessed in humans by recording pupil light reflexes at different wavelengths of light under scotopic and photopic states of retinal adaptation.

Application of the newly discovered physiology of the pupil light reflex may provide an objective clinical means of differentiating retinal from optic nerve disease and determining which class of photoreceptive neurons are being affected by disease.⁷³

Box 25.4 Dorsal midbrain lesions and the pupil

Damage to the posterior commissure from tumors compressing the dorsal midbrain from above (e.g. pinealomas) or from encephalitis (e.g. tertiary syphilis) may block the impulse pathway from the pretectal neurons to the Edinger-Westphal nucleus.

This situation can result in a loss of the pupil light reflex but spares the near pupil response (which originates from a more rostral location in the midbrain, before synapsing with the Edinger-Westphal nucleus), causing a light-near dissociation of the pupil.

the brain. This helps to explain why some patients blind from photoreceptor loss still exhibit both a pupil light reaction to bright blue light⁷² and also maintain a circadian rhythm, while patients blind from optic nerve lesions (loss of melanopsin ganglion cell input) often lack a normal circadian rhythm.

As stated earlier, the melanopsin-containing retinal ganglion cells appear to mediate the classic midbrain pathway of the pupil light reflex. However, there is also evidence that ganglion cells conveying visual information to the occipital cortex may also play a role in modulation of pupil movement in response to different types of visual stimuli. For example, patients with isolated occipital infarcts have homonymous visual field defects that show corresponding pupil defects to small (2 degrees in diameter) focal lights presented to the same cortically blind visual field area. This phenomenon has been reported previously, but only recently has the correspondence between the shape characteristic of the homonymous pupil and visual field defect been fully appreciated.^{1,3,4,12,20–23,26,30,44,46} This correspondence provides compelling evidence for a role of cortical mediation of the pupil light reflex when small, focal light stimuli are used. In addition, the pupil has also been shown to respond to changes in complex stimuli such as spatial frequency, motion, and contrast, providing additional evidence for a higher-level cortical process that is capable of mediating pupil contractions to visual stimuli.^{5,6,13,49,54,58,59} Such evidence implies that other types of ganglion cells, in addition to the classic luminance responding cells that project to the midbrain, may also participate in the pupil reflex, perhaps the same ones that also mediate visual perception.

The interneuron arm of the pupil light reflex

The ganglion cell axons conveying light input to the classic pupil light reflex pathway segregate from the rest of the ganglion cell axons at the distal portion of the optic tract before the lateral geniculate nucleus. As in the visual input pathway, the pupil ganglion cell axons from the nasal retina (temporal field) decussate at the chiasm to the opposite side, and the axons from the temporal retina (nasal field) stay on the same side. Therefore pupil ganglion cell axons from homonymous areas of the visual field (temporal field from the contralateral eye and nasal field from the ipsilateral eye) distribute within the optic tract. From there, they travel in the brachium of the superior colliculus and synapse in the

midbrain with the next neurons in the light reflex located at the olfactory pretectal nucleus. These neurons represent interneurons because they serve to integrate the afferent input coming from the retina with the efferent output of the pupil light reflex exiting the midbrain.

The receptive field properties of the pretectal neurons have been elucidated in the awake primate.^{18,19} These interneurons are the way-station for the converging receptive field impulses of the retinal ganglion cells from the retina and are fewer in number, summing the ganglion cell input at this location. The receptive field of each pretectal neuron has been found to receive input from ganglion cells over a large area of retina (up to 20 degrees). Some of these neurons exhibit a "flat" response, firing equally well from input over its entire receptive field. However, another subset exhibits a "foveal-weighted" response, discharging at a higher frequency when a stimulus is placed near the center of the visual field (and receptive field of the neuron). This may partly explain why the pupil light reflex appears to be more sensitive to light coming from the center of the visual field.

Patients with a relatively small area of damage to their central visual field have also been found to show an obvious decrease in the pupil light reflex in the affected eye compared with the fellow eye, which may relate to the receptive field properties of the pretectal interneurons. The pretectal neurons discharge at a frequency that is linear to the log of intensity of the light stimulus given. However, not all of these neurons respond in the same range; it appears that some are more sensitive in different ranges of intensities, so together, there is an interneuron response covering at least a 4 log unit range of input. Neurons in the pretectum send crossed and uncrossed fibers, through the posterior commissure, to the small population of neurons comprising the paired Edinger-Westphal nuclei. This allows afferent input from the pretectal nucleus on each side to be distributed almost equally to the pupil efferent pathway originating in the Edinger-Westphal nucleus (Box 25.4).

The uncrossed pathway appears to have evolved during development of binocularity and stereovision. Animals with eyes located more to the side of the head (e.g. birds, rabbits) have almost completely crossed pathways with no significant uncrossed component. That is why shining a light in one eye of these animals produces an almost totally crossed input to the pretectum, which then sends an almost completely crossed output to the Edinger-Westphal nucleus. The result is that only the pupil of the eye being stimulated will contract. Cats are between birds and primates in this

Box 25.5 Pupil-involving third nerve palsy

The pupillary preganglionic fibers are located on the superior aspect of the oculomotor nerve as it exits the midbrain, but soon come to lie on the medial aspect.³⁴

This is the reason aneurysms of the circle of Willis that lie in this area, such as aneurysms of the posterior communicating artery, often cause pupillary efferent deficits early on, because of the medial location of the artery with respect to the oculomotor nerve.

evolutionary respect, with approximately 70 percent of their pupil pathway crossed. Placing a pet cat so that one of its eyes points more toward a light produces a greater reaction of the pupil in the eye facing the light, causing an anisocoria. In humans, in whom the crossed and uncrossed pathways are almost equal, the direct and consensual pupil light reflex is equal. This is why illuminating one eye normally does not result in pupil inequality (anisocoria). Similarly, input deficits to one eye caused by damage to the retina or optic nerve should not normally produce an anisocoria in humans.

In some individuals the crossed pathway slightly exceeds the uncrossed pathway in both the retina and midbrain, leading to a slightly greater pupil response in the eye stimulated compared with the pupil contraction of the fellow eye, similar to cats, but not to the same extent. This consensual deficit, termed *contraction anisocoria*, is small and can usually be recognized only with the aid of pupillographic recordings.

The efferent arm of the pupil light reflex

The efferent arm of the pupil light reflex is diagrammatically summarized in Figure 25.4, which also shows the site of common lesions along this pathway that may be encountered in clinical practice. The neurons in the Edinger-Westphal nucleus send preganglionic axons into the right and left fascicle of the oculomotor nerve (third nerve) to join the motor axons destined for the eye muscles, as well as the preganglionic accommodative fibers that originate in nearby nuclei. The right and left fascicles of the third nerve exit the midbrain through the subarachnoid space, where each continues as the third nerve toward the orbital apex (Box 25.5).

After passing through the cavernous sinus to the orbital apex, the preganglionic pupillary fibers and accommodative fibers synapse in the ciliary ganglion (parasympathetic ganglion). A lesion at this site may produce an Adie's pupil. From here, the last neurons in the chain, the postganglionic neurons, pass into the eye by way of the short ciliary nerves, located in the suprachoroidal space, where they distribute to the anterior segment of the eye to innervate the iris sphincter muscle. The postganglionic accommodative fibers, which outnumber the pupil fibers 30:1, supply the ciliary muscle within the ciliary body of the eye. The postganglionic pupillary neurons appear to innervate the iris sphincter muscle in a segmental distribution over approximately 20 clock-hour sections. This is why lesions of the ciliary ganglion, such as in Adie syndrome, usually cause a number of sectors of the iris sphincter to become acutely denervated, with loss of the pupil contraction only in these segments (Box 25.6).

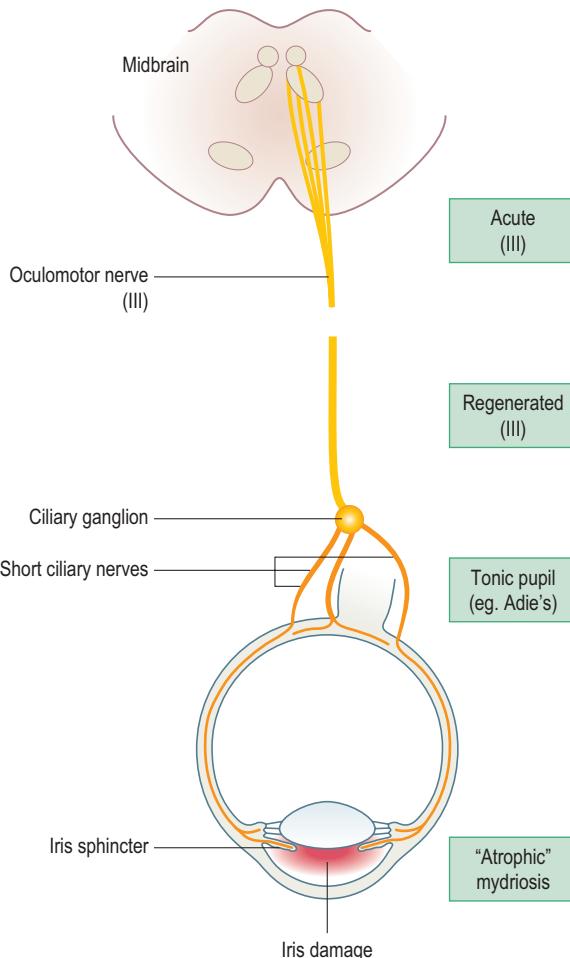

Figure 25.4 Innervation of the iris sphincter, from the Edinger-Westphal nucleus by way of oculomotor nerve, ciliary ganglion, and short ciliary nerves, with some of the causes of a fixed dilated pupil.

Box 25.6 Light-near dissociation

The postganglionic parasympathetic accommodative axons, which innervate the smooth muscle of the ciliary body, outnumber the postganglionic light reflex axons, which innervate the iris sphincter muscle in a ratio of 30:1.

Damage to the postganglionic parasympathetic axons can occur as a result of an Adie's pupil or trauma or after orbital surgery. After acute injury, the surviving nerve cell bodies within the ciliary ganglion sprout axons and grow toward the ciliary body muscle and the iris sphincter after about 8 to 12 weeks.

Because the accommodative cell bodies outnumber the pupil light reflex cell bodies, almost all of the axonal sprouts reaching the iris sphincter muscle originate from the accommodative cell bodies. This reinnervation of the iris sphincter is therefore aberrant because the pupil sectors that were denervated still do not respond to light, but they now contract in response to activation of the accommodative neurons, hence producing a light-near dissociation of the pupil reflex.

The pupil near reflex and accommodation

When fixation of the eye is shifted from a far to a near object of interest, the eyes converge, the intraocular lenses accommodate, and both pupils constrict. This triad of ocular vergence, accommodation, and pupil constriction is called the *near response*. Despite many contentions in the literature claiming that this pupil constriction is exclusively dependent on either convergence or accommodation, clinical and experimental data indicate that any one of the three functions can be selectively abolished or elicited without affecting the others. These experimental and clinical observations have resulted in general agreement that the impulses that cause accommodation, convergence, and pupil constriction must arise from different cell groups within the oculomotor nucleus and travel by way of separate fibers to their effector muscles. Accommodation, convergence, and pupillary constriction are associated movements and are not tied to one another in the manner usually referred to by the term *reflex*. They are controlled, synchronized, and associated by supranuclear connections, but they are not caused by one another. The components of the near pupil reflex were recently summarized.^{28,34}

The miosis of the near response and the pupillary constriction to light have a single final common efferent pathway from the Edinger-Westphal nucleus to the iris sphincter by way of the ciliary ganglion. They primarily differ in the origin of the supranuclear pathways that are elicited by light and near that both converge on the Edinger-Westphal nucleus. With a near stimulus, such as accommodation, the pupil normally constricts even with no change in retinal luminance. It is important to realize that this near reflex of the pupil is mediated by the same efferent nerve pathway originating from the same neurons in the Edinger-Westphal nucleus that mediate the pupil light reflex. There does not appear to be a separate neuronal efferent pathway that mediates the near pupil constriction.

However, the supranuclear control over this response is different from the one mediating the light reflex. In the case of the light reflex, the supranuclear input comes from the pretectal nucleus, as described in the previous section. In the case of the near reflex involving accommodation, convergence, and miosis, the supranuclear input is thought to originate from cortical areas surrounding visual cortex and from cortical areas within the frontal eye fields. The cortical neurons providing input for the near reflex are thought to synapse at least once, before passing ventral toward the visceral neurons overlying the oculomotor complex in the midbrain. This is because a cortical lesion in this area does not produce atrophy within the oculomotor nuclear complex (it is at least one synapse removed). It is also important to realize that the near reflex consists of convergence of the eyes, accommodation, and pupil contraction, all of which should be thought of as co-movements and, as stated earlier, are not strictly dependent on one another. Any one of the three co-movements may occur in the absence of the others, as discussed by Loewenfeld.³⁷ Because the supranuclear pathway for the near reflex passes ventral in the midbrain and the supranuclear pathway for the light reflex passes dorsal in the midbrain, the two systems may be differentially affected by disease processes (Box 25.4).

The supranuclear neuronal input from a near visual task stimulates the pupil constrictor neurons located in the

visceral part of the Edinger-Westphal nuclei. The same supranuclear neuronal input also stimulates the more numerous accommodative neurons, located nearby in the remaining visceral portion of the Edinger-Westphal nucleus. These preganglionic neurons give rise to accommodative axons that travel together with the pupil preganglionic light reflex neurons within the oculomotor nerve to synapse at the ciliary ganglion in the orbit (see previous section).

In summary, with a near stimulus, both the accommodative neurons (which mediate ciliary muscle contraction) and light reflex neurons (which mediate iris sphincter contraction) in the Edinger-Westphal visceral motor nuclei are stimulated from a supranuclear level. This gives rise to a separate neuronal output of accommodative and light reflex preganglionic neurons by way of the oculomotor nerve to the ciliary ganglion, which in turn gives off separate postganglionic innervation to the ciliary body and iris sphincter muscles. The preganglionic and postganglionic light reflex pathways make use of the same neurons to mediate pupil constriction to either near or light stimuli.²⁶

Pupil reflex dilation: central and peripheral nervous system integration

Normally, when the pupil dilates, two integrated processes take place: the iris sphincter relaxes, and the iris dilator contracts, helping actively pull the pupil open.^{38,39} Because the iris sphincter is stronger than the dilator muscle, pupil dilation does not readily occur until the sphincter muscle relaxes. Relaxation of the iris sphincter is accomplished by supranuclear inhibition of the Edinger-Westphal nucleus at a central nervous system level, most notably from the reticular activating formation in the brainstem. It appears from animal studies that this neuronal inhibitory pathway involves the central nervous system's sympathetic class of neurons. These sympathetic neurons pass through the periaqueductal gray area and innervate the pupil efferent neurons at the Edinger-Westphal nucleus and at the synapse there is an α_2 -adrenergic receptor activation.³⁵ When this central inhibition is active, the preganglionic parasympathetic output from the Edinger-Westphal nucleus is suppressed, resulting in a relative relaxation of the iris sphincter and pupil dilation. When this inhibition is inactive, such as during sleep, with anesthesia, or with narcotics, the preganglionic neurons fire at a high rate, causing miosis. The neurons of the Edinger-Westphal nucleus are unique in this respect because their baseline discharge frequency, without any input, is high. If all input to these neurons is disconnected, they fire at a high rate, which results in a sustained pupil contraction and miosis. This is why deep sleep or anesthesia, which reduces almost all inhibitory supranuclear input to the Edinger-Westphal nucleus, results in small pupils.

Alternatively, during a state of wakefulness, the supranuclear inhibition is active and the neurons of the Edinger-Westphal nucleus are suppressed, causing the pupils to become larger again. If a light stimulus is given at this point, a train of neuronal impulses from the retina and then the pretectal interneuron will arrive at the Edinger-Westphal nucleus, which momentarily overcomes this inhibition, causing the pupil to constrict. If the light is turned off or the retina begins to become light adapted, the supranuclear inhibition again dominates, causing a reflex dilation of the pupil.

Almost all of the conditions mentioned previously cause changes in pupil diameter resulting from the modulation of the neuronal output from the Edinger-Westphal nucleus. In addition, the same factors causing a reflex dilation of the pupil also result in an increase in output to the peripheral sympathetic nervous system innervating the iris dilator muscle. The sympathetic nerve activity can be thought of as a “turbo-charge” for pupil dilation. Peripheral sympathetic nerve activation is not a requirement for pupil dilation to occur (parasympathetic inhibition alone can accomplish that to some extent), but it greatly enhances the dynamics of pupil dilation in terms of speed and maximal pupil diameter attained.

The sympathetic outflow to the iris dilator muscle can be thought of as a paired three-neuron chain (Fig. 25.5) on both the right and left side of the central and peripheral nervous system without decussations. The first neuron originates in the hypothalamus and descends through the brainstem on each side into the lateral column of the spinal cord, where it synapses at the cervicothoracic level of C7–T2. The second preganglionic neuron leaves this level of the spinal cord and travels over the apical pleura of the lung and into the spinal rami to synapse at the superior cervical ganglion at the level of the carotid artery bifurcation on the right and

left side of the neck. The third neuron, the postganglionic neuron, follows a long course along the internal carotid artery into the head and orbit. As these neurons pass through the cavernous sinus, they are associated with the abducens and then the trigeminal nerve before entering the orbit and distributing to the iris dilator muscle via the long ciliary nerves.²⁵

In addition to the neuronal mechanisms involved in pupil dilation, humoral mechanisms also may contribute to pupil diameter. Circulating catecholamines in the blood (e.g. a bolus released from the adrenal glands) may act directly on the iris dilator muscle either through the bloodstream or, potentially, indirectly through the tears, resulting in mydriasis. Clinical conditions that influence the integration of the parasympathetic inhibition, sympathetic stimulation, and humoral release of neurotransmitters may take various forms and may affect the dynamics of reflex dilation in a characteristic manner that may be diagnostic of clinical conditions. This is revisited later in this chapter when pupil inequality and conditions that impede pupil dilation are discussed.

Other neuronal input to the iris

In addition to the autonomic nerves supplying the iris, sensory innervation to the iris is provided by the ophthalmic division of the trigeminal nerve.^{24,48} However, these sensory nerves may play an additional role in modulating pupil diameter. It is well known to cataract surgeons that mechanical and chemical irritation of the eye can cause a strong miotic response that is non-cholinergic and fails to reverse with autonomically acting drugs. In rabbits and cats the response seems to be caused by the release of substance P or closely related peptides from the sensory nerve endings, but in monkeys and humans, substance P has little or no miotic effect. Cholecystokinin (in nanomolar amounts) caused contraction of isolated iris sphincter from monkeys and humans.² Intracameral injections in monkeys caused miosis that was not prevented by tetrodotoxin or indomethacin, indicating that the miosis was not caused by either stimulation of nerve endings or release of prostaglandins but by direct action on sphincter receptors. The cholecystokinin antagonist lorglumide caused competitive inhibition of the response.

Structure of the iris

Iris sphincter, iris dilator, and iris color

It is important to understand the structure of the iris and its histology to understand how the iris tissue accommodates changes in pupil diameter during contraction and dilation and how disorders of the iris tissue affect pupil movement. The iris can be divided into two main layers: the posterior leaf and the anterior leaf (Fig. 25.6). The posterior iris leaf contains the dilator muscle, the sphincter muscle, and the posterior pigmented epithelium. From a front view of the iris, the dilator muscle is located circumferentially, in the midperiphery of the iris.

The sphincter muscle is located just inside the pupillary border; its circumference is made up of approximately 20

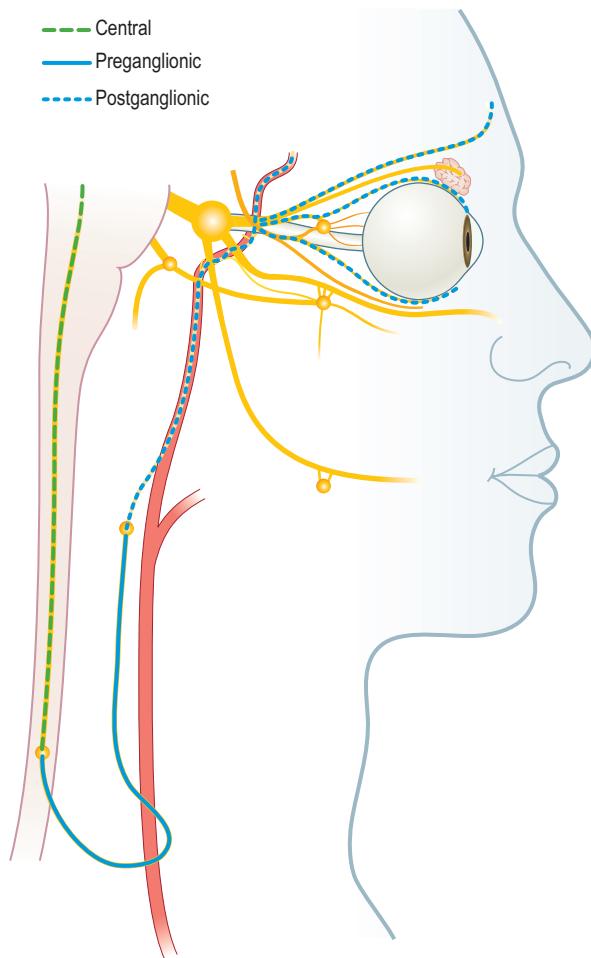

Figure 25.5 Sympathetic innervation to the eye, showing the three-neuron chain of central, preganglionic, and postganglionic fibers. (Modified from Maloney WF et al: Am J Ophthalmol 1980; 90:394.)

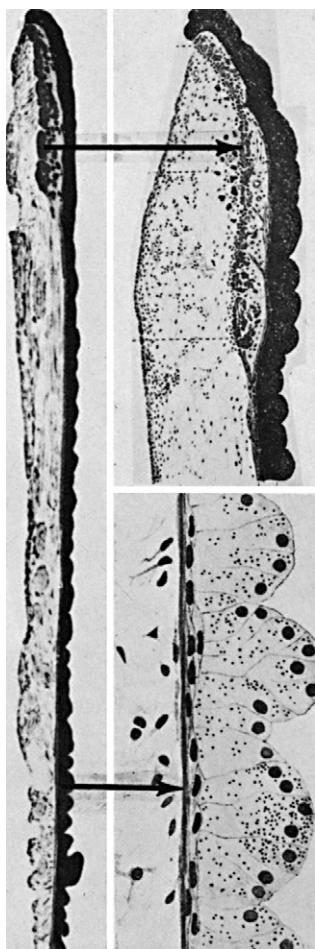

Figure 25.6 Histology of the iris in cross section. (From Saltzmann M: Anatomy and histology of the human eye-ball, Chicago: University of Chicago Press, 1912.)

motor segments connected together but innervated individually by postganglionic branches of the ciliary nerve. In the normal iris these segments receive nerve excitation in a roughly simultaneous fashion, and the entire circumference contracts in concert. Both the dilator and sphincter muscles are derived embryologically from the anterior layer of the two layers of posterior pigmented epithelium.

The more superficial, anterior iris leaf consists of connective tissue stroma with cells, blood vessels, and nerves supplying the sphincter and dilator, but there is no epithelial layer in primate species. The different components of the posterior and anterior iris undergo structural alterations to accommodate changes in pupil diameter during contraction and dilation.⁴⁵ These alterations in structure confer mechanical non-linearities influencing how much the pupil can constrict or dilate in response to changes in light or pharmacologic stimulus and was extensively studied by Loewenfeld.⁴⁰

The mechanical non-linearities are important because they impose limitations on the range of pupil diameter over which the extent of pupil movement can be used for assessing neuronal reflexes to light stimuli or near stimuli or for pharmacologic testing of the pupil. For example, a person

with small, 3-mm diameter pupils in dim light would obviously not show as large a pupil contraction to a standard light stimulus compared with a person with 5-mm diameter pupils, but the retina and optic nerves of both persons may be completely normal. A similar situation would occur if one attempts to quantify the response to a topical miotic or mydriatic agent. Therefore, the structure of the iris can pose physical constraints on pupil movement in response to sensory stimuli or pharmacologic agents, and this should be considered carefully when comparing the response in different eyes.

The color of the iris is determined by its mesodermal and ectodermal components. In Caucasians, the stroma is relatively free of pigment at birth. The stroma absorbs the long wavelengths of light, allowing the shorter (blue) wavelengths to pass through to the pigmented epithelium, where they are reflected back, causing the iris to appear blue. If pigmentation does not develop in the anterior stromal layers, the iris remains blue throughout life. If the stroma becomes denser and contains significant numbers of melanosomes, the blue color gives way to gray. The accumulation of pigment in the iris melanocytes of individuals destined to have non-blue irides occurs during the first year of life and is dependent on sympathetic innervation of the melanocytes (derived from neural crest cells). Interruption of the oculosympathetic nerve supply to one eye during this time period usually results in heterochromia, with the denervated iris remaining blue. In a heavily pigmented iris, the fine pattern of iris vessels is hidden by pigment and the surface of the iris looks brown and velvety.

Properties of light and their effect on pupil movement

Properties of light stimulating the retina that affect the pupil response include intensity, duration, temporal frequency, area, perimetric location, state of retinal adaptation, wavelength, and spatial frequency. There is a wealth of information on how these properties of light stimuli affect the pupillary response with regard to latency and amplitude of movement. Loewenfeld^{41,42} has presented the most complete review of this topic in her book on the pupil, which should be consulted for a detailed literature review and for examples illustrating these different light effects. In general, the amplitude of pupil movement increases in proportion to the log light intensity of the stimulus, whereas the latency time of the pupil light reflex (time from stimulus onset to beginning of pupil contraction) becomes shorter (Fig. 25.7). With increasing duration of light stimulus, the contraction amplitudes become greater and more prolonged. With long-duration light stimuli, after an initial contraction, the pupil may undergo oscillations (hippus) and undergo slow dilation, or 'pupil escape,' because of light adaptation (Fig. 25.7). Table 25.1 summarizes the different light effects.

Most investigations of the pupillary light reflex have focused on the response of the pupil to changes in light level because the neuronal pathway for this reflex was thought to respond only to stepwise changes in light intensity. With the advent of computer graphics and sophisticated software programs, more complex stimuli can be presented to allow properties of spatial frequency, color, motion, and

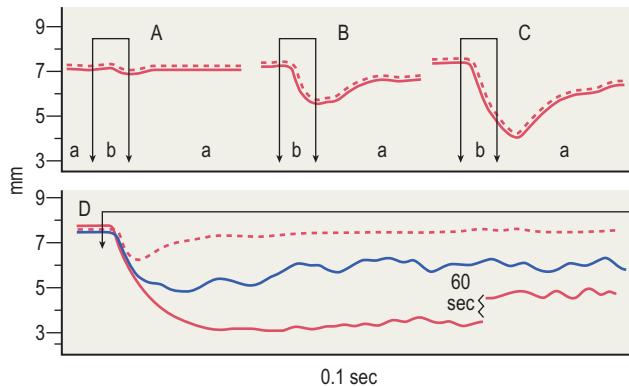

Figure 25.7 (A), (B), and (C): Dark-adapted normal subject. Light flashes, b, of increasing intensity were given to the right eye to produce increasing pupillary constriction. Latent period decreases with intensity of flash. Both pupils were recorded simultaneously using an infrared pupillography device. The right pupil tracing (solid line) and the left pupil tracing (broken line) move in synchrony. **(D)** Reactions of the pupil to prolonged light of different intensities. At the dimmest intensity there was a short pupil light constriction and the pupil dilated (escaped) during the light stimulus. At the brighter intensities, the contractions were larger and more sustained, also exhibiting oscillations (hippus). (From: Lowenstein O, Loewenfeld IE. In: Davso H, ed. *The eye*, vol 3. New York: Academic Press, 1962.)

luminance to be controlled more carefully. A number of investigators have taken advantage of this technology to investigate whether the pupil is capable of responding to visual stimuli that change in color or spatial frequency when the average luminance does not change.^{21–25,28,31}

The results of these studies provide evidence that the pupil contracts to either an onset or offset of spatial frequency or color exchanges. From a practical standpoint, these responses allow the pupil response to be used as an objective indicator of visual acuity and color discrimination. From a theoretical standpoint, the pupil response to isoluminant stimuli provides a means to explore how and where different signals are processed in the visual system. From these studies it is becoming more apparent that visual cortex plays a role in modulating the pupil response to these complex stimuli, providing evidence that small pupil reflexes elicited by properties of visual stimuli besides luminance involve more than just midbrain processing.

Relative afferent pupillary defects

Clinical observation of the pupil light reflex

One of the most important clinical uses of the pupil has to do with its role in assessing afferent input from the retina, optic nerve, and anterior visual pathways (chiasm, optic

Table 25.1 Effect of properties of light stimuli on the pupillary light reflex

Stimulus property	Effect on pupillary light reflex
Light intensity	Amplitude of contraction increases linearly over at least a 3 log unit range of stimulus intensity (stimulus under photopic conditions). The entire stimulus-response function resembles an 'S'-shaped curve. Latency time, the time from stimulus onset to the start of pupil contraction (200–450 msec), becomes more prolonged with dimmer light stimuli (in the range of 20–40 msec further delay/log unit decrement of light intensity).
State of light adaptation	In the dark-adapted state, the threshold light intensity needed to produce a pupil contraction becomes less as rods are brought into play. However, rods in the dark-adapted state do not produce as much increase in pupil contraction in response to increases in stimulus intensity, compared with cones in the mesopic and photopic states.
Duration	When stimulus duration is shorter than 70 msec, there is a reciprocal relationship between the duration and intensity, which is required to produce a given pupil contraction amplitude. With longer-duration stimuli, the pupil contracts more, there is a shorter latency time (up to a point), and the pupillary contraction is more sustained; however, pupil escape (relative dilation) may occur as a result of light adaptation.
Area	The pupillary light reflex shows much greater area summation properties than visual perception (for visual threshold of perception, summation is minimal with stimuli greater than 1 degree). With full-field Ganzfeld stimuli, the pupil threshold can be equal to visual threshold (or even smaller); with stimuli smaller than 1–2 degrees, visual threshold is usually more sensitive (by 0.5–1.0 log units).
Perimetric location	Under dark adaptation, the fovea shows a decreased sensitivity compared with surrounding retinal areas because of the lack of rods here. In mesopic and photopic adaptation, the pupil responds greatest in the central field; the temporal field response is usually greater than the nasal field response.
Spectral sensitivity	The wavelength sensitivity of the pupillary light reflex follows that of visual perception with a blue shift under dark adaptation and a peak sensitivity at green under photopic conditions.
Temporal frequency	The normal pupil cannot move much faster than 4 Hz because of the relatively slow contraction of smooth muscle. Animals with striated iris muscle (pigeons) can easily follow a 10-Hz stimulus. At frequencies of 9–25 Hz, the steady-state pupil diameter increases, indicating loss of sensitivity in neuronal integration of light within this frequency range.
Spatial frequency	When the change in average luminance across a stimulus patch is kept constant, the pupil undergoes small contractions when a sinusoidal grating is presented or when the grating bars are alternated between dark and light. The mechanism is thought to be independent of a luminance response. The greater the spatial frequency, the less the pupil contracts to the stimulus and this has been correlated with visual acuity.
Motion	Recent evidence suggests that the pupil may respond to a motion stimulus even under isoluminant conditions.

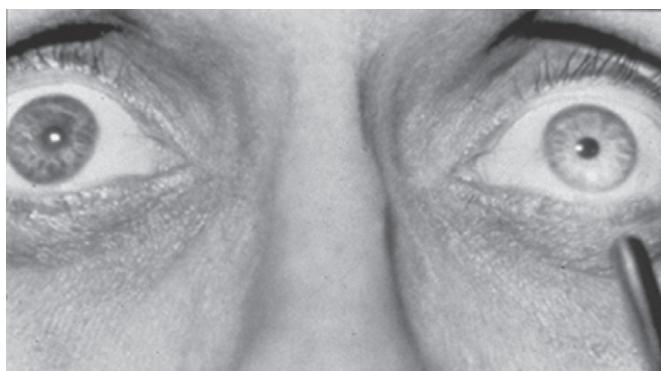

Figure 25.8 A patient is shown with a large relative afferent pupil defect of the right eye. In the top photograph a light is shined in the normal left eye and both pupils constrict to a small diameter. When the light is alternated to stimulate the right eye (bottom photograph), the pupils hardly constrict at all.

tract, and midbrain pathways). The pupil light reflex sums the entire neuronal input from the photoreceptors, bipolar cells, ganglion cells, and axons of ganglion cells. Therefore, damage at any one of these sites along the visual pathway will reduce the amplitude of pupil movement in response to a light stimulus.^{42,43} The pupil light reflex can show considerable variation even among normal individuals as a result of supranuclear influences on the midbrain pupillomotor center that are not related to afferent input of the retina and optic nerve. However, the pupil light reflex is symmetric between the two eyes of a normal individual. The normal symmetry of input between the two eyes allows the clinician to pick up any asymmetric damage between the two eyes by simply comparing how well the pupil contracts to a standard light shined into one eye compared with alternating the light over to the other eye.³⁶ Observation of the pupil movement in response to alternating the light back and forth between the two eyes (Figs 25.8 and 25.9) is the basis for the alternating light test or swinging flashlight test for assessing the RAPD.^{51,52} The RAPD, or input asymmetry, can be quantified in log units using neutral density filters of increasing strength placed in front of the better responding eye. A log density filter that neutralizes or balances the asymmetry of pupil movement between the two eyes, until they are matched, is chosen and is taken as the log unit RAPD.

Another important property of the pupil light reflex is that when a diffuse light stimulus enters the eye, the entire area of the visual field is summated into the pupil response, with some increased weight given to the central 10 degrees.⁴² The area summing properties of the pupil light reflex make the amplitude of its movement roughly proportional to the

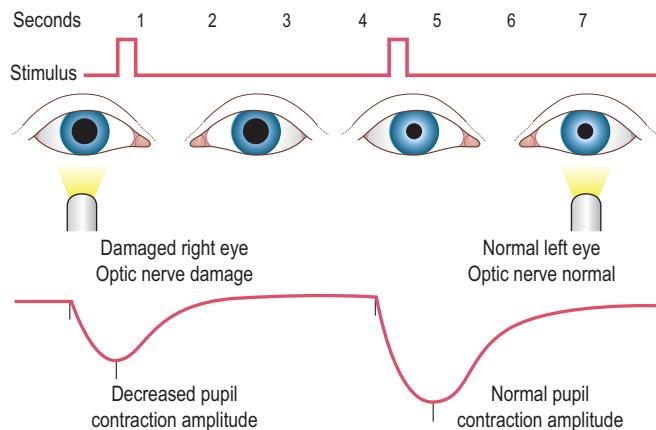

Figure 25.9 Pupillographic demonstration of a right relative afferent pupil defect. With short light pulses the pupil light reflex (bottom tracings) are of lesser amplitude when the stimulus was given to the right eye compared with stimulus to the left eye.

amount of working visual field. Therefore, damage to peripheral portions of the retina and visual field defects outside of the central field can also reduce the amplitude of the pupil light reflex. This is in contrast to other objective tests of visual function such as the Ganzfeld electroretinogram (which measures diffuse damage to the retina and not local damage) and visual evoked potentials (which are center weighted and therefore affected mainly by central field loss). The pupil light reflex is one of the few objective reflexes that can be used as a clinical test for detecting and quantifying abnormalities in the retina, optic nerve, optic chiasm, or optic tract, and is also able to detect regional visual field damage in the center or periphery.

Estimating the amount of the RAPD in log units is important to confirm and validate how much visual field damage (asymmetry between the two eyes) is present and whether it is consistent with the results of the visual field test. For example, a patient with a small amount of macular degeneration in one eye and not the other might be expected to have only a 0.3 log unit RAPD. However, if that patient had a 1.0 log unit RAPD, some other cause of visual loss, such as a previous branch retinal artery occlusion or optic neuropathy, would have to be considered. In addition, the area and extent of visual field loss would be expected to be more than that caused by a small amount of macular degeneration. The importance of quantifying the RAPD cannot be overemphasized. In general, in the case of unilateral visual damage, loss of the central 5 degrees of the visual field results in an RAPD of approximately 0.3 log units. Loss of the entire central area of field (10 degrees) causes about a 0.6 to 0.9 log unit RAPD. Each visual field quadrant outside of the macula is worth about 0.3 log units (Fig. 25.10), but the temporal field loss seems to result in more loss of pupil input compared with the nasal field quadrants. Examples of the log unit magnitude of the RAPD expected for common clinical disorders are given in Table 25.2. The correlation between the relative afferent defect and the area and extent of visual field loss, however, is only approximate. Differences between the two may be important clues as to the cause and extent of damage to the anterior visual system (Box 25.7).

Recent studies using computerized pupillography to more precisely quantify the log unit RAPD have also revealed that

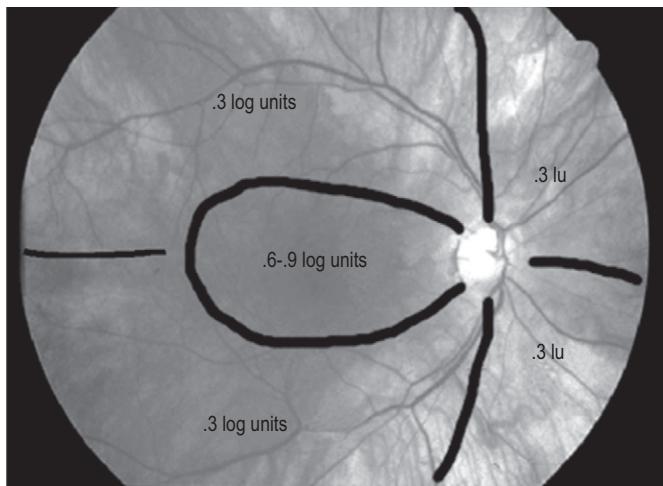

Figure 25.10 Approximate distribution of the amount of log unit relative afferent pupil defect expected for corresponding loss of input in the regions of the retina shown, assuming the other eye is normal.

some normal subjects with normal visual fields and examination can have a small 0.3 log unit RAPD.^{25,33,55} Therefore small RAPDs discovered incidentally in a patient without ocular complaints and a normal examination can probably be dismissed.

Estimating the amount of the pupillomotor input asymmetry (the RAPD) can also be done more subjectively, without using neutral density filters, by grading the asymmetry of pupil response as +1, +2, +3, or +4. This subjective grading can also be classified according to the amount of pupil escape or dilation of the pupils as the light is alternated to the other eye.⁷ However, most subjective grading of the RAPD has serious limitations; it is subject to some large errors resulting from age variations in pupil diameter and pupil mobility. For example, a patient with small pupils and small pupil contractions to light may have a large RAPD that may appear deceptively small on the basis of the small differences in pupil excursion observed as the light is alternated between the two eyes. However, the amount of neutral density filter needed to dim the better eye until the small

Table 25.2 Common diseases producing relative afferent pupillary defects (RAPD) and expected magnitude of defect

Condition	Site	Log unit RAPD	Influencing factors
Intraocular hemorrhage	Anterior chamber or vitreous (dense)	0.6–1.2	Density of hemorrhage
Intraocular hemorrhage	Anterior chamber (diffuse)	0.0–0.3	Density of hemorrhage
Intraocular hemorrhage	Preretinal (central vein occlusion or diabetic)	0.0	Preretinal location does not significantly reduce light
Diffusing media opacity	Cataract or corneal scar	0.0–0.3 (in opposite eye)	Dispersion of light producing increase in light input
Unilateral functional visual field loss	None	0	
Central serous retinopathy (CSR) or cystoid macular edema (CME)	Retina (fovea)	0.3 log units	Area of retina involved
Central or branch retinal vein occlusion (CRVO, BRVO)	Inner retina	0.3–0.6 (non-ischemic) 0.9 (ischemic)	Area of visual field defect and degree of ischemia
Central or branch retinal artery occlusion (CRAO, BRAO)	Inner retina	0.3–3.0	Area and location of retina involved
Retinal detachment	Outer retina	0.3–2.1	Area and location of detached retina (e.g. 0.6 log units for macula + 0.3 log units for each quadrant)
Anterior ischemic optic neuropathy	Optic nerve head	0.6–2.7	Extent and location of visual field defect
Optic neuritis (acute)	Optic nerve	0.6–3.0	Extent and location of visual field defect
Optic neuritis (recovered)	Optic nerve	0.0–0.6	No visual field defect, residual RAPD
Glaucoma	Optic nerve	Usually none, if symmetric damage to both eyes	Degree of visual field asymmetry between the two eyes correlates with the log unit RAPD
Compressive optic neuropathy	Optic nerve	0.3–3.0	Extent and location of visual field defect
Chiasmal compression	Optic chiasm	0.0–1.2	Asymmetry of visual field loss, unilateral central field involvement
Optic tract lesion	Optic tract	0.3–1.2 (in the eye with temporal field loss)	Incongruity of homonymous field defect, hemifield pupillomotor input asymmetry
Postgeniculate damage	Visual radiations Visual cortex	0.0	Stimulus light area (no RAPD but definite pupil perimetry defects)
Midbrain tectal damage	Olivary pretectal area of pupil light input region of midbrain	0.3–1.0	Similar to optic tract lesions, but no visual field defect

Box 25.7 Relative afferent pupillary defect and management

The amount of the relative afferent papillary defect (RAPD) is correlated largely with the amount of asymmetry of visual field deficit between the two eyes, and helps substantiate abnormal results of visual field testing.^{8,25,31,53} This can often help the clinician determine whether a patient's visual field defects are reliable and reflect the true pathologic state.

The correlation between the visual field asymmetry and the RAPD is also useful in following the course of disease to determine whether there is a worsening or improvement in function over time.

The RAPD is a relative measure of the input of one eye compared with the other. Bilateral symmetric damage should not produce an RAPD.

A patient who exhibited a definite RAPD in one eye on the first visit may show no RAPD at all on the follow-up visit. This may represent improvement in the previously damaged eye. However, it may also indicate that there is now damage in what was previously the better eye, matching the damage to the other eye, so that there are now symmetric visual field defects and no RAPD.

contractions are equal could easily approach 0.9 to 1.2 log units, representing substantial input damage. Estimating the size of an RAPD without using filters is much like estimating an ocular deviation "by Hirschberg" without doing a prism cover test. More accurate quantification of the RAPD is accomplished by determining the log unit difference needed to balance the pupil reaction between the two eyes using photographic neutral density filters, as described previously. If one pupil does not move well because of weakness of the sphincter or pharmacologic immobility, one can still check for a RAPD by observing the pupil that still works – and comparing its direct reaction with its consensual reaction.

Computerized pupillometry

Various computerized, infrared-sensitive pupillometers are commercially available. Most of these elegant instruments can precisely record the dynamics of pupillary movement in the light or in the dark (Fig. 25.11). Once recorded, the pupillary information can be analyzed by sophisticated software (see pupil tracings in the alternating light test, shown in Fig. 25.9). This allows quantitative information about the pupillary light reflex to be assessed. In the near future, this may help automate the clinical determination of pupil input deficits caused by retinal and optic nerve diseases.^{14,15,17,31–33} Such instrumentation is also useful for detecting and diagnosing causes of anisocoria (unequal pupils) when both pupils are recorded simultaneously (refer to the section on oculosympathetic defects).

Pupil perimetry

The pupil light reflex may also be used to obtain objective information about the sensitivity of local areas of the visual field by recording small pupil contractions in response to focal light stimuli placed in different perimetric locations. An automated perimeter can be modified to record pupil responses to each focal light stimulus to produce a form of

Figure 25.11 Computerized infrared pupillographic instrument, which records the bright image of both pupils simultaneously, is shown. This instrument can be used to give full-field light stimuli to either eye produced on a monochrome monitor inside the box, or it may also be used to present focal light stimuli to provide a form of objective pupil perimetry.

objective pupil perimetry.^{26,30} A video camera is pointed at the pupil, and the amplitude of each light reaction is measured and stored in the computer. This has turned out to be helpful as an objective form of perimetry and as a way to localize lesions in the pupillary pathways (Fig. 25.12). Pupil perimetry is also useful in cases of non-organic, functional visual loss to show objectively that messages are indeed going normally into the brain from parts of the visual field in which the patient claims to see nothing.

Efferent pupillary defects

Anisocoria

When a pupil inequality is seen, it usually means that damage has occurred to either the iris sphincter or dilator muscle, their innervation has been interrupted, or there are external pharmacologic factors influencing pupil movement (Fig. 25.13). To sort out which muscle is not working right, it helps to know how the anisocoria is influenced by light. It is worth noting that an anisocoria always increases in the direction of action of the paretic iris muscle, just as an esotropia increases when gaze is in the direction of action of a weak lateral rectus muscle. If the iris sphincter is paretic, the lighting condition that normally brings into action that muscle accentuates the weakness; adding bright light tends to increase the anisocoria. Alternatively, if the iris dilator is paretic, the anisocoria is expected to increase as light is taken away because reflex dilation to darkness is impaired. Table 25.3 provides a summary of the common causes of anisocoria that are discussed in the following section.

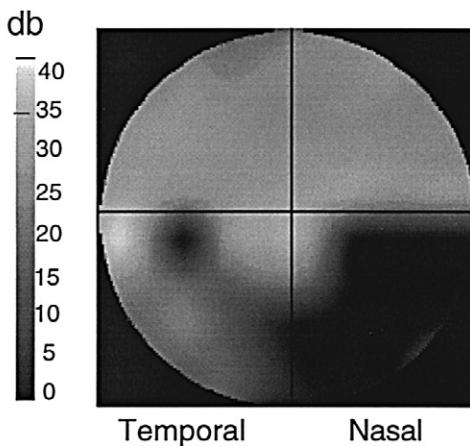

Figure 25.12 Example of a patient with anterior ischemic optic neuropathy showing the correspondence between the visual field and pupil field defect.

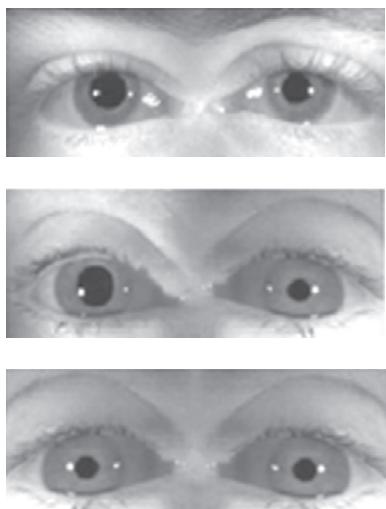

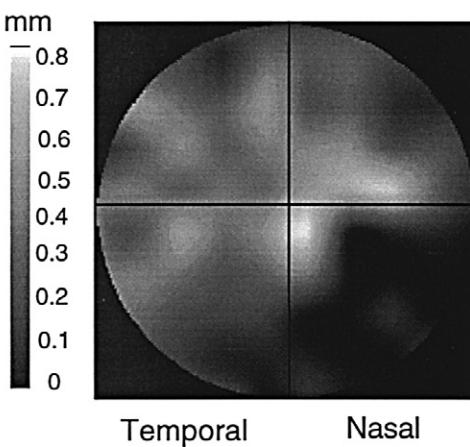

Figure 25.13 The cause of anisocoria in room light (top panel) is determined by first adding bright light to determine whether the anisocoria increases (middle panel) or decreases (bottom panel).

Pupil inequality that increases in the dark

In patients who have pupil inequality that increases in the dark, the problem is distinguishing Horner syndrome from a simple anisocoria (or physiologic anisocoria). In both of these conditions, the pupil inequality becomes greater in

dim light but the dynamics of pupil dilation is impaired in oculosympathetic defects, but not in simple anisocoria. Other features also characterize simple anisocoria from Horner syndrome.

A simple anisocoria may vary from day to day, or even from hour to hour, and it is visible in about one-fifth of the normal population. In some people it may be present most of the time, and the larger pupil may always be in the same eye. In other people it may come and go, and the larger pupil may often switch to the other eye. Physiologic anisocoria is not related to refractive error. The cause of physiologic anisocoria is not known with certainty, but current evidence favors a transient, asymmetric, supranuclear inhibition of the Edinger-Westphal nucleus. This would cause the pupil on the more inhibited side to be larger. If this mechanism is correct, it would also explain why any stimulus that transiently overcomes supranuclear inhibition, such as bright light, near stimulus, sleep, or anesthesia, causes the physiologic anisocoria to decrease. Simple anisocoria is considered benign.

The characteristic dilation lag of the Horner's pupil can easily be seen in the office with a hand light shining from below. At the time the room lights are switched off, the reflex dilation of the two pupils should be simultaneously observed and the smaller pupil assessed to see whether it dilates slower than the other pupil does (Box 25.8). Pupil dilation is normally a combination of sphincter relaxation and dilator contraction. This combination produces a prompt dilation in a normal pupil when the illumination is abruptly decreased.

Table 25.3 Common causes of anisocoria and associated features

Condition	Cause	Anisocoria	Light response	Near response	Slit lamp	Pharmacologic testing
Acute Adie's pupil	Denervation of parasympathetic postganglionic nerves to pupillary sphincter (segmental)	Anisocoria increases in bright light	Segmental loss of light reaction in some sphincter areas around the circumference	Same areas where light response is lost also show loss of near constriction	Remaining innervated sphincter areas pucker with light and pull denervated segments	Supersensitivity to 0.1% pilocarpine; check response of both pupils in darkness after 30 minutes
Chronic Adie's pupil (greater than 8 weeks after event)	Reinnervation of denervated sphincter segments by postganglionic accommodative nerves	May be no anisocoria in room light or affected pupil may be the smaller pupil	Poor response to light; poor dilation in darkness as a result of tonically contracted segments that have reinnervation	Light-near dissociation is present with good near effort from the patient	Similar appearance as in the acute state, reinnervated segments show diffuse contraction to near	As segments become reinnervated, cholinergic supersensitivity is lost; small, tonic pupil dilates normally to anticholinergics
Pharmacologic mydriasis (anticholinergic)	Scopolamine patch, eyedrops, plants (jimson weed)	Anisocoria increases in bright light	Loss of response to light; residual small reaction may occur with submaximal exposure or after sufficient time has elapsed	Same degree of loss of near response as loss of light response; near point of accommodation is more remote	Any residual light response of the sphincter is diffuse and not segmental	Subsensitivity to pilocarpine of all concentrations compared with the opposite unaffected eye (observed in dim light or darkness)
Pharmacologic mydriasis (adrenergic)	Low concentration of adrenergics found in over-the-counter eyedrops for red eyes, cocaine, Neo-Synephrine	Anisocoria increases in bright light, but not as much as in anticholinergic mydriasis	Diminished response to light, but dilator muscle can be overcome by strong sphincter constriction to bright light	Same diminished response as light reaction; near point of accommodation is unaffected and is normal	Besides diminished reaction, the pupil movement looks normal and is not segmental	Reversal of anisocoria with adrenergic blockade (diprydanol or thymoxamine); may be overcome with pilocarpine
Damage to iris sphincter	Ischemia, angle-closure glaucoma, herpes zoster, trauma, after anterior segment surgery	Anisocoria increases in bright light	Loss of response to light, some sphincter segments may be more affected than others	Usually affected to the same degree as the light reflex, may have normal accommodative amplitude	Transillumination defects may be present	Lack of response to 1% pilocarpine in damaged areas of the iris sphincter
Iron or copper mydriasis	Intraocular foreign body	Anisocoria increases in bright light	Loss of response to light, not usually segmental	Usually affected to the same degree as the light reflex	Usually heterochromia is present, with the iris being darker	May show cholinergic supersensitivity
Third nerve palsy	Trauma, compression, rarely ischemia	Anisocoria increases in bright light	Loss of response to light, not usually segmental unless aberrant regeneration is present	Usually affected to the same degree as the light reflex; accommodative amplitude is decreased	Usually symmetric weakness along the circumference of the sphincter to light reaction	May show cholinergic supersensitivity
Mechanically scarred iris	Trauma, iritis	Anisocoria increases in bright light	Loss of response to light when viewed without slit lamp	Usually affected to the same degree as the light reflex; accommodative amplitude is normal	Small movement of the scarred down iris can usually be observed; synechiae can often be seen after dilation	Lack of response to 1% pilocarpine
Physiologic anisocoria	Asymmetric inhibition at the Edinger-Westphal nucleus	Anisocoria increases in bright light	Normal; normal dilation in response to darkness and auditory stimulation	Normal; anisocoria lessens with a good near response	Normal	Normal response to topical agents; cocaine lessens the anisocoria
Oculosympathetic defect (Horner syndrome)	Sympathetic nerve palsy; ptosis is usually present of the upper and lower lid; anhidrosis may be present	Anisocoria increases in bright light	Normal; slow dilation in response to darkness and auditory stimulation	Normal; anisocoria lessens with a good near response	Normal; heterochromia is common if palsy occurred early in life	Cocaine increases the anisocoria; supersensitivity is usually demonstrated to adrenergic agents
Congenital pseudo-Horner syndrome	Unknown; anisocoria is often present in old photographs from infancy	Anisocoria increases in bright light	Appears normal, but the smaller pupil does not dilate well to darkness or auditory stimulation	Normal; anisocoria lessens with a good near response	Normal	May give a false-positive cocaine test; when direct-acting agents or anticholinergic drops are used, the pupil still fails to dilate as well as the fellow eye

Box 25.8 Horner syndrome

Clinically, Horner syndrome is recognized by looking for the associated signs, such as ptosis, “upside-down ptosis” of the lower lid, and in a fresh case, conjunctival injection, decreased sweating on the involved side, and in some cases, lowered intraocular pressure on the affected side.

Pain on the side of the face with the smaller pupil (jaw, ear, and cheek pain) is often an important sign pointing to a carotid artery dissection as a cause of the Horner syndrome (Fig. 25.14).

The patient with Horner syndrome has a weak dilator muscle in one iris, and as a result, that pupil dilates more slowly than the normal pupil (Fig. 25.15). If the sympathetic lesion is complete, the affected pupil will dilate only by sphincter relaxation; this process takes longer than with an intact sympathetic innervation to the dilator muscle. This asymmetry of pupil dilation produces an anisocoria that becomes largest 4 to 5 seconds after the lights are turned out. Dilatation of the eye with the oculosympathetic defect is a much slower process than most people imagine. After the lights have been out for

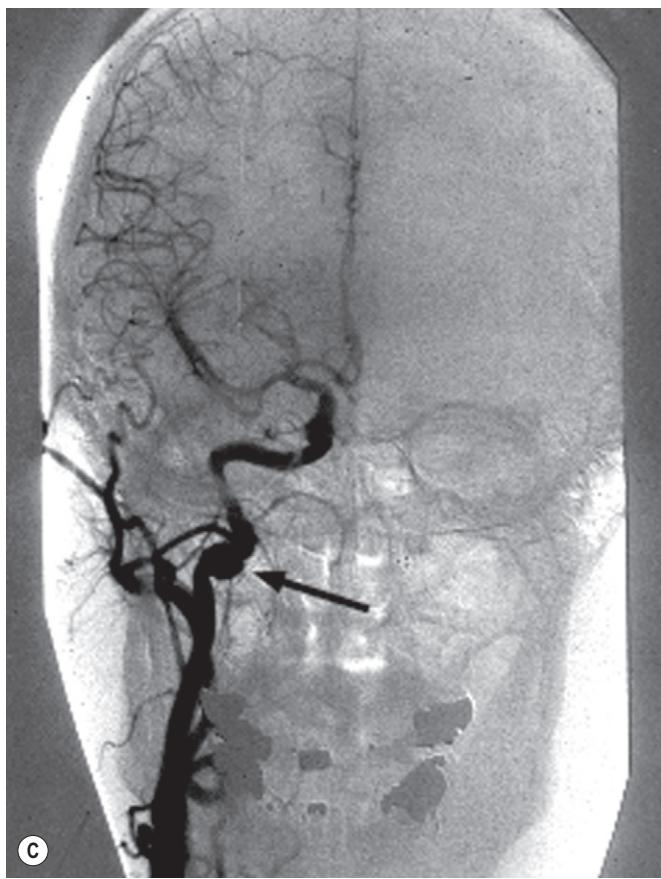

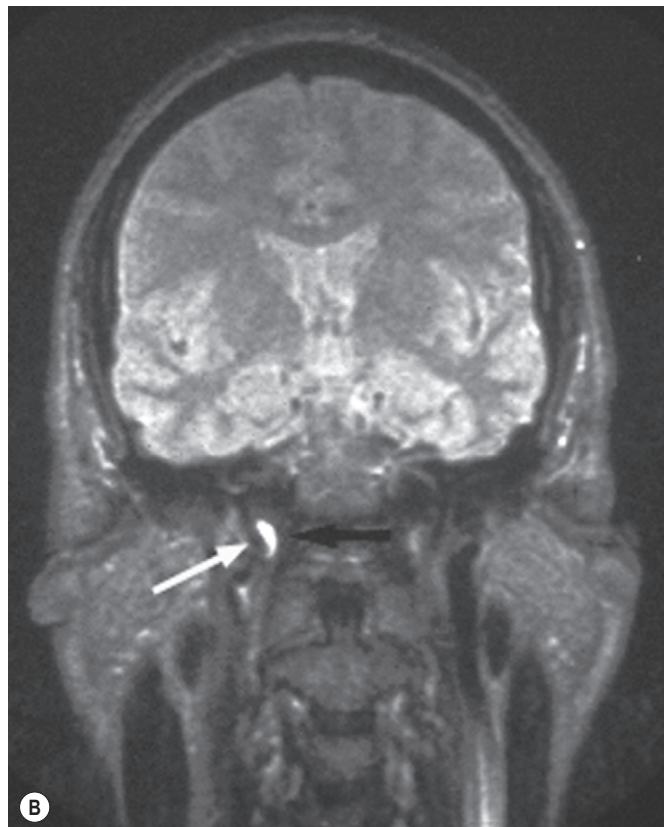

Figure 25.14 (A) Example of a patient with acute Horner syndrome on the right with accompanying facial pain. Note the miosis and ptosis on the right eye. This patient had a dissection of the internal carotid artery demonstrated by the magnetic resonance imaging scan (B) showing a bright signal in the wall of the carotid artery resulting from blood (white “comma” adjacent to carotid lumen in lower left; arrow). The dissection created a false lumen that appears as a focal enlargement of the lumen of the carotid artery demonstrated in the carotid angiogram on the right (arrow) (C).

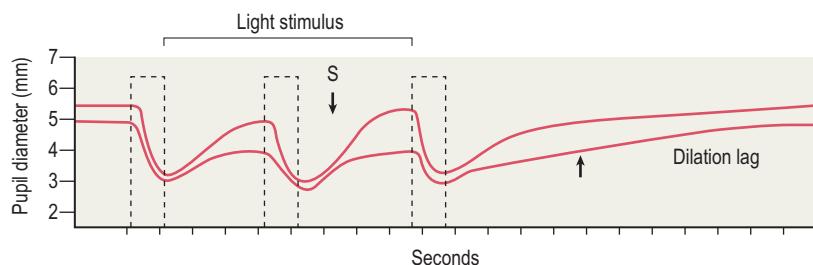

Figure 25.15 Example of a pupillographic demonstration of dilation lag of the pupil in the eye with Horner syndrome. The smaller pupil is slow to dilate, causing an increase in anisocoria during the early phase of dilation and accentuated by a loud sound (S). In the last part of the tracing, no further stimulus was given to allow the dilation lag to be observed in the tracing. The dilation lag is a delayed dilation of the smaller pupil; after 5 seconds in darkness, the smaller pupil slowly dilates as a result of inhibition of the sphincter muscle, despite loss of sympathetic nerve contribution to pupil dilation.

10 to 20 seconds, the anisocoria lessens as the sympathectomized pupil gradually catches up because of continual relaxation of the iris sphincter due to central inhibition of the parasympathetic pathway at the Edinger-Westphal nucleus. The delayed dilation of the involved eye due to a deficit of sympathetic innervation to the dilator muscle is a process referred to as *dilation lag* (Fig. 25.15).

Often, the initial increase in anisocoria during the first few seconds of darkness can be accentuated by adding an auditory stimulus just after the lights are turned out. This causes the normal pupil to dilate forcefully in response to the extra sympathetic stimulation evoked by the loud noise, but in the eye with the oculosympathetic defect, this maneuver has little effect. Comparison of the dynamics of dilation of the two pupils is a quick and simple way of distinguishing Horner syndrome from simple anisocoria, and it is a test that does not require pupillary drug testing. It works well most of the time, especially in young people with mobile pupils, but if the dilation lag is inconclusive, cocaine eye drops should be used to confirm the diagnosis of Horner syndrome.

Pharmacologic diagnosis of Horner syndrome with cocaine or apraclonidine

Cocaine's action is to block the reuptake of the norepinephrine that is normally released from the nerve endings. If, because of an interruption in the sympathetic pathway, norepinephrine is not being released, cocaine has no adrenergic effect. A Horner's pupil will dilate less to cocaine than the normal pupil, regardless of the location of the lesion. Forty-five minutes after cocaine drops have been placed in both eyes, the anisocoria should have clearly increased because the normal pupil has dilated more than the Horner's pupil.

A solution of 4 percent cocaine HCl drops in both eyes is recommended (never more than 2 drops) to be sure that the iris gets a full mydriatic dose; this concentration of cocaine does not normally produce a corneal epithelial defect. It should be said that 2 percent, 4 percent, and 5 percent cocaine have also been used as a diagnostic test for Horner syndrome and work well. The pH of the solution usually causes significant burning after topical application. Pre-application of topical anesthetic helps counteract the discomfort. After 40 to 60 minutes have elapsed, the anisocoria is measured in room light. The patient should stay active during that time so that adequate sympathetic discharge is

occurring (sleeping during this time might result in neither pupil dilating to cocaine). If there is little dilation of the eye with a suspected oculosympathetic defect and this pupil never dilated well in darkness before the drop was given, even after 30 seconds of darkness, a false-positive cocaine test also must be considered. This can occur if the iris is in some way held in a miotic state by either scarring or aberrant reinnervation of the iris sphincter. In such cases, adding a direct-acting sympathomimetic agent to both eyes (i.e. 2.5 percent phenylephrine) at the conclusion of a positive cocaine test should easily dilate the iris of the suspected eye if there really is an oculosympathetic defect, and the cocaine-induced anisocoria should almost be eliminated. In some cases the 2.5 percent phenylephrine may even cause the eye with the oculosympathetic defect to have the larger pupil as a result of supersensitivity. Pseudo-Horner syndrome, caused by the reasons stated earlier, results in inadequate dilation to direct-acting sympathetic agents.

The likelihood of a diagnosis of Horner syndrome with cocaine testing increases in proportion to the amount of anisocoria (measured 50 to 60 minutes after the instillation of cocaine). Unlike the hydroxyamphetamine test (used for localizing the lesion to either the preganglionic or postganglionic neuron), calculation of the change in the anisocoria from before to after cocaine application is unnecessary. It has been found that if there is at least 0.8 mm of pupillary inequality after cocaine, the presence of Horner syndrome is highly likely.²⁹

Recently, it has been proposed that a new pharmacologic test using 0.5 percent apraclonidine be used for the diagnosis of Horner's syndrome in place of cocaine.⁷⁴⁻⁷⁸ Typically, 30 minutes following topical apraclonidine administered to both eyes, the miotic eye with the oculosympathetic defect dilates and if anything, the normal pupil becomes smaller (in dim light), causing the anisocoria to reverse, or at least lessen. In patients with anisocoria of other causes, such as physiologic anisocoria, no mydriasis occurs. Apraclonidine has an advantage over cocaine in that it will actively dilate the affected eye and not the normal eye, making its action a positive (mydriatic) one in the affected eye rather than a negative one in the affected eye and a positive (mydriatic) one in the unaffected eye, as with cocaine. Unlike phenylephrine, whose corneal penetration varies widely among individuals, apraclonidine readily penetrates the cornea and gains access to the iris, so the limiting factor to its mydriatic effect is whether α_1 supersensitivity is present in the iris dilator muscle. Apraclonidine has potential advantages over

phenylephrine, not only in its ease of corneal penetration, but also in the fact that it does not need to be diluted. Further studies will clarify the diagnostic efficacy of apraclonidine for the diagnosis of oculosympathetic defects.

Pharmacologic localization of the denervation in Horner syndrome

The site of the oculosympathetic lesion in Horner syndrome is a question of considerable clinical importance because many postganglionic defects are caused by benign vascular headache syndromes or more serious carotid dissections and a preganglionic lesion is sometimes the result of the spread of a malignant neoplasm.

Hydroxyamphetamine eye drops help localize the site of the lesion in Horner syndrome. The clinician would like to know where the lesion is because that knowledge directs the radiographic workup (e.g. to the internal carotid artery rather than to the pulmonary apex). Horner syndrome sometimes presents itself in such a characteristic setting that further efforts at localizing the lesion are not needed. This is true of patients with cluster headaches or after surgical procedures that interrupt the oculosympathetic chain in a known location.

Hydroxyamphetamine acts by releasing norepinephrine from storage in the sympathetic nerve endings. When the lesion is postganglionic, most, if not all, of the nerves are dead, and no norepinephrine stores are available for release. When the lesion is complete, a pupil like this will not dilate at all in response to hydroxyamphetamine. However, a period of almost 1 week from the onset of damage may be needed before the dying neurons and their stores of norepinephrine are gone. Therefore a hydroxyamphetamine test given within a week of a postganglionic lesion may give a false preganglionic localization if the norepinephrine stores have not yet disappeared. Horner's pupils resulting from preganglionic or central lesions dilate *at least* normally because the postganglionic neuron with its stores of norepinephrine, although disconnected, is still intact. In fact, when the lesion is in the preganglionic neuron, the Horner's pupil often becomes larger than the normal pupil – apparently resulting from "decentralization supersensitivity."

The hydroxyamphetamine test is simple: The pupils are measured *before* and 40 to 60 minutes *after* hydroxyamphetamine drops have been put in both eyes, and the change in anisocoria from baseline state to the after drops state in room light is noted. If the Horner's pupil – the smaller one – dilates less than the normal pupil, the anisocoria increases and it can be concluded that the lesion is in the postganglionic neuron. If the smaller pupil dilates so well that it becomes the larger pupil, the lesion is preganglionic and the postganglionic neuron with its norepinephrine stores is still intact. The examiner should wait at least 2 to 3 days after using cocaine drops before using hydroxyamphetamine; cocaine seems to block hydroxyamphetamine's effectiveness because it blocks the uptake of hydroxyamphetamine into the postganglionic nerve terminal, thus inhibiting its action.

To understand how to better interpret the hydroxyamphetamine test, we studied hydroxyamphetamine mydriasis in patients with a known lesion location and in those in whom the location of the lesion was unknown. It appears that postganglionic lesions (along the carotid artery) can be

separated from the non-postganglionic lesions (in the brainstem, spinal cord, upper lung, and lower neck) with a degree of certainty that varies with the amount of change in anisocoria induced when the drops are put in both eyes.¹⁶ An increase in the anisocoria of greater than 0.5 mm (change in anisocoria from prehydroxyamphetamine to posthydroxyamphetamine) makes a postganglionic lesion highly likely.

Congenital and childhood Horner syndrome

When a child has a unilateral ptosis and miosis, the first question is whether it is really Horner syndrome. The ptosis of Horner syndrome is moderate, never complete. Sometimes, the elevation of the lower lid (upside-down ptosis) is persuasive. A child with a congenital Horner syndrome and naturally curly hair has, on the affected side of the head, hair that will seem limp and lank. The shape of the hair follicles appears to depend on intact sympathetic innervation, as does the iris pigment. In children, iris color usually occurs after the first 9 to 12 months of life because of accumulation of melanosomes in iris melanocytes that are innervated by the sympathetic nerves. Therefore, if the iris in the eye with Horner syndrome does not develop pigmentation during this period, i.e. there is heterochromia, then an oculosympathetic defect was present early in life. However, the presence of heterochromia does not indicate the cause or whether it was congenital versus acquired during the first year of life.

Cocaine eye drops may be of some help in diagnosing Horner syndrome in children. If there is no significant dilation of the smaller pupil, a drop of 2.5 percent phenylephrine should then be administered to each eye to substantiate that the pupil can dilate to a direct-acting sympathomimetic agent and that this is not pseudo-Horner syndrome (see previous section on the cocaine test). Other signs may also be helpful for diagnosing Horner syndrome in children. The most telling sign is a hemifacial flush that can occur on the normally innervated side in contrast to the blanch that occurs on the side with the oculosympathetic defect when the infant is nursing or crying. In an air-conditioned office it may be hard to decide whether there is an asymmetry of sweating. A cycloplegic refraction can sometimes produce an atropinic flush everywhere except on the affected face and forehead and thus can unexpectedly solve the diagnostic problem.

In infants the hydroxyamphetamine drop test is not very helpful in localizing the lesion because orthograde trans-synaptic dysgenesis takes place at the superior cervical ganglion after an early interruption of the preganglionic oculosympathetic neuron. This results in fewer postganglionic neurons, even though there was no postganglionic injury, and this, in turn, produces weak mydriasis and ambiguous answers from the hydroxyamphetamine test in children.⁵⁶ Therefore, if a hydroxyamphetamine drop test is used, the interpretation needs to take this possibility into consideration. If, in response to hydroxyamphetamine, the affected eye with relative miosis dilates as well as or better than the fellow eye, it is probably a preganglionic lesion. However, any result showing less mydriasis in the affected eye compared with the fellow eye cannot be localized with certainty because of the reasons listed earlier. Horner syndrome that has been clearly acquired in infancy should be evaluated for neuroblastoma, a treatable tumor, using a

combination of imaging and testing the urine for metabolites of adrenergic compounds secreted from the tumor.

Pupil inequality that is increased in bright light

When the anisocoria increases with bright light, this implies that the larger pupil is abnormal and may not contract well to light because of direct damage to the iris sphincter muscle from trauma or surgery or because of ischemic atrophy, scarring (synechia) of the iris to the lens from previous inflammation, pharmacologic mydriasis, or denervation of the parasympathetic nerve supply to the iris sphincter (see Fig. 25.4). The following sections outline the most important clinical observations and tests that may be needed to sort out the cause of the efferent pupil defect (see Table 25.2).

Examination of the iris with high magnification using the slit-lamp biomicroscope

Trauma to the globe usually results in a torn sphincter or an iris that shows transillumination defects at the slit lamp. The pupil is often not round, and there may be other evidence of ocular injury. Naturally, such a pupil does not constrict well to light. The residual reaction is often associated with the remaining normal sectors of the iris sphincter because the traumatic tears are usually segmental. An atrophic sphincter resulting from previous herpes zoster iritis may also reveal large geographic areas of transillumination defects seen with the slit lamp from previous ischemic vascular insults to the iris during the uveitis.

However, if the iris tissue looks normal, the examination is focused on whether any part of the iris sphincter is contracting with light. If some contraction occurs, it should be determined whether the residual contraction is diffuse over the whole circumference or segmental. If there is no segmental movement of the iris, the possibility of atropinic mydriasis should be considered.²⁷ However, a completely blocked light reaction can sometimes be seen when the sphincter is totally denervated by a preganglionic lesion (third nerve palsy) or a postganglionic lesion (fresh tonic pupil), in acute angle closure (iris ischemia), or in the presence of an intraocular iron foreign body (iron mydriasis). If the dilated pupil still has some response to light, the dilation could be caused by partial denervation of the sphincter or by incomplete atropinization or adrenergic mydriasis. When the light reaction is poor because the dilator muscle is in spasm (because of adrenergic mydiatics like phenylephrine), the pupil is large, the conjunctiva blanched, and the lid retracted. In such a case, the near point of accommodation is usually normal but may be slightly decreased as a result of spherical aberration and a shallow depth of field caused by the dilated pupil. However, in the case of adrenergic mydriasis, there usually is some light reaction to very bright lights because the stronger iris sphincter can usually overcome pulling by the adrenergic effects on the dilator muscle.

If there is some residual light reaction, the next step is to look with the slit lamp for sector palsies of the iris sphincter. When the dilator is in a drug-induced adrenergic spasm or when the cholinergic receptors in the iris sphincter are

blocked by an atropine-like drug, the entire 360 degrees of the sphincter muscle is less effective. This is not the case when the postganglionic nerve fibers have been interrupted: Adie's pupils with a residual light reaction (about 90 percent of them) have segmental contractions of the remaining normal segments of the sphincter. Some preganglionic partial third nerve palsies also have regional sphincter palsies, but these can usually be attributed to an associated preexisting diabetic autonomic neuropathy or aberrant regeneration. This means that when the examiner sees a pupil with a weak light reaction but no segmental palsy, he or she should consider a drug-induced mydriasis and then perhaps look again for lid and motility signs of a third nerve paresis.

Pharmacologic response of the iris sphincter to cholinergic drugs

Cholinergic supersensitivity

If weak pilocarpine (0.0625 percent, 0.1 percent, or 0.125 percent) is applied to both eyes and the affected (dilated) pupil constricts more than the normal pupil (actually becoming the smaller pupil in darkness), the iris sphincter has probably lost some of its innervation and has become supersensitive (Fig. 25.16). Cholinergic supersensitivity can occur within 5 to 7 days. The conclusion that cholinergic supersensitivity exists assumes that corneal penetration of the drug is the same in each eye (i.e. both corneas are healthy and untouched, tear function is normal, and the eyelids are working properly in both eyes). It seems likely that with postganglionic denervation (damage at the ciliary ganglion or distal to it) the sphincter will show more supersensitivity than in the preganglionic case (third nerve palsy). However, it appears that the differences are not great. For all of these reasons, cholinergic supersensitivity of the iris sphincter is now considered only a confirmatory sign of Adie syndrome. In fact, the results of supersensitivity testing may be ambiguous in Adie syndrome, depending on the chronicity of the condition. As reinnervation takes place over time in Adie syndrome (with accommodative cholinergic nerves growing into the iris sphincter), the reinnervated sphincter segments may lose their cholinergic supersensitivity.⁵⁹ If a patient shows the presence of cholinergic supersensitivity in one eye without any segmental palsies, other causes besides Adie's pupil should be reconsidered. Subtle signs of ptosis or diplopia should be looked for once more to leave no doubt that the oculomotor nerve is not affected. It is rare for an ambulatory patient to have an isolated sphincter palsy without other signs of oculomotor nerve palsy as a result of compressive damage to the intracranial third nerve caused by a tumor or aneurysm.

Testing of iris cholinergic sensitivity is best performed when comparing an affected eye with its fellow, normal eye. Testing for whether cholinergic supersensitivity is present in both eyes, without comparing the response with the normal fellow eye in the same subject, is problematic because there is considerable variation in the cholinergic response among different individuals. Even some normal eyes can respond to 0.05 percent pilocarpine, so for supersensitivity testing to be the most meaningful, the test is best used in the setting of unilateral causes.

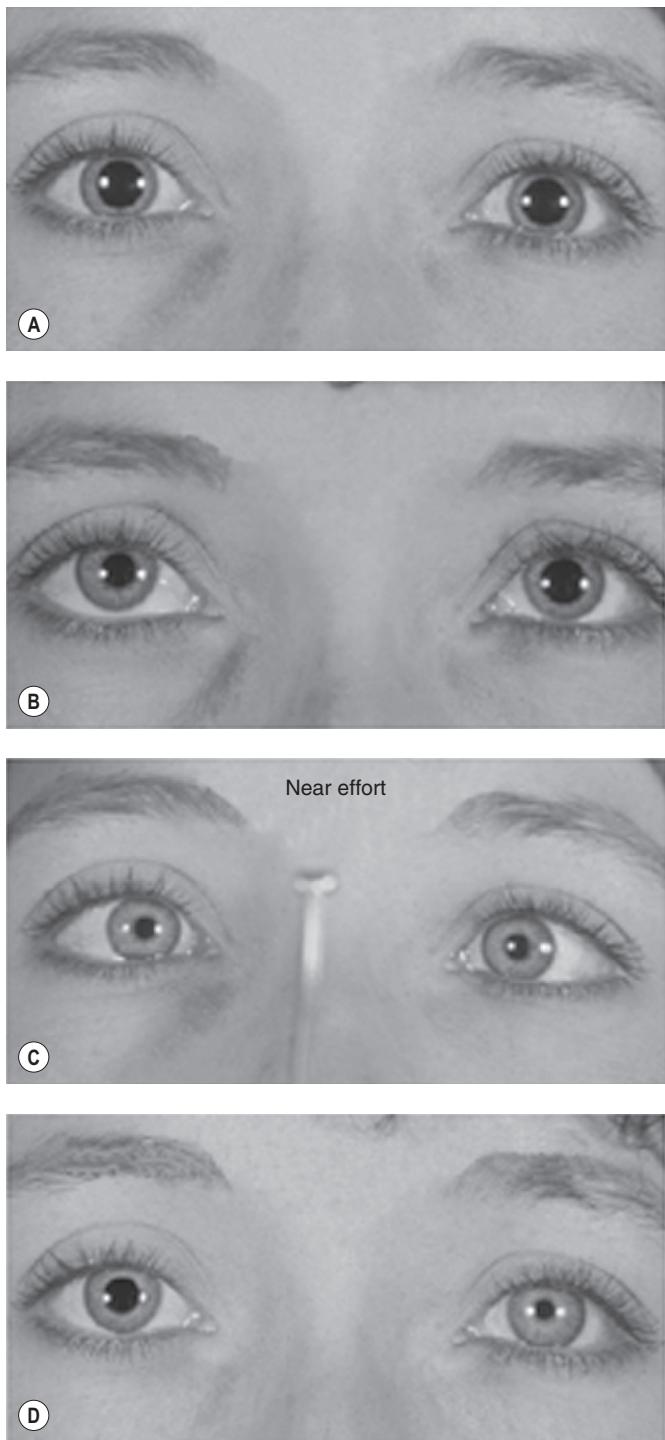

Figure 25.16 Example of Adie's pupil (**A**) showing little anisocoria in darkness (**B**) and an increasing anisocoria in room light (**C**). A light-near dissociation with a greater contraction of the left pupil to a near stimulus compared with light (**D**), indicating a chronic state resulting from reinnervation of the iris sphincter by accommodative neurons. The patient still exhibited signs of cholinergic supersensitivity (lower right), with the involved pupil contracting more to 0.1 percent pilocarpine than the fellow pupil.

Subsensitivity of the iris sphincter to cholinergic testing

If the normal pupil constricts only a small amount to dilute cholinergic agents and the dilated pupil not at all, the mydriasis may be caused by the presence of an anticholinergic drug like atropine, which inhibits the receptors on the iris sphincter muscle. A stronger concentration of pilocarpine is then needed to settle this point. If, on application of 1 percent pilocarpine in each eye, the affected pupil does little or nothing and the unaffected pupil constricts normally, the pupil is not larger because of nerve denervation, but rather, because of a problem in the sphincter muscle itself. The following are different non-neuronal causes of mydriasis:

- anticholinergic mydriasis (e.g. scopolamine, cyclopentolate, atropine)
- traumatic iridoplegia (look for sphincter tears, appearing as divots at the pupil border; pigment dispersion on the corneal endothelium or lens; and angle recession)
- angle-closure glaucoma (ischemia of the iris sphincter that occurs during the time when the intraocular pressure is high)
- previous herpes zoster iritis causing direct damage to the iris sphincter
- synechiae causing a bound-down iris that is mechanically immobile
- fixed pupil following anterior segment surgery
- ocular ischemia to the anterior segment, damaging the iris sphincter.

The cause for a loss of function of the iris muscle following anterior segment surgery is unknown. In some cases with a postoperative rise in intraocular pressure, the cause may be an ischemic insult to the iris sphincter. An autoimmune process may be responsible, but it has not been proven. It may be related to the same process as Urrets-Zavalia syndrome, in which a dilated, fixed pupil may occur following penetrating keratoplasty.

Adie's tonic pupil: postganglionic parasympathetic denervation

Young adults (more commonly women than men) may suddenly find that one pupil is large or that they cannot focus as well with one eye at near. Slit-lamp examination usually shows segmental denervation of the iris sphincter, with some remaining normal segments still reacting to light. Within the first week, supersensitivity of the iris and ciliary muscle to cholinergic substances can be demonstrated. After about 2 months, nerve re-growth is active and fibers originally bound for the ciliary muscle (they outnumber the sphincter fibers by 30:1) start arriving (aberrantly) at the iris sphincter and the ciliary muscle. The light reaction of the denervated segments does not return, but the re-innervated segments now show contraction to a near stimulus. This produces the characteristic "light-near dissociation" of Adie syndrome (Fig. 25.16), as well as a return of some accommodative amplitude. Therefore the presence of light-near dissociation in this setting is a sign of a chronic Adie's pupil with reinnervation and is not a sign of an acute Adie's pupil. The pupil contraction to a near stimulus is

often tonic, being slow to dilate when gaze is shifted to a distant target. Although there is also some return of accommodative amplitude, the dynamics of focusing in the affected eye are also slowed and not normal. Patients often complain of difficulties when trying to refocus from near to far because the relaxation of accommodation is slower in the affected eye. Eventually, the affected pupil becomes the smaller of the two pupils, especially in dim light, as a result of the amount of reinnervation by cholinergic accommodative neurons, which keep the sphincter in a contracted state. It turns out that the segmental palsy of the iris sphincter in Adie syndrome and the individual sphincter segment responses to light, near and pilocarpine, can be seen especially well by infrared video recording of transillumination of the iris (Fig. 25.17). Many of these patients also lack normal motor jerk reflexes and may also have decreased vibratory sensation, indicating a similar process occurring in the spinal cord neurons. However, Adie syndrome is not associated with any major neurologic disorder or significant dysfunction. The cause of Adie's pupil is not well understood, but it has been hypothesized that an immune reaction may mediate the damage to ciliary ganglion and spinal neurons. Younger children may get an Adie's pupil after having chickenpox. After about 10 years, almost 50 percent

of patients with Adie's pupil show evidence of a similar process occurring in the other eye.

Pupil involvement in third nerve palsy

There is an old clinical rule of thumb stating that if the pupillary light reaction is spared in the setting of a third nerve palsy, the palsy is probably not caused by compression or injury, but more likely, it is caused by small vessel disease, such as might be seen in diabetes. It is still a fairly good rule, provided one bears in mind that a small but definite number of pupil-sparing third nerve palsies are caused by midbrain infarcts and should have neuroimaging studies. Because the preganglionic parasympathetic nerves for the pupil light reflex are located on the medial side of the intracranial portion of the third nerve as it exits the midbrain, compression of the third nerve in this location results in some element of iris sphincter palsy (Box 25.5). The most common cause of this would be an aneurysm (i.e. of the posterior communicating artery) or pituitary apoplexy (sudden lateral expansion of a pituitary adenoma pressing on the medial aspect of the third nerve). Pupil involvement is often incomplete, so it is important to look for iris sphincter weakness by observing for anisocoria in bright light. In the absence of

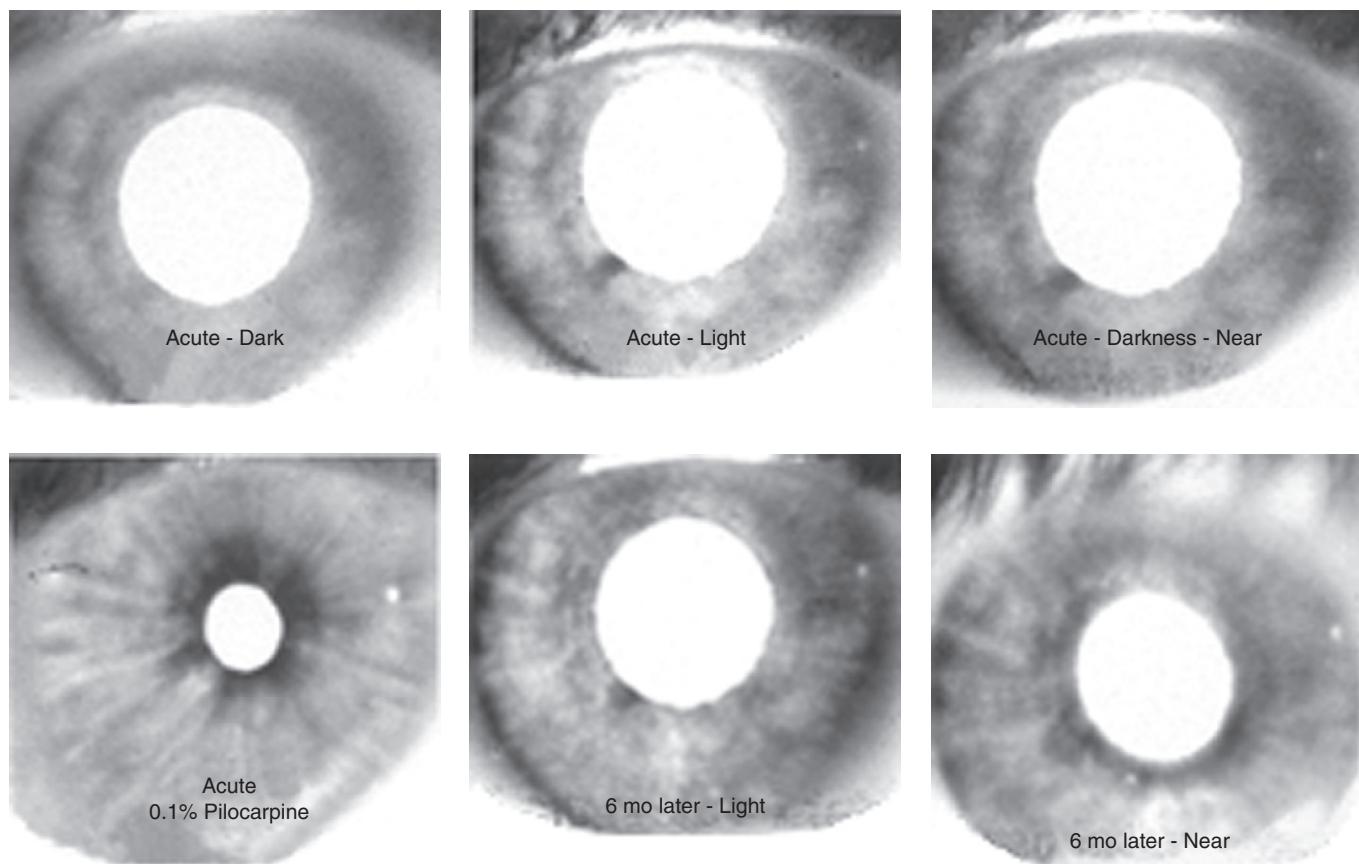

Figure 25.17 Infrared iris transillumination in Adie's pupil. The iris sphincter appears as a dark ring at the pupillary border when it contracts, as observed with infrared iris transillumination. In the patient shown, almost all of the iris sphincter was denervated, except for the segment at the 7 o'clock meridian, which darkened when made to contract with light or near (top row, center and right panels). With low-dose pilocarpine, the rest of the sphincter muscle that was denervated is the area where supersensitivity was present (bottom row, left panel). Every area darkened after the pilocarpine, except the normal segment at the 7 o'clock position, which remains lighter (not contracted), as shown in the upper right panel. After 6 months, the pupil started to become smaller and contracted to near (bottom right panel), but it remained unresponsive to light, except for the 7 o'clock segment (center right panel).

aberrant regeneration (from chronic compression), we have yet to observe a case of a pupil involving third nerve palsies from an aneurysm that showed segmental palsies; all of the cases so far have shown symmetric involvement of the iris sphincter over its circumference. Some patients with ischemic third nerve palsies and diabetes have shown mild pupil involvement with elements of segmental palsies. It appears that these patients may have had preexisting pupil involvement from diabetic autonomic neuropathy.

Aberrant regeneration in the third nerve

The third cranial nerve carries bundles of nerves supplying different extraocular muscles (medial rectus, inferior rectus, inferior oblique, superior rectus, and levator palpebrae muscles), as well as preganglionic parasympathetic nerves to the iris sphincter and ciliary body. Injury to the third nerve and glial scaffolding, through which individual nerve bundles pass, causes the nerve fibers to regrow, and they often end up in the wrong place. For example, the eye may inappropriately turn in when the patient is trying to look down, or the pupil may inappropriately constrict with depression, adduction, or supraduction of the globe (Fig. 25.18). With eyelid involvement, the lid fissure may widen with infraduction, adduction, or supraduction of the eye. Aberrant regeneration of the oculomotor nerve may be primary or secondary. In secondary aberrant regeneration, a third nerve palsy precedes the aberrant regeneration by at least 8 weeks. In primary aberrant regeneration, there is no preceding nerve palsy; the damage to the nerve slowly progresses simultaneous with the process of aberrant regeneration. Primary aberrant regeneration is clinically important to recognize because it is almost always caused by a slow compression of the intracranial third nerve by a tumor or aneurysm.

Light-near dissociation: evaluation of the near response

The pupil response to a near effort should be observed as a standard part of the pupil evaluation. Any time the pupil light reaction seems weak, it is important to check to see whether the pupils constrict better to near than they do to light. If they do, this is called a *light-near dissociation*. Causes of light-near dissociation are summarized in Table 25.4. These are categorized by three major mechanisms:

- Loss of light input resulting from severe damage to the afferent visual system (retina or optic nerve pathways)

- Interruption of the light input pathways to the Edinger-Westphal nucleus from the pretectum (Argyll Robertson pupils, dorsal midbrain syndrome)
- Aberrant regeneration of the pupillary sphincter from accommodative fibers (Adie syndrome) or extraocular muscle neurons from the oculomotor nerve (medial rectus fibers or accommodative fibers from third nerve aberrant regeneration).

When the pupil fails to dilate

When one or both pupils stay small and miotic, even in darkness, a number of reasons may be responsible (Table 25.5). To better understand the different possible

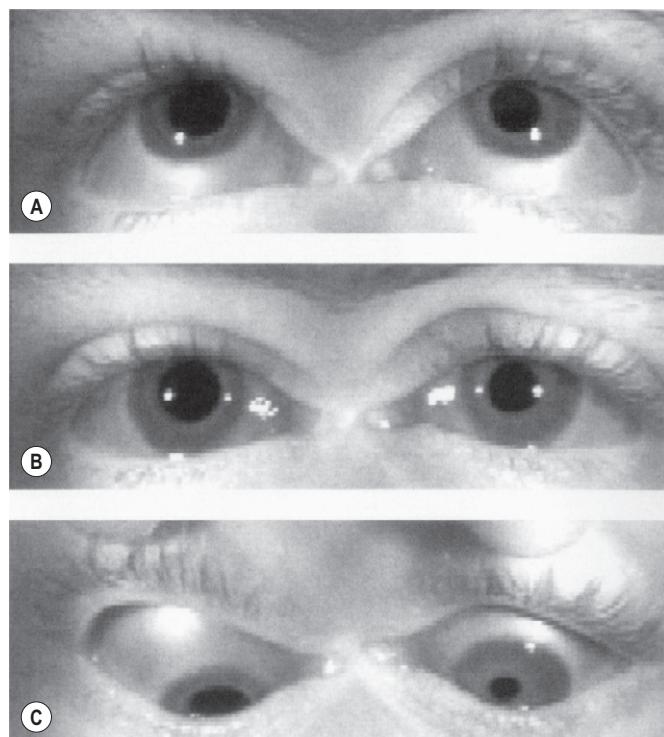

Figure 25.18 Primary aberrant regeneration of the left third nerve following chronic compression of the oculomotor nerve by a meningioma. In darkness (top and center panels) the left pupil is the smaller of the two pupils as a result of innervation by motor nerves. Nerves that normally would have supplied the inferior rectus muscle now are innervating the iris sphincter muscle, causing pupil contraction on downgaze (lower panel).

Table 25.4 Causes of light-near dissociation of the pupil

Cause	Location	Mechanism
Severe loss of afferent light input to both eyes	Anterior visual pathway (retina, optic nerves, chiasm)	Damage to the retina or optic nerve pathways
Loss of pretectal light input to Edinger-Westphal nucleus	Tectum of the midbrain	Infectious (Argyll Robertson pupils) or compression (pinealoma) or ischemia (stroke)
Adie syndrome	Iris sphincter	Aberrant reinnervation of sphincter by accommodative neurons
Third nerve aberrant reinnervation	Iris sphincter	Aberrant reinnervation of sphincter by accommodative neurons or medial rectus neurons

Table 25.5 Causes of poor pupil dilation in darkness

Cause	Location	Mechanism
Past inflammation or surgical trauma	Posterior iris surface or sphincter	Scarring or synechiae of the iris resulting from past iritis
Acute trauma	Sphincter	Prostaglandin release causing sphincter spasm
Adie tonic pupil	Sphincter	Aberrant reinnervation of iris sphincter by accommodative or extraocular motor neurons that are not inhibited in darkness
Third nerve aberrant reinnervation		
Pharmacologic miosis	Iris sphincter	Cholinergic influence
Unilateral episodic spasm of miosis	Postganglionic parasympathetic neuron	Uninhibited episodic activation of postganglionic neurons
Congenital miosis (bilateral)	Sphincter	Developmental abnormality
Fatigue, sleepiness	Edinger-Westphal nucleus	Loss of inhibition at midbrain from reticular activating formation
Lymphoma, inflammation, infection	Periaqueductal gray matter	Interruption of inhibitory fibers to the Edinger-Westphal nucleus
Central acting drugs	Reticular activating formation, midbrain	Narcotics, general anesthetics
Old age (bilateral miosis)	Reticular activating formation, midbrain	Loss of inhibition at midbrain from reticular activating formation
Oculosympathetic defect	Sympathetic neuron interruption	Horner syndrome

mechanisms it is important to understand what normally happens in darkness to allow the pupil to dilate. When a light stimulus is terminated, two mechanisms cause the pupil to dilate. The majority of pupil dilation comes about from inhibition to the Edinger-Westphal nucleus in the midbrain. This reduces the firing of the preganglionic parasympathetic neurons in the Edinger-Westphal nucleus, causing relaxation of the iris sphincter. Within a few seconds, sympathetic nerve firing increases, serving to augment the pupil dilation by active contraction of the dilator muscle. The combined inhibition of the iris sphincter and stimulation of the iris dilator is a carefully integrated neuronal reflex. The inability of the pupil to dilate in darkness may result from the following causes:

1. Mechanical limitations of the pupil (scarring)
2. Pharmacologic miosis
3. Aberrant reinnervation of cholinergic neurons to the iris sphincter that are not normally inhibited in darkness (accommodative or extraocular motor neurons)
4. Lack of inhibitory input signal getting to the Edinger-Westphal nucleus
5. Lack of sympathetic input to the dilator muscle.

Ganglion-Cell Photoreceptors and Non-Image-Forming Vision

Kwoon Y. Wong & David M. Berson

Overview

In the past decade, compelling evidence has emerged for a novel class of photoreceptors in the mammalian retina. These neurons are ganglion cells that express the photopigment melanopsin and respond autonomously to bright light with a sustained depolarization and increase in spike frequency. These intrinsically photosensitive retinal ganglion cells (ipRGCs) differ radically in form and function from the classical rod and cone photoreceptors. In this chapter, we discuss the origins of this discovery, the idiosyncratic physiology of these cells and roles they play in retinal processing and visual behavior in health and disease.

Historical roots

For most contemporary retinal scientists, the recent discovery of photoreceptors in the inner retina may have come as a shock, but the roots of the idea are actually traceable to the very beginnings of retinal science (see reviews^{1–3}). Beginning with Descartes and through the first half of the 19th century, it was assumed that the photoreceptive elements of the retina lined its inner surface, nearest the incoming light.³ For example, Treviranus,⁴ the first to conduct systematic microscopic studies of the retina, suggested that optic fibers passed through all retinal layers to end as photosensitive papillae at the vitreal surface. Bidder⁵ accurately described the outer retinal location of the rods, but hypothesized that they served a reflective function, like a tapetum, and continued to view optic fibers in the inner retina as the locus of phototransduction. The lack of photosensitivity of the fibers of the optic disk, as indicated by the blind spot, eventually undermined this view, and prompted Bowman⁶ and Helmholtz⁷ to propose ganglion cells as the true photoreceptors. It was not until the latter half of the 19th century that photoreception was convincingly localized to the outer retina. The key insights were made by Heinrich Müller, who inferred the retinal depth of the photoreceptors by a clever geometric analysis of the parallactic displacement of shadows of retinal vasculature (the “Purkinje tree”). He also detected “visual purple” or rhodopsin in the rods, which Franz Boll soon thereafter demonstrated was a photosensitive pigment.

Fifty years would pass before interest in the possibility of inner-retinal photoreception would re-emerge. The catalyst was the groundbreaking work of Clyde Keeler, who identified the first animal model of inherited retinal degeneration. This strain of mice – which Keeler termed “rodless” – is allelic with the *rd1* strain (formerly *rd*); both carry the *Pde6b^{rd1}* mutation and phenotypically resemble human autosomal recessive retinitis pigmentosa (OMIM 180072).^{8,9} Keeler eventually achieved wide acclaim for this seminal contribution to the genetics of retinal disease, but a key observation he made in these mice received little notice at the time. Though his *rodless* mice were apparently blind when tested behaviorally or electroretinographically, they unexpectedly retained robust pupillary responses to light.¹⁰ This led him to suggest that “in mammals the iris may function independent of vision” either through intrinsic photosensitivity of the smooth muscle itself or by “direct stimulation of the internal nuclear or ganglionic cells” by light.^{10,11}

Over the next 70 years, a series of studies in retinally degenerate mammals confirmed the persistence of the pupillary response and suggested that the functional blindness might not be as complete as Keeler had believed. Various photic effects on behavior or physiology were noted, despite the absence of an outer retina in histological material or a detectable electroretinogram (see reviews^{12,13}). These included avoidance of a visual cliff, photic suppression of activity in open field test, visually guided avoidance of shock in a shuttlebox, chromatic discrimination, entrainment of circadian rhythms, suppression of pineal melatonin synthesis, and suppression of spontaneous firing in the superior colliculus.^{12,14–19} A number of these studies demonstrated that eye removal abolished these residual photoresponses and overtly echoed Keeler’s speculation about the possible existence of inner retinal photoreceptors, including ganglion cells.^{15,17,18} These suggestions gained only limited currency, probably because improved anatomical studies had begun to cast doubt on the completeness of the loss of outer retinal photoreceptors, especially in the peripheral retina. These studies showed that the mouse retina, once believed to possess only rod photoreceptors, actually had a modest population of cones as well, and that these degenerated far more slowly than rods in the *rd1* model. Perhaps 20 percent survived beyond 80 days of age, albeit without intact outer

segments, and a few lasted at least a year.²⁰ This clouded the interpretation of the behavioral studies, virtually all of which had been conducted in mice young enough to have had many surviving cones. With the benefit of hindsight, however, it seems plausible that at least some of the residual light-driven effects reported in these early studies were indeed mediated by inner retinal photoreceptors. Even in *rd1* animals as young as 6–10 weeks old, surviving rods or cones seem unable to support visual function: silencing ganglion-cell phototransduction in such animals (as described below) abolishes the photic influences on circadian rhythms, the pupil, locomotor activity, and melatonin synthesis that these mice would otherwise exhibit.²¹

In the 1990s, Russell Foster and colleagues took up the work on retinally degenerate mice, applying more rigorous methods to provide compelling evidence for inner retinal photoreception.^{13,22–28} Their innovations included appropriate controls for genetic background and the use of very old *rd1* animals and several genetically modified mouse strains in which they confirmed nearly complete loss of cones as well as rods. They also showed that there was no loss of sensitivity of circadian photoreception as rod and cone degeneration progressed and that the residual visually evoked behaviors extended beyond circadian regulation to other outputs of what they called the non-image-forming (NIF) visual centers of the brain. These included pupillary constriction, acute suppression of locomotor activity and acute suppression of melatonin release by light. The case for novel inner photoreceptors was bolstered by parallel observations in human patients with advanced outer retinal disease^{29–31} and by assessment of the spectral tuning of residual photoresponses in retinally degenerate animals. Yoshimura & Ebihara showed that the photic influence on circadian rhythms in retinally degenerate mice was most effective at 480 nm, clearly distinct from the optimal wavelength for the known rod and cone photopigments.^{32,33} Remarkably similar spectral data were obtained for residual pupillary responses.²⁶

Discovery of melanopsin and ganglion-cell photoreceptors

The identities of the mysterious inner-retinal photoreceptors and their photopigment were established in a flurry of studies in the years 2000 to 2005. These developments have been thoroughly reviewed elsewhere,^{28,34–37} so we provide only an abbreviated summary here. A pivotal contribution was the discovery of melanopsin.^{38,39} This novel opsin (coded by the *opn4* gene) derives its name from the dermal melanophores of frogs, the photosensitive cells of the skin in which the gene was first identified.³⁸ Ignacio Provencio and colleagues showed that in mice and primates, including humans, the protein was expressed solely in a small minority of cells in the inner retina, mainly in the ganglion cell layer. They speculated that melanopsin could be the photopigment of the postulated inner-retinal photoreceptors and that the neurons expressing it might be the cells of origin of the retinohypothalamic tract. These ideas were at odds with an alternative suggestion, introduced a few years earlier, that the relevant photopigment might not be an opsin but, rather, a cryptochromes, a blue-light-absorbing flavoprotein (see

reviews^{35,40}). However, overwhelming evidence for melanopsin's central role soon emerged from studies in rodents and in heterologous expression systems.

Two key studies in this cohort focused on rat retinal ganglion cells shown by retrograde axonal tracing to innervate the suprachiasmatic nucleus (SCN) of the hypothalamus, the brain's circadian pacemaker.^{41–44} The first showed that these ganglion cells expressed melanopsin,^{45–47} while the second demonstrated that they generated robust electrical responses to light even when pharmacologically or mechanically isolated from other retinal neurons.^{48,49} Because this capacity for autonomous phototransduction distinguishes these cells from all other RGCs, they are termed intrinsically photosensitive retinal ganglion cells (ipRGCs) or ganglion-cell photoreceptors. Both mice and primates were also soon shown to possess ipRGCs with structural and functional properties much like those in the rat (see Box 26.1).^{46,50–53}

The presence of melanopsin within physiologically identified ipRGCs was first demonstrated directly by Hattar et al.^{46,50,53} The opsin was found not only in the cell body, but also in their dendrites^{46,54} which, like the soma, are directly photosensitive.⁴⁸ Further support for the view that melanopsin was the sensory photopigment in these cells came from the opsin-like action spectrum of the light response in ipRGCs^{48,51,53} and from the observation that the intrinsic photosensitivity of these cells was abolished in melanopsin knock-out mice.^{51,55} The capacity of melanopsin to function as a sensory photopigment was first

Box 26.1 An Unrecognized Drawback of Enucleation or Evisceration?

Ocular enucleation and evisceration are common surgical therapies for managing chronic debilitating ocular pain and improving cosmesis of blind eyes.^{157,158} Such surgery is typically indicated only in eyes lacking useful vision. However, the recent discovery of inner retinal photoreceptors should prompt a reassessment of best practices in such cases. When the blindness is attributable to outer retinal diseases such as retinitis pigmentosa or Leber's congenital amaurosis, or to chronic retinal detachment, ganglion-cell photoreceptors may continue to provide functionally useful signals to the brain.^{29,30,31,66,159} These signals may not be consciously perceived by the patient and may escape detection by most standard clinical tests of visual function. Such residual functions can nonetheless have significant impact on the quality of life for blind patients, since they may entrain their circadian rhythms.³⁰ Loss of ipRGCs through enucleation or evisceration would be expected to abolish such synchronization of circadian rhythms, with associated disruption of normal sleep patterns, daytime sleepiness, and other complications that plague many blind patients.¹⁶⁰ It seems likely that photic effects on physiology, including regulation of neuroendocrine physiology, alertness and mood, may also persist in such patients and be sacrificed when the eyes are removed. There is thus a pressing need to develop both a more inclusive concept of "useful vision" in ocularly blind patients and a more comprehensive panel of assessments of photosensory capacity when enucleation or evisceration is being weighed as a treatment option. Although tests of circadian or neuroendocrine effects would in principle allow residual inner retinal photoreceptor function to be evaluated, these would require highly specialized testing. Assessments of residual pupillary responses may be a promising avenue to explore.^{133,159,161}

demonstrated biochemically,⁵⁶ and subsequently confirmed by electrophysiology and calcium imaging in heterologous expression systems.^{57–59} There is remarkably good concordance in the spectral sensitivity in this system, as assessed from absorbance of heterologously expressed or purified melanopsin, from the action spectrum of ipRGCs, and from behaviors mediated by inner retinal photoreceptors; all closely adhere to a retinaldehyde template function with a best wavelength near 480 nm^{26,32,33,48,51,53,58–63} (but see refs 56 & 57).

Distinctive functional properties of ipRGCs

Ganglion-cell photoreceptors have physiological properties that are optimized for their roles in NIF vision and contrast markedly with those of the rod and cone photoreceptors that feed the cortical circuits mediating the perception of form, color and motion.

Melanopsin chromophore and pigment bistability

In both vertebrate and invertebrate photopigments, the opsin apoprotein is covalently linked to a retinaldehyde molecule derived from vitamin A that serves as the light-absorbing moiety, or chromophore. In darkness, the retinaldehyde is in the 11-cis form. Absorption of a photon converts it into all-trans retinaldehyde. This triggers a conformational change in the opsin which in turn activates a G-protein, initiating the transduction cascade. Before the photopigment can undergo another cycle of photoexcitation, the all-trans retinaldehyde must be reisomerized to 11-cis. For rod and cone photoreceptors, such reisomerization is carried out through multiple enzymatic steps. Several of these occur in cells of the retinal pigment epithelium (RPE), which are essential for the visual cycle in rods and important, if not obligatory, for cones (see Chapter 13 for more information). The visual cycle in invertebrate photoreceptors appears to be radically different, in part because their photopigments are bistable: after photoexcitation, all-trans retinaldehyde remains covalently bound to the opsin and is reisomerized to 11-cis by subsequent absorption of light in a process known as photoreversal.⁶⁴

The visual cycle of melanopsin in ipRGCs has not been well characterized. The chromophore of melanopsin in situ is unknown, but is doubtless a retinoid, and is most likely to be 11-cis retinaldehyde.^{56–61,65} Sequence homology indicates that melanopsin resembles invertebrate opsins more than it does vertebrate ones,^{38,39} implying that it might be bistable. There is growing evidence in support of this view^{57,61,65–68} (but see ref. 69). If melanopsin is indeed bistable, it would be expected to be less reliant than rods or cones on the enzymatic machinery of the RPE for the regeneration of its chromophore, and might be utterly independent. Indeed, ipRGC photoresponses can be recorded for many hours in vitro in retinas isolated from the RPE.⁴⁸ Furthermore, neither acute pharmacological disruption of the retinoid cycle nor genetic deletion of the essential isomero-hydrolase of the RPE (RPE65) abolishes the melanopsin-based photoresponse of ipRGCs or their ability to

Box 26.2 Sparing of ipRGC Function in Conditions Involving the RPE: Retinal Detachment and Leber's Congenital Amaurosis

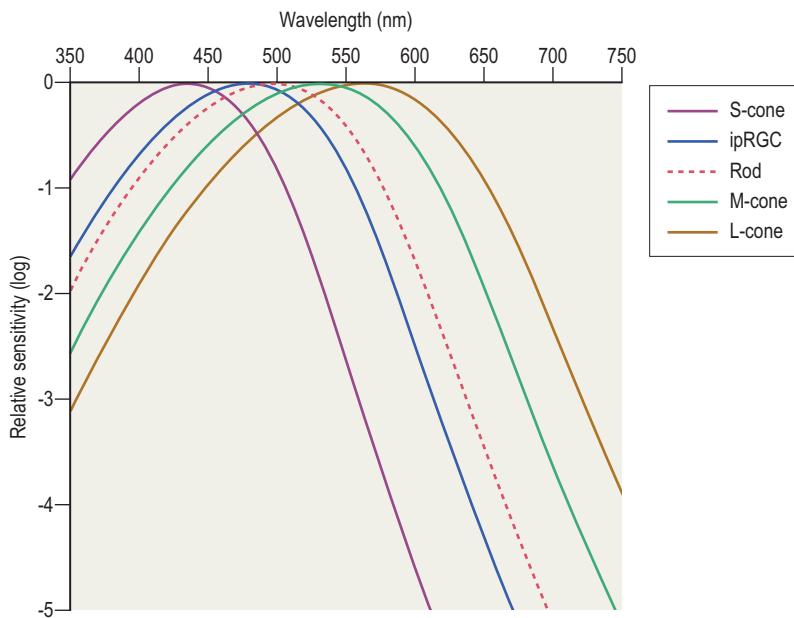

There are at least two clinical conditions in which disruption of normal interactions between RPE and neural retina compromise rod and cone function but may permit continued phototransduction by ipRGCs. Retinal detachment disrupts the close contact between rod and cone outer segments and the RPE. This compromises the bidirectional exchange of retinoids across the subretinal space and thus the photosensitivity of rods and cones. Leber's congenital amaurosis (LCA), an autosomal recessive, early-onset form of retinitis pigmentosa, is caused in some cases by mutations in the *rpe65* gene. This disrupts the function of RPE65, a retinoid isomerase essential for the regeneration of 11-cis chromophore for rod and cone photopigments. Both retinal detachment and LCA have devastating consequences for photosensitivity of rods and cones. Evidence from animal studies (see main text) predicts that photosensitivity of ipRGCs should be substantially preserved under these conditions and should thus provide some useful photic information to the brain.

photoentrain circadian rhythms^{66,70} (but see ref. 65). The evidence implies that to a remarkable degree, the melanopsin in ipRGCs can be loaded with its chromophore and can recover from photoactivation independent of retinoid processing by RPE. Melanopsin might acquire its retinoid mainly in the form of all-trans retinal which it then photoisomerizes to a cis isomer to form a photoexcitable pigment. This autonomy is important for the intrinsic photosensitivity of ipRGCs, because these cells are located far from the RPE (see Box 26.2).

Spectral tuning

As noted above, melanopsin has peak sensitivity in the blue region at around 480 nm, different from the spectral sensitivities of the rod and cone visual pigments (Fig. 26.1). This wavelength roughly coincides with the peak of solar emission, perhaps the result of evolutionary pressures to optimize the sensitivity of this system to daylight. Though melanopsin is often described as a blue-light-sensitive pigment, it is important to recognize that, like other opsin-based photopigments, its spectral tuning is rather broad. Throughout the spectral range from 340 to 590 nm, sensitivity is within 2 log units of that seen with the optimal wavelength (Fig. 26.1). Though there is evidence that ipRGCs project to the lateral geniculate nucleus (LGN) and could thus contribute to cortical function,^{53,71} we are unaware of any evidence that the unique spectral tuning of melanopsin is exploited in the conscious appreciation of color, which is well accounted for by the three cone photopigments and trichromatic theory (see Box 26.3).

The spectral behavior of the ipRGC output signal is much more complex than predicted simply from the action spectrum of the intrinsic light response as measured in dark-adapted ipRGCs. This is in part because melanopsin appears to be a bistable photopigment (see the previous section). The absorption spectrum of the activated form of the pigment, and thus of photoreversal, is shifted to longer wavelengths with respect to that of melanopsin in the dark

**Figure 26.1 Spectral tuning of human photoreceptors.**

The spectral sensitivity of melanopsin-based phototransduction in intrinsically photosensitive retinal ganglion cells (ipRGCs) differs from that of the other four types of human retinal photoreceptors. The best wavelength for ipRGCs is at about 480 nm, as compared to 437 nm for the short-wavelength cone ("S-cone"), 498 nm for the rod, 533 nm for the mid-wavelength cone ("M-cone"), and 564 nm for the long-wavelength cone ("L-cone").

Box 26.3 Spectral Issues in the Design of Intraocular Lens Implants

Designers of intraocular lens implants must grapple with the fact that there are both harmful and salutary effects of short-wavelength visible light. The goal must be to strike the appropriate balance between photoprotection and photoreception. High-pass filters that block blue as well as ultraviolet wavelengths offer better retinal photoprotection than those that block only ultraviolet light, while leaving rod and cone photoresponses (which peak near 500 nm and 555 nm respectively) relatively unaffected. However, because melanopsin is most sensitive to blue light with peak sensitivity at 480 nm, lenses that block blue wavelengths can compromise NIF photoreception.¹⁶² On the other hand, reducing NIF photoreception in this manner might have the benefit of reducing the harmful effects of light exposure at night on the NIF visual system, as discussed in the main text below. These factors need to be considered in the design and selection of lens implants. A recent study showed that for the typical person, long-pass filtering with a sharp filter cutoff near 445 nm may provide the best compromise between photoprotection and light reception.¹⁶³

state (e.g. refs 61 & 67). How this shapes the ipRGC output signal under physiologically relevant lighting conditions is still in dispute,^{67,69,72} but it suggests the possibility of a form of spectral opponency under some conditions. A second source of complexity and potential spectral opponency is the functional input to the ipRGCs from classical rod and cone photoreceptors, discussed in detail below. Because the threshold for melanopsin activation is above that for rods and cones, the spectral tuning of ipRGCs can be expected to be intensity dependent. Furthermore, there is evidence in primates that the cone input to ipRGCs is itself spectrally opponent, with activation of short-wavelength cones driving OFF responses in ipRGCs, and activation of mid- and long-wavelength cones driving ON responses.⁵³

Invertebrate-like phototransduction cascade

In a photoreceptor cell, the light-absorbing pigment signals through an intracellular biochemical pathway to transduce light into electrical activity across the cell membrane. Interestingly, in ipRGCs this phototransduction cascade is more similar to those in invertebrate photoreceptors than to those in rods and cones. We have already noted that melanopsin has greater sequence homology with invertebrate photopigments than with the rod and cone opsins.^{38,39} Upon stimulation by light, melanopsin activates a G-protein belonging to the $G_{q/11}$ family, which in turn signals to the effector enzyme phospholipase C (PLC).^{58,59,61,76-77} PLC then somehow causes the opening of a cation channel, which has been proposed to belong to the family of transient receptor potential (TRP) channels.⁷⁷⁻⁷⁹ While the signaling intermediates coupling PLC to the cation channel remain to be elucidated, the critical components are likely to be within or closely associated with the plasma membrane because patches of cell membrane isolated from ipRGCs continue to exhibit light-evoked electrical responses.⁷³ Thus, the entire ipRGC phototransduction cascade is very similar to that in *Drosophila* photoreceptors⁸⁰ but differs drastically from the rod/cone cascade⁸¹ (see also Chapter 18) (Fig. 26.2). This invertebrate-like phototransduction cascade has prompted speculation that ipRGCs and invertebrate photoreceptors share a common evolutionary origin.⁸² It also confers upon ipRGCs properties well suited to NIF vision, as discussed below.

Depolarizing photoresponse with action potentials

The endpoint of the melanopsin phototransduction cascade is the opening of ion channels in the plasma membrane. These behave like cation-selective channels.^{48,49} The interior of an ipRGC is negatively charged relative to the extracellular space so the opening of light-gated channels results in net influx of cations and membrane depolarization. In this

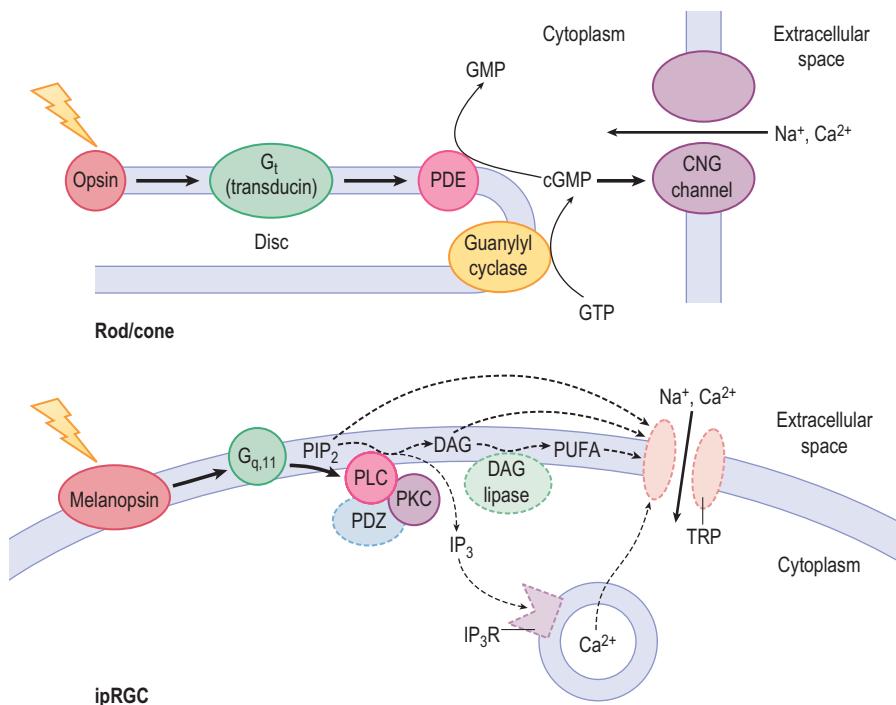

Figure 26.2 Contrasting phototransduction cascades in vertebrate photoreceptors. *Top:* Phototransduction cascade in rod and cone photoreceptors. In darkness, guanylyl cyclase converts GTP into cGMP, which binds to and opens cyclic nucleotide-gated (CNG) channels in the plasma membrane. The resulting continuous influx of cations maintains the cell in a depolarized state. Light absorption excites the opsin molecule within the disk membrane. This activates the G-protein transducin (G_i), which in turn stimulates phosphodiesterase ("PDE"). PDE cleaves cGMP to GMP, closing the CNG channels and hyperpolarizing the cell. *Bottom:* Phototransduction cascade in ipRGCs. Solid lines indicate established components and pathways; dotted lines indicate those that are possible but not proven. When melanopsin is excited by light, it signals through a G-protein of the $G_{q/11}$ -family to activate phospholipase C ("PLC"). This ultimately opens a cation channel that probably belongs to the TRP superfamily, but the identity of the channel and the gating mechanism remain unknown. The signaling pathway is closely linked to the membrane and may involve depletion of the PLC substrate phosphatidyl 4,5-bisphosphate (PIP_2), its metabolite diacylglycerol ("DAG"), or polyunsaturated fatty acids ("PUFA") generated from DAG by DAG lipase. An isoform of protein kinase C (PKC) also appears to play an important role and, by analogy with *Drosophila* phototransduction, may be linked to PLC by an INAD-like scaffolding protein that contains PDZ domains. The cytosolic product of PIP_2 hydrolysis, inositol 1,4,5-trisphosphate (IP_3), acts at its cognate receptor (IP_3R) to liberate calcium from intracellular stores. Though such calcium mobilization is not necessary for phototransduction, it appears to play a significant modulatory role.

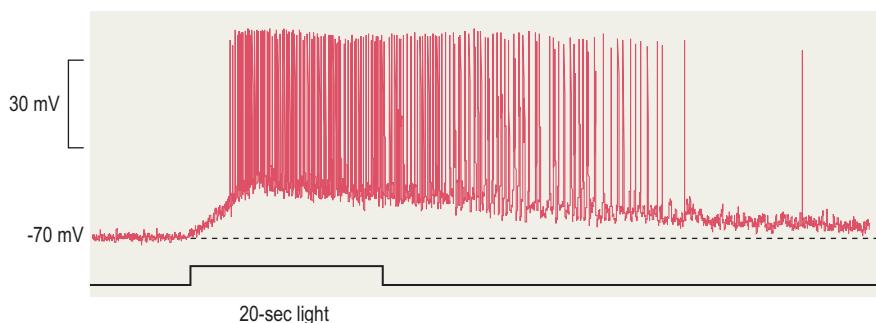

Figure 26.3 Melanopsin-driven light response of an ipRGC. Ganglion-cell photoreceptors can respond to light through not only their melanopsin phototransduction but also rod/cone-driven synaptic input. Here, the light-evoked response of a rat ipRGC was recorded intracellularly in the presence of pharmacological agents that blocked synaptic input, thus isolating the intrinsic photosensitivity of this cell. The dotted black line marks the prestimulus level of the membrane potential. Notice that the light-evoked action potentials begin long after stimulus onset and that they persist throughout and even long after the stimulus (K. Y. Wong, unpublished).

ipRGCs once again resemble invertebrate rhabdomeric receptors, which likewise depolarize when illuminated, and differ from the vertebrate rods and cones, which are hyperpolarized by light. If the depolarizing ipRGC light response is large enough, it brings the membrane potential above the threshold for activating voltage-gated sodium channels,

triggering action potentials (Fig. 26.3). This represents yet another divergence from the rod/cone photoreceptors, which do not spike. Action potentials are necessary for ipRGCs, as for other RGCs, to propagate electrical information faithfully along the optic nerve and tract to relatively distant central visual centers. By contrast, rod and cone

axons are very short, and passive spread of the electrical signals generated in the outer segment is sufficient for appropriate voltage modulation of the axon terminal.

Sensitivity

A salient feature of ipRGCs is the relative insensitivity of their melanopsin-mediated responses to light. The threshold intensity for the ipRGC intrinsic photoresponse is 1 to 2 orders of magnitude (i.e. 10–100 times) higher than that for cones, and up to 5 log units higher than that for rods.^{48,53,83} Such insensitivity is apparently due mainly to the low abundance of melanopsin molecules in ipRGCs, and the resulting low probability of photon absorption.⁸⁴ This in turn is related to the fact that ipRGCs lack any structural specialization for increasing the packing of pigment-laden membrane in the cell, such as the disks in the outer segments of rods and cones or the rhabdomeric microvilli of invertebrate photoreceptors. The insensitivity of intrinsic, melanopsin-based responses in ipRGCs means that such responses are triggered mainly by bright sunlight during the day, which is the most effective stimulus for circadian photoentrainment and full pupillary constriction. Because the dynamic range of these responses complements those of the rod and cone photoreceptors, and because all three of these signals converge on the ipRGCs (see below), the ipRGCs and at least some of the NIF visual responses they drive are able to function over the entire intensity range of naturally encountered light stimuli.^{53,55}

Kinetics

The temporal characteristics of the melanopsin-based ipRGC photoresponse are drastically different from those of the rod and cone photoreceptors, with remarkably slower onset and termination, and great stability in the face of sustained illumination. Rod and cone photoresponses begin within several milliseconds of light onset and peak within tens of milliseconds. Even the fastest ipRGC intrinsic responses, evoked by very high light intensities ($>10^{14}$ photons/cm²/sec at 480 nm), are much slower, with the first action potential appearing no earlier than a few hundreds of milliseconds after light onset and peak firing rate achieved only after several seconds. Latencies rise dramatically for less intense flashes, and for near-threshold light stimuli ($\sim 10^{11}$ photons/cm²/sec at 480 nm) can be as long as tens of seconds to the first spike and several minutes before the peak discharge is reached.⁴⁸ The basis for such sluggish onset is unknown, but it is of interest that when melanopsin was heterologously introduced into three different cell culture systems, the photoresponses recorded had very slow onset in all three cases.^{57–59} Such sluggishness appears unlikely to be an intrinsic property of melanopsin, because single-photon responses in ipRGCs reportedly have relatively brisk onsets.⁸⁴ The long latencies, especially near threshold, seem more likely to result from the temporal integration of many low-amplitude, long-lasting, single photon events.

In response to a prolonged light flash, the melanopsin-driven response gradually decays from an early peak to a lower steady-state level. This reflects light adaptation, which prevents saturation of the phototransduction cascade.⁸⁵ After light adaptation is complete (which typically requires several minutes), membrane potential and thus spike frequency remain elevated for as long as the light stimulus persists.

Analysis of activity-dependent induction of the immediate early gene *cfos* in putative ipRGCs implies that these photoreceptors can respond continuously to light for at least 19 hours.⁸⁶ Thus, the ipRGC intrinsic photoresponse is far more sustained (Fig. 26.3) than the cone response, which adapts much faster and more completely, making the response very transient. The ability of ipRGCs to continuously signal the presence of bright light for many hours is a key feature of the NIF visual system, which features tonic responses to steady diffuse illumination and the ability to integrate photon flux over periods of more than an hour, as explained in further detail below.

The termination of the melanopsin light response is extraordinarily slow. After the cessation of light stimulation, cone and rod responses terminate within hundreds of milliseconds and several seconds, respectively. But termination of the intrinsic photoresponse of ipRGCs takes up to several minutes, especially for very high light intensities.^{48,51,53} The reason for this slow recovery is not established, but the similarity of melanopsin to invertebrate rhabdomeric opsins suggests that it results in part from the thermal stability of the light-activated (metarhodopsin) form of the photopigment.^{61,68} If so, the slowly decaying post-stimulus voltage response is directly analogous to the persistent depolarizing afterpotential of invertebrate photoreceptors.⁶⁴ This is supported by the observation that the poststimulus depolarization can be suppressed by exposure to long-wavelength light, presumably by triggering photoreversal of the pigment.⁶⁸ However, light is not required for response termination, because this can occur in complete darkness. The light-independent mechanisms for response termination are unknown. By analogy to other better characterized phototransduction cascades, however, they seem likely to involve phosphorylation of melanopsin followed by arrestin binding.

Morphology, retinal distribution and receptive field

In all mammals studied to date, melanopsin-expressing retinal ganglion cells represent a small minority of all RGCs. These are now recognized as comprising multiple cell types. The best studied type has a very large, sparse dendritic arbor stratifying in outermost inner plexiform layer (IPL), abutting the inner nuclear layer (INL).^{46,48,49,53,54,87} In mouse and primate retinas, there is an additional wide-field melanopsin ganglion cell type stratifying in inner IPL^{53,54,71,87–89} (Fig. 26.4). In humans, there are roughly equal numbers of these two cell types, and most of the outer-stratifying type have somas displaced to the INL. Bistratified cells have also been described,^{49,88,89} although it is not clear if these define a distinct cell type. Recent evidence in the mouse suggests there are several additional types with very low levels of melanopsin expression.⁹⁰ Differences among these cell types in functional properties or projections to the brain are just beginning to be explored.^{90,91} A very few human cones of the far retinal periphery have been reported to express melanopsin, but their functional significance is unknown.⁹²

The morphology and distribution of human ipRGCs have been described in detail.^{52,53} Of the ~1.2 million RGCs in humans, only about 3000 (about 0.2 percent) express melanopsin. The somas of these cells are relatively large in

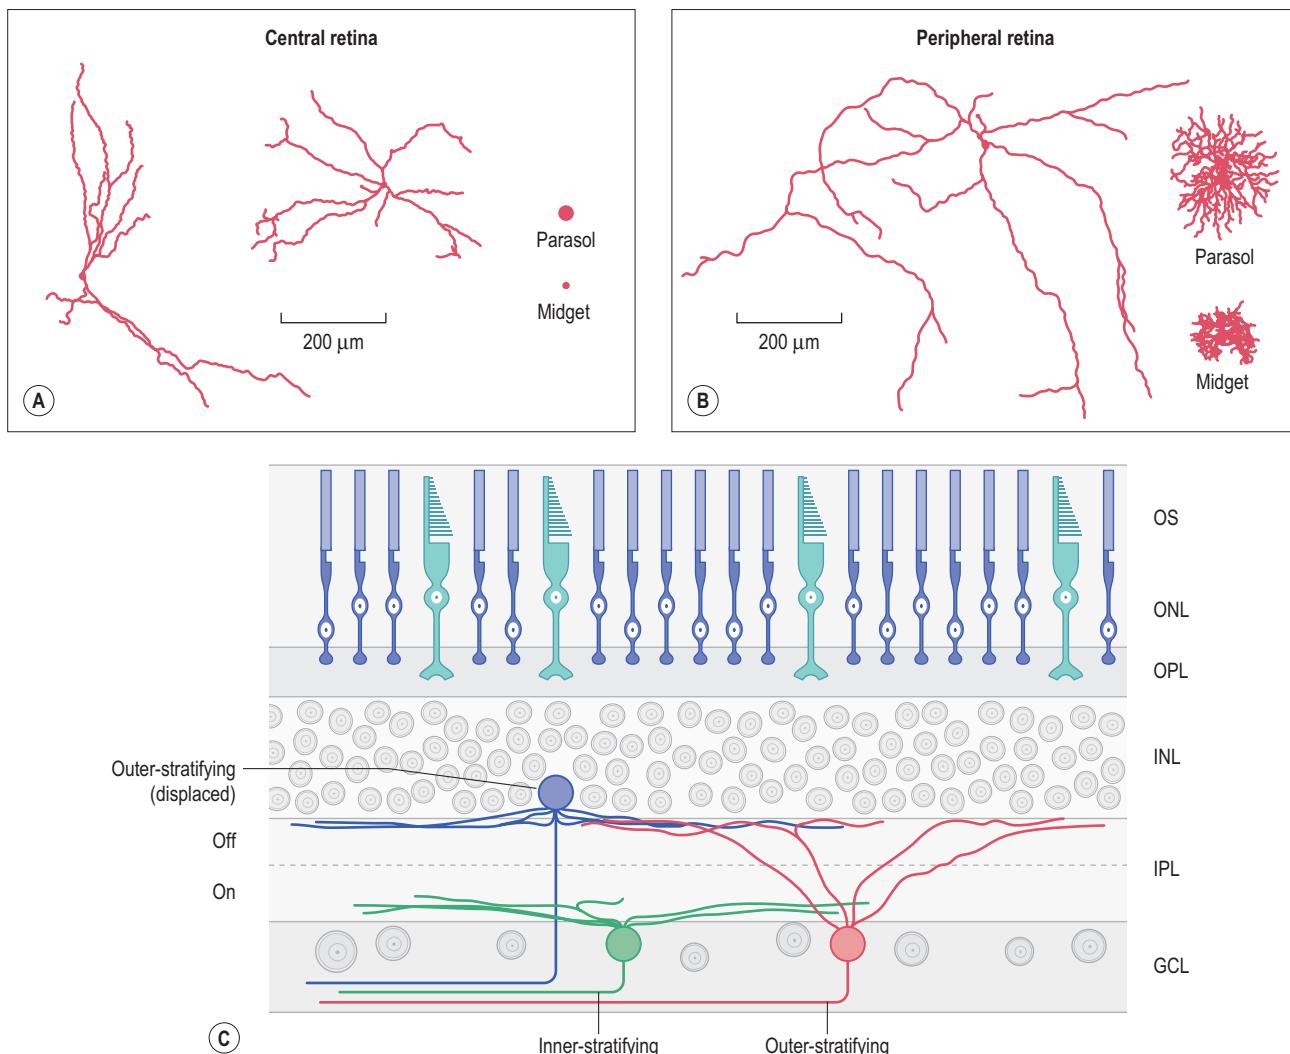

Figure 26.4 Morphology of ipRGCs. Top: Morphology of primate ipRGCs as seen in wholermounted retina. The dendritic arbors of these cells cover much less area in the central retina (*left*) than they do in the periphery (*right*), but at all eccentricities they have among the largest fields of any primate ganglion cells. For comparison, the much smaller and more densely branching dendritic fields of midget and parasol cells (two ganglion cell types mediating image-forming vision) are also shown. (Reproduced with permission from Dacey DM, Liao HW, Peterson BB, Robinson FR, Smith VC, Pokorny J, et al. Melanopsin-expressing ganglion cells in primate retina signal colour and irradiance and project to the LGN. *Nature*. 2005 Feb 17;433(7027):749-54. By permission from Macmillan Publishers Ltd.⁵³) Bottom: Dendritic stratification of ipRGCs as seen in a schematic cross-section of the retina. There are two main types of ipRGCs, differing in the level at which their dendrites arborize within the inner plexiform layer ("IPL"). Outer-stratifying ipRGCs have dendrites that terminate in the OFF sublamina of the IPL and their cell bodies are located either in the ganglion cell layer ("GCL"; *red cell*) or displaced to the inner nuclear layer ("INL"; *blue cell*). The inner-stratifying ipRGCs (*green cell*), by contrast, have dendrites restricted to the ON sublamina of the IPL and have somas in the GCL. In primates, including humans, inner-stratifying cells and displaced outer-stratifying cells apparently predominate. OS, outer segments; ONL, outer nuclear layer; OPL, outer plexiform layer.

primates, typically 15–25 μm in diameter. Their dendritic fields are the largest of any ganglion-cell type, ranging from 300 μm in the central retina to 1200 μm in the periphery (Fig. 26.4). The dendrites of neighboring cells overlap extensively so that the entire retina, except for the fovea, is covered by a network of melanopsin-containing processes (Fig. 26.5). Because both the cell bodies and the dendrites of these cells are intrinsically photosensitive,^{48,53} each ipRGC integrates photons over a region comparable to its dendritic field size. These large receptive fields and low spatial densities make ipRGCs ill-suited for fine spatial discriminations, but ideal for the pronounced spatial integration that characterizes NIF functions. They contrast sharply with the very small receptive fields of rods and cones (<10 μm in diameter), the foundation for the fine-grained retinal

representations at the cortical level that permit high acuity spatial vision.

Resistance to pathological states

Several studies have suggested that ipRGCs are more resistant to certain types of retinal damage than are other ganglion-cell types. For instance, after axotomy, melanopsin-expressing RGCs have a higher survival rate.⁹³ In addition, melanopsin RGCs are less susceptible to artificially induced chronic ocular hypertension in Sprague-Dawley rats,⁹⁴ although their number are certainly reduced.⁹⁵ Furthermore, ganglion cells exhibiting cFos induction by light (presumably including ipRGCs) were much less vulnerable to systemically administered monosodium glutamate,⁹⁶ suggesting that ipRGCs

are relatively resistant to excitotoxicity. The molecular basis for these kinds of resistance is largely unknown, although the PI3 K/Akt signaling pathway appears to be involved.⁹⁷ Further investigation into the molecular basis of ipRGC survival after retinal injuries may lead to novel strategies for preventing and/or treating various retinal diseases (see also Box 26.4).

Synaptic input

Unlike conventional RGCs, ipRGCs do not require synaptic input to respond to light because they are directly photosensitive. Nonetheless, both primate and rodent ipRGCs receive synaptic inputs from amacrine and bipolar cells, and these have consequences for the timing, spectral behavior and sensitivity of the light-evoked discharges of these cells. A schematic diagram summarizing the intraretinal synaptic inputs to ipRGCs appears in Figure 26.7.

Bipolar cell input

There is strong structural and physiological evidence for synaptic contacts from bipolar cells onto ipRGC dendrites. The earliest anatomical evidence came from electron-microscopic immunohistochemical data in mice showing ribbon synaptic (bipolar) contacts onto melanopsin-expressing dendrites⁹⁸ and this has been supported by subsequent structural observations.^{87,88,99} Bipolar-cell input to ipRGCs has also been confirmed electrophysiologically. Rodent ipRGCs are excited by applied glutamate, the transmitter released by

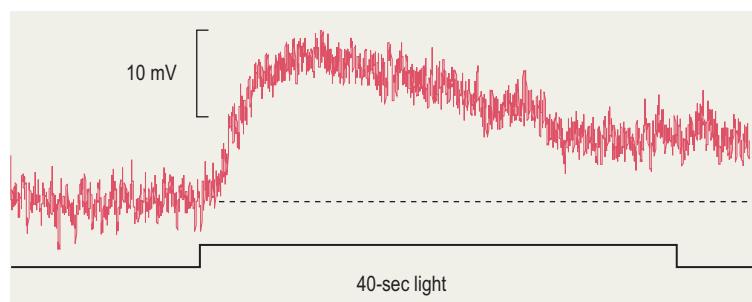

Box 26.4 Promise of Melanopsin-based Gene Therapy for Blindness

Transient transfection with the melanopsin gene is sufficient to induce photosensitivity in a variety of cell types in culture^{57–59} (Fig. 26.6 *top*). Introduction of melanopsin into inner retinal cells thus holds promise as a candidate gene therapy for restoring sight in retinitis pigmentosa and other forms of outer retinal blindness. The practicality of this approach is enhanced by the fact that ipRGCs do not depend upon the RPE for chromophore regeneration. Another advantage is that all of the critical elements of melanopsin-driven phototransduction appear to be associated with the plasma membrane, thus reducing the requirements for specialized cytosolic machinery. Indeed, two recent studies using a mouse model of retinitis pigmentosa report that transfected conventional RGCs with the melanopsin gene renders most of them photosensitive and can rescue some light-driven behavioral responses^{156,164} (Fig. 26.6 *bottom*).

However, several disadvantages of this approach need to be considered. First, in both ipRGCs and the various heterologous expression systems, the melanopsin-based photoresponse is far more sluggish than those of the rods and cones. Thus, even if image-forming vision is restored, the patient's perception of stimulus motion and of the timing of transient visual events would presumably be highly distorted. Second, ipRGCs are even less sensitive to light than cones, so visual threshold would be even higher than for people suffering from night blindness. Still, melanopsin is ~3–5 log units more sensitive than the most promising alternative candidate for gene therapeutic induction of inner-retinal photosensitivity, namely the microbial light-gated ionophore channelrhodopsin-2.^{165,166} Threshold intensities are approximately 10^{11} photons/cm²/sec for melanopsin as compared to $\sim 10^{14}$ to 10^{16} photons/cm²/sec for channelrhodopsin-2. Third, if melanopsin is targeted to RGCs, all of which have dendritic fields vastly larger than the profile of rod and cone outer segments, then spatial resolution would be quite poor. The average receptive field diameter of melanopsin-transfected mouse RGCs in one study was about 100 μm.¹⁶⁴ To improve spatial resolution, it might be better to selectively target bipolar cells for melanopsin transfection,¹⁶⁶ though it is unknown if these cells express critical components of the melanopsin phototransduction cascade. Even if they do, sensitivity is likely to be an even greater concern than in ganglion cells; the relatively small area of surface membrane in bipolar cells would presumably limit the number of melanopsin molecules available for photon absorption.

bipolar-cell terminals. Spontaneous glutamate-mediated excitatory postsynaptic currents are detectable in ipRGCs, and these almost certainly derive from bipolar cell synapses.^{83,100} Under appropriate recording conditions, white light elicits two excitatory ON response components in ipRGCs. The first has a high threshold, is sluggish in its onset and termination, and is insensitive to synaptic blockers; these properties testify to its origin in intrinsic melanopsin-based phototransduction. The other component occurs much more rapidly after light onset, can be abolished by pharmacological blockade of synaptic transmission, and is attributable to excitatory synaptic input from ON bipolar cells.^{53,83,100} Both rods and cones contribute to these extrinsic light responses, making them about five orders of magnitude more sensitive to light than the melanopsin photoreponse^{53,83} (Fig. 26.8).

It is surprising that the ON channel provides the dominant bipolar input to all ipRGCs. ON bipolar cell axons are thought to contact ganglion cell dendrites only in the inner

Human embryonic kidney cells**Figure 26.6 Induction of photosensitivity by ectopic melanopsin expression.**

Artificially expressing the gene for melanopsin in cells that normally lack photosensitivity can render them light-responsive. *Top:* Intracellular recording of the light-evoked depolarization in a human embryonic kidney cell transiently transfected with the mouse melanopsin gene (K. Y. Wong, unpublished). *Bottom:* An intracellular recording of light response in a ganglion cell in a retinal degeneration mouse retina virally transfected with the melanopsin gene. (Reproduced with permission from Lin B, Koizumi A, Tanaka N, Panda S, Masland RH. Restoration of visual function in retinal degeneration mice by ectopic expression of melanopsin. *Proc Natl Acad Sci U S A.* 2008 Oct 14;105(41):16009–14.¹⁶⁰) This light sensitivity was induced by the genetic manipulation because this morphological type of ganglion cell is not intrinsically photosensitive in control retinas. In both cases, the artificially induced light responses resemble the intrinsic light response of ipRGCs (compare with Fig. 26.3).

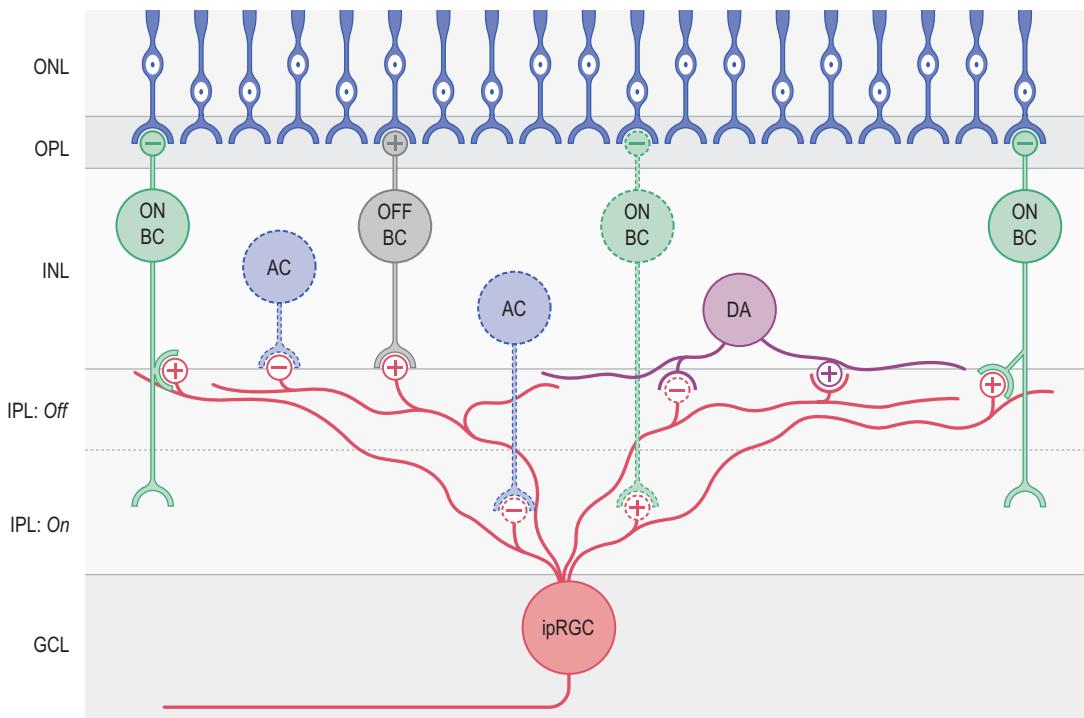

rd/rd mouse retinal ganglion cell

Figure 26.7 Synaptic circuits involving outer-stratifying ipRGCs. In rat and mouse retinas, outer-stratifying ganglion-cell photoreceptors are known to receive direct synaptic inputs from ON bipolar cells ("ON BC"), OFF bipolar cells ("OFF BC"), and amacrine cells ("AC"). ON bipolar cells normally innervate ganglion cells in the proximal, ON sublamina of the IPL, but because the dendrites of outer-stratifying ipRGCs are mainly in the distal, OFF sublamina, ON bipolar cells use ectopic synapses in the OFF sublamina to signal to these ipRGCs (*left and right ON BCs*). However, since the proximal dendrites of these ipRGCs are in the ON sublamina, it is conceivable that some ON bipolar cells synapse onto these proximal dendrites (*middle ON BC*). Weak input from OFF bipolar cells is presumably mediated by synaptic contacts in the OFF sublamina. Amacrine cells provide a strong inhibitory input to outer-stratifying ipRGCs, although it remains to be determined whether this takes place in the OFF sublamina, the ON sublamina, or both. In addition, outer-stratifying ipRGCs exert synaptic output to some dopaminergic amacrine cells ("DA"), whose processes costratify in the OFF sublamina with the ipRGC dendrites. It is possible that dopaminergic amacrine cells signal to outer-stratifying ipRGCs through the inhibitory transmitter GABA and there is evidence that their release of dopamine modulates phototransduction in these ganglion cells.

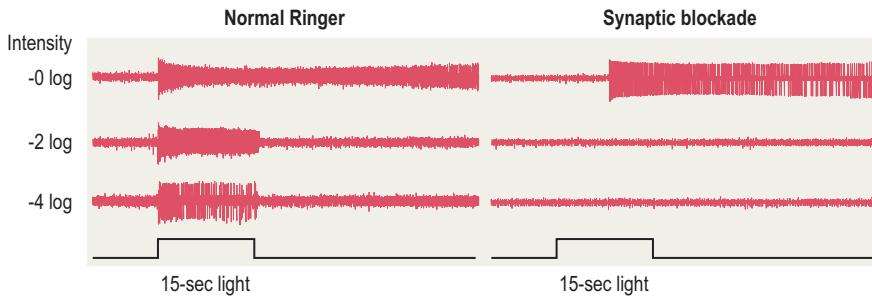

Figure 26.8 A rat ipRGC generating rod/cone-driven and melanopsin-based light responses. Extracellular recordings of spiking in a rat ipRGC evoked by light stimuli at three intensities (dimmest at bottom, brightest at top); the vertical lines in the traces are action potentials. *Left:* Under normal physiological conditions, this cell is capable of generating both rod/cone-mediated responses and melanopsin-based light responses. At the two dimmest light intensities, only rod/cone-mediated responses are induced, and they have fast onset and termination. At the highest intensity, the melanopsin response is also activated, resulting in prolonged poststimulus spiking. *Right:* In the presence of drugs that block synaptic transmission, only the intrinsic melanopsin light response is induced. Notice the slow response onset and prolonged poststimulus persistence, which are similar to those in the intracellular recording shown in Figure 26.3. (K. Y. Wong, unpublished)

half of the IPL, that is, in the ON sublamina.^{101,102} While this arrangement is congruent with the ON input to the inner-stratifying variety of ipRGCs, it seems at odds with the observation that the ON channel also dominates the synaptic inputs to the outer-stratifying type, which arborizes largely or exclusively within the OFF sublamina.^{48,53,54,87–90} Because many of the outer-stratifying cells have somas in the ganglion cell layer, their dendrites must traverse the ON sublayer en route to the OFF sublayer, so some of the ON channel input may occur in the ON sublayer on proximal dendrites (Fig. 26.7). Indeed, Belenky et al⁹⁸ reported that virtually all bipolar cell contacts onto melanopsin dendrites were found in the inner half of the IPL, although they did not indicate whether these dendrites derived from the outer- or inner-stratifying subtype of melanopsin RGCs. Østergaard et al⁹⁹ have also suggested that rod bipolar cells (a subtype of ON bipolar cells) make direct contact onto the somas of melanopsin-expressing RGCs in the ganglion cell layer. However, contacts solely on the soma or proximal dendrites would severely restrict the size of the synaptically driven receptive fields of these cells, when in fact they are large and coextensive with the dendritic arbor.^{53,83} This suggests that there must be additional ON bipolar input to distal dendrites in the OFF sublayer. This inference is further supported by the observation that displaced ipRGCs, which have somas in the INL and dendrites restricted to the OFF sublamina, nonetheless exhibit synaptically mediated ON responses.^{53,103} There is emerging evidence that these paradoxical ON bipolar inputs are made by ectopic ON bipolar cell axon terminals in the OFF sublamina¹⁰³ (Fig. 26.7).

Pharmacological blockade of ON bipolar cells and amacrine cells reveals in some outer-stratifying ipRGCs a very small depolarizing ipRGC response at light offset, indicating a relatively weak input from OFF bipolar cells.⁸³ The anatomical basis for this influence may be the sparse bipolar cell contacts onto melanopsin dendrites in the OFF sublamina reported in the marmoset retina,⁸⁷ although these contacts could also be ectopic ON bipolar terminals.

Amacrine cell input

Ganglion-cell photoreceptors also receive substantial synaptic input from amacrine cells. Initial evidence came from an

electron microscopic study in mouse documenting amacrine cell synaptic release sites in close apposition to melanopsin-containing dendrites in the IPL.⁹⁸ The dominant effect of these inputs is almost certainly inhibitory because virtually all amacrine cells contain one of two major inhibitory transmitters – γ -aminobutyric acid (GABA) or glycine. However, excitatory amacrine cell influences cannot be excluded because a wide variety of neurotransmitters or modulators have been found to be co-expressed with GABA or glycine in amacrine cells, including dopamine, acetylcholine and various neuropeptides, and some of these can exert excitatory effects. To date, however, only inhibitory modulation on ipRGCs has been documented. Studies in rodent retina have demonstrated that exogenously applied or endogenously released GABA or glycine trigger inhibitory chloride currents in ipRGCs and that such currents can be activated by light, primarily at light onset.^{83,88,100} In primate ipRGCs, amacrine inputs have not been investigated electrophysiologically but there is anatomical evidence for them in the marmoset, where they contact both outer- and inner-stratifying melanopsin-expressing dendrites and outnumber those from bipolar cells,⁸⁷ consistent with electrophysiological evidence in rat ipRGCs that inhibitory synaptic conductances can dominate excitatory ones.⁸³ However, under normal physiological conditions, the net effect of light-driven synaptic input to ipRGCs is depolarizing (Fig. 26.8). This is presumably because the resting potential of ipRGCs is close to the reversal potential for chloride, so that increased chloride conductance triggered by amacrine-cell synaptic input induces little change in membrane potential.

There are at least two dozen subtypes of amacrine cells in mammalian retinas, differing in dendritic stratification and field size as well as in their neurochemical signature.^{104–106} Work to identify which of these amacrine types innervate the ipRGCs has barely begun, but several have already been identified in the mouse.⁸⁸ One of these is the dopaminergic amacrine cell,^{88,99,107} which has processes stratifying almost exclusively in the most distal sublayer of the IPL,¹⁰⁸ the same stratum in which dendrites of outer-stratifying ipRGCs arborize.^{46,48,53,54} Dopamine is a key retinal neuromodulator, and its primary role is to help retinal cells and circuits adapt to different background lighting conditions.^{104,109} Thus, ipRGCs can potentially adapt to light not only through

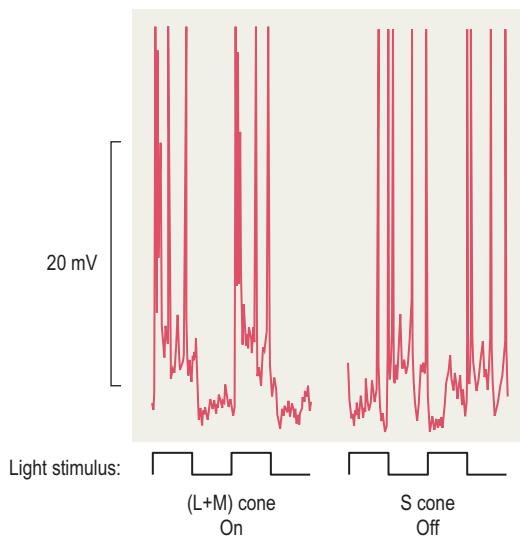

Figure 26.9 Color-opponent light responses in macaque ipRGCs.

Light stimuli selectively modulating L-cone and M-cone influences on ipRGCs drive depolarizing or “ON” responses to light (left), whereas S-cone-isolating stimuli trigger hyperpolarizing or “OFF” responses (right). (Reproduced with permission from Dacey DM, Liao HW, Peterson BB, Robinson FR, Smith VC, Pokorny J, et al. Melanopsin-expressing ganglion cells in primate retina signal colour and irradiance and project to the LGN. *Nature*. 2005 Feb 17;433(7027):749-54. By permission from Macmillan Publishers Ltd.⁵³)

intrinsic mechanisms (“photoreceptor adaptation”⁸⁵), but also through synaptic inputs (“network adaptation”). Supporting this possibility, dopamine has been shown to regulate the transcription of melanopsin in rat over a time course of several hours,¹¹⁰ and preliminary studies have demonstrated additional, more acute effects of dopamine on the intrinsic photoresponse of ipRGCs (Van Hook, Wong & Berson, unpublished observations). There is indirect evidence that cholecystokinin-containing amacrine cells might also be presynaptic to the ipRGCs.¹¹¹

Color coding of synaptic inputs

In primate ipRGCs, the intrinsic melanopsin-based responses are invariably depolarizing, but the polarity of the extrinsic, synaptically mediated light response is wavelength-dependent.⁵³ Blue light elicits hyperpolarizing extrinsic responses, whereas longer wavelengths evoke depolarizing ones (Fig. 26.9). While the depolarizing responses are almost certainly driven by ON bipolar cells, the circuit responsible for the hyperpolarizing response to short-wavelength light remains to be determined. Inhibitory input from amacrine cells may be involved. The overall spectral behavior of ipRGCs is unusually complex, because it is shaped not only by their synaptic inputs but also by the two spectrally distinct states of their melanopsin photopigment which exert opposing photic effects on the phototransduction cascade (see above).

Synaptic output and physiological functions

Ganglion-cell photoreceptors send axons to various brain regions involved in NIF visual functions, such as the pupillary light reflex, circadian photoentrainment, and masking

of circadian rhythms. Melanopsin phototransduction enables ipRGCs to drive these visual behaviors in the absence of functional rods and cones (see above). Conversely, when the melanopsin gene is genetically knocked out in mice, abolishing the intrinsic photosensitivity of ipRGCs, these behaviors are largely, though not completely, preserved (see below), indicating that the rod/cone photoreceptors can also drive these visual functions.^{21,33,55,112,113} However, when the ganglion-cell photoreceptors are selectively killed either genetically or pharmacologically, leaving the rest of the retina including the rods and cones intact, these NIF behavioral responses to light were largely abolished.^{114–116} Thus, ipRGCs are essential for channeling rod/cone-driven light signals to the various NIF visual brain centers, presumably by relaying their synaptic inputs from bipolar and amacrine cells, as described earlier. The ipRGCs also make synaptic outputs within the retina and to at least some brain regions involved in image-forming vision. This section surveys both the intraretinal and extraretinal outputs of these ganglion cells and their possible functional roles.

Intraretinal output

The first suggestion of a possible intraretinal output of ganglion-cell photoreceptors emerged almost simultaneously with the definitive proof of their existence. Hankins & Lucas¹¹⁷ reported that light alters the latency of the human cone electroretinogram (ERG) through an intraretinal mechanism driven by a non-classical opsin (Fig. 26.10). While their study did not identify that opsin, subsequent work leaves little doubt that it is melanopsin. The spectral tuning, high threshold, and extensive temporal integration of the ERG modulation they reported closely parallel those of the melanopsin-dependent responses of ipRGCs and the behavioral responses they mediate. Related findings in the mouse support a role for melanopsin in the regulation of the ERG, although the nature of that regulation appears somewhat different than in the human eye.¹¹⁸

Another early indication of possible intraretinal outputs of ipRGCs came from the imaging study of Sekaran et al.⁵⁰ In retinas of retinally degenerate mice, they detected light-evoked calcium signals in many more cells of the ganglion cell layer than were melanopsin immunoreactive. Similar findings were reported in a study using photic induction of the immediate early gene *cfos* to identify retinal neurons activated directly or indirectly by ipRGCs in a functionally rodless/coneless mouse.¹¹⁹ The interpretation of these results has been complicated somewhat by the recent evidence that immunohistochemical staining underestimates the number and diversity of ganglion cells expressing melanopsin.⁹⁰ However, the prevalence of Fos immunopositive cells in the inner nuclear layer¹¹⁹ seems greater than can be accounted for by the rare displaced ipRGCs and seems to suggest that some amacrine and/or bipolar cells might receive excitatory input from ipRGCs.

Evidence strongly indicating just such an input has recently emerged from studies of dopaminergic amacrine (DA) cells. As mentioned previously, ipRGC dendrites co-stratify with those of DA cells and seem to receive synaptic inputs from them. Studies of the light responses of the dopamine cells suggest that this synaptic input is reciprocated.¹²⁰ Most DA cells have brisk, relatively transient ON responses to light. These are abolished by the ON

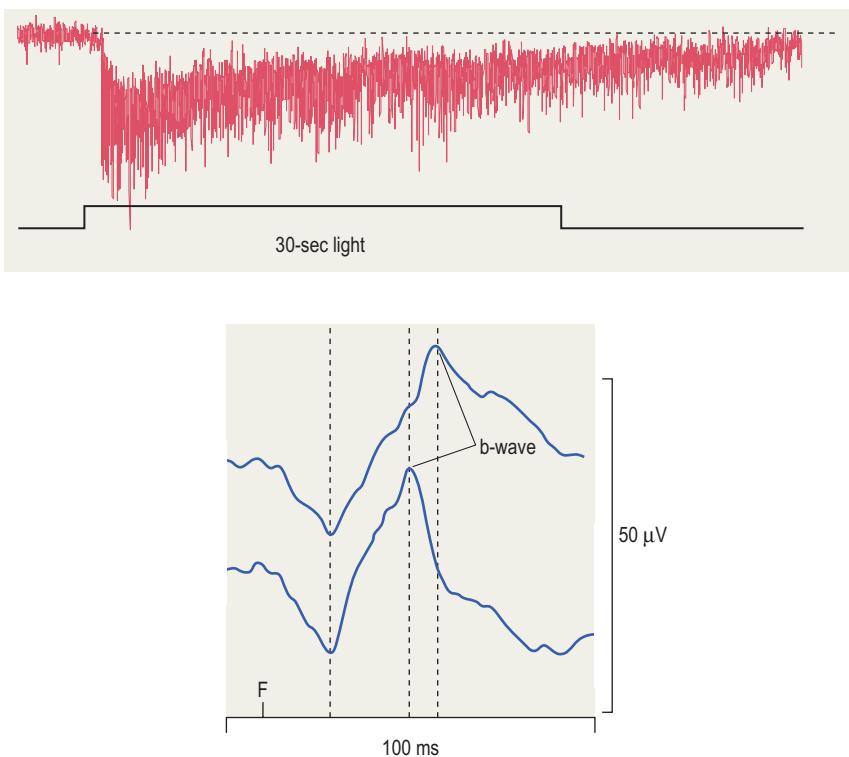

Figure 26.10 Intraretinal synaptic outputs and modulatory influences of ipRGCs. *Top:* Intracellular recording of a dopaminergic amacrine cell made under conditions blocking rod/cone-driven inputs, and revealing excitation from ipRGCs. The signatures of melanopsin photoresponses – sustained excitation, slow onset, and poststimulus persistence – are evident. Unlike the intracellular recordings shown in the previous figures, this is a “voltage clamp” recording, which monitors the ionic currents across the cell membrane. Downward deflection indicates that light induces an inward flow of cations into the dopaminergic amacrine cell. The black dotted line marks the prestimulus baseline level (K. Y. Wong, unpublished). *Bottom:* ipRGC signaling to dopaminergic amacrine cells might modulate the image-forming visual system in human. These electroretinograms were recorded from a human subject at night under dark-adapted conditions. The top recording was obtained at 9:00 p.m., showing a b-wave (which arises from ON bipolar cell light responses) with a relatively long latency to peak. A 15-min bright light pulse delivered at 11:00 p.m. accelerated the b-wave recorded at 3:00 a.m. (bottom). A plausible explanation for this phenomenon is that the bright light stimulated ipRGCs and consequently dopaminergic amacrine cells, elevating the release of dopamine which then modulated the kinetics of the ON bipolar cell photoresponse. “F” = flash. (From Hankins MW, Lucas RJ. The primary visual pathway in humans is regulated according to long-term light exposure through the action of a nonclassical photopigment. *Curr Biol*. 2002 Feb 5;12(3):191–8. Copyright Elsevier 2002.¹¹⁷)

bipolar cell blocker L-(+)-2-amino-4-phosphonobutyric acid (L-AP4),¹²¹ indicating that they are driven exclusively by ON bipolar cell input. However, a minority of DA cells continue to be excited by light in the presence of L-AP4. These residual responses have all the hallmarks of mediation by melanopsin-expressing ipRGCs: they are sluggish, very sustained (Fig. 26.10), and exhibit the action spectrum of melanopsin-based phototransduction, peaking in sensitivity near 480 nm. The inference that ipRGCs mediate this excitatory influence is further supported by the finding that it can be recorded from about 25 percent of the DA cells in *rd/rd* mice.¹²⁰ This centrifugal transmission of ipRGC signals can potentially regulate the intraretinal release of dopamine. In fact, two studies have shown significant light-evoked retinal dopamine release in retinally degenerate rats lacking virtually all rod and cone photoreceptors^{122,123} (but see ref. 124). Because retinal dopamine plays a key role in modulation of retinal physiology by light adaptation and circadian phase, the influence of ipRGCs on DA cells may mediate the centrifugal influences of melanopsin on the ERG discussed earlier.

This centrifugal influence is likely to involve dendrodendritic synapses between presynaptic ipRGCs and postsynaptic DA cells in the most distal sublayer of the IPL, where these two cell types costratify (Fig. 26.7). An ionotropic

glutamatergic synapse is probably involved, because the sustained, L-AP4-resistant light responses in DA cells could be abolished by blockade of AMPA/kainate-type receptors.^{120,125} This is the first known instance in the mammalian retina of a ganglion cell’s dendrites as the presynaptic element at a chemical synapse, though there is a precedent in catfish.¹²⁶ Gap junctional contacts constitute an alternative route by which ipRGCs might influence other retinal neurons. Sekaran et al⁵⁰ argued for just such communication based on their observation that the gap junctional blocker carbenoxolone abolished the light-evoked calcium signal in some neurons in *rd* mice. This intriguing suggestion needs to be followed up with more definitive tests for the presence of gap junctions, heterotypic tracer coupling and functional electrical synapses between ipRGCs and other retinal neurons. In any case, gap junctions do not seem likely to be the conduit for ipRGC signals to DA cells because these are blocked by glutamate receptor antagonists, as noted above.^{120,125}

Central projections

The axonal projections of melanopsin RGCs have been characterized in greatest detail in rodents^{45,46,71,90,127–130} (Fig. 26.11), though some data are available in primates.⁵³ Most of the available information concerns the projections of the

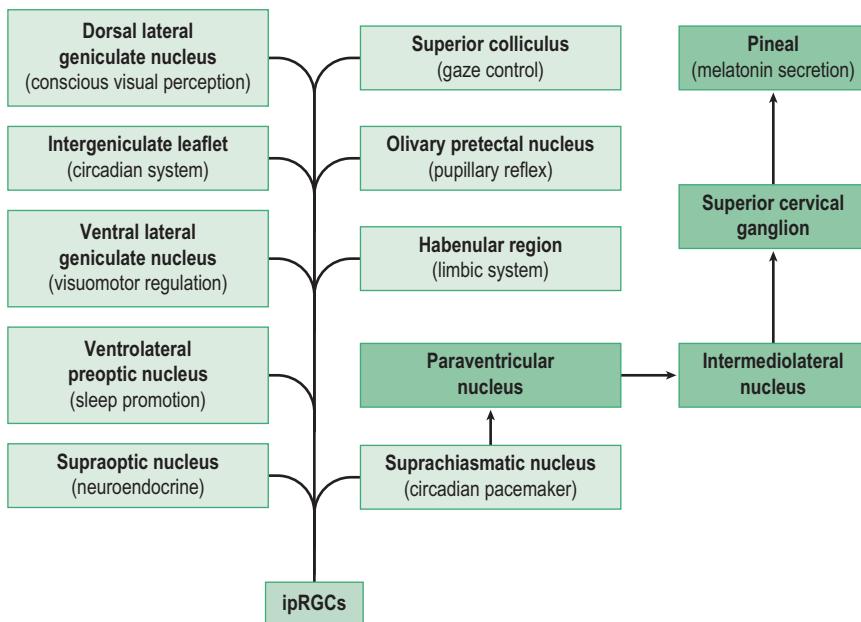

Figure 26.11 Central projections and possible functional roles of ipRGCs. The major brain nuclei receiving axonal innervations from melanopsin RGCs are listed in this diagram, with the monosynaptic projections in light green and the indirect pathway leading to the pineal in dark green. The visual behaviors served by these nuclei (summarized in parentheses) are mainly reflexive, non-image-forming functions.

outer stratifying variety, and characterizing the outputs of other subtypes remains an important near-term goal. Ganglion-cell photoreceptors are believed to influence their postsynaptic targets by releasing both L-glutamate and pituitary adenylate cyclase-activating polypeptide (PACAP).^{129,131,132}

The pupillary light reflex

One of the three main targets of melanopsin RGCs is the olfactory pretectal nucleus (OPN). This small component of the pretectal region, which lies just rostral to the superior colliculus, is an essential link in the polysynaptic circuit driving the pupillary light reflex (PLR). The direct input from ganglion-cell photoreceptors to the OPN is thought to account for the persistence of the PLR when rod and cone contributions are lost either through inherited degeneration, or by genetic or pharmacological manipulation.^{10,11,26,55,133} The properties of this persistent PLR are strikingly concordant with those of the direct light responses of ipRGCs, including a very high threshold, an action spectrum peaking near 480 nm, and a complete loss of the response when the melanopsin gene is deleted.^{26,31,55,133} Rods and cones also clearly drive the PLR. Thus, in melanopsin-knockout mice with intact rods and cones, the PLR is normal at low or moderate light intensities that are subthreshold for melanopsin activation; it is only at high intensity ($>10^{11}$ photons/cm²/sec) that the PLR is incomplete.⁵⁵ The outer and inner retinal photoreceptor contributions to the PLR differ in terms of kinetics, as revealed by experiments involving humans and macaques. The time course of the PLR closely mirrors that of the light response in ipRGCs, with rod/cone photoreceptors mediating the fast component and the endogenous phototransduction generating the slower component which outlasts the light stimulus^{133,134} (Fig. 26.12). When pharmacological agents were injected into the eye of a macaque to block rod/cone signaling to the inner retina but leaving melanopsin phototransduction intact, only the sluggish component of the ipRGC light response and of the PLR remained.¹³³ Thus, the classical photoreceptors mediate brisk pupillary responses to dim and moderate intensities,

whereas melanopsin-based phototransduction by ipRGCs drives sluggish pupillary responses to bright light. As noted earlier, ipRGCs receive substantial synaptic inputs from rod and cone circuits, and are thus a likely conduit for the influence of classical photoreceptors on the PLR. Indeed, when most ipRGCs are killed by genetic modification, the rod-component of the PLR is effectively abolished.¹¹⁴ Available evidence leaves no doubt that the outer-stratifying type of ipRGCs contributes to the pupillomotor circuit, but leaves open the possibility that inner-stratifying types may contribute as well.¹³⁰ Further information about the PLR is available in Chapter 25.

Circadian photoentrainment and photic modulation of the pineal

Other than the OPN, the main brain targets of ipRGC axons are the SCN of the hypothalamus and the intergeniculate leaflet (IGL), which is a part of the lateral geniculate nucleus of the thalamus. Both of these are components of the circadian visual system. In all living organisms, many physiological processes (e.g. sleep-wake cycles, body temperature, food intake) display daily rhythms that help the organisms cope with predictable environmental change. In mammals, the central pacemaker for these rhythms is the SCN. Clock cells in the SCN have neuronal activities that exhibit intrinsic rhythms with a period of about 24 hours. These rhythms are known as circadian rhythms (*circa* = approximately; *dies* = day). During the “subjective night,” the SCN coordinates hormonal, physiological and behavioral adaptations to the nocturnal environment, and during the “subjective day,” it adapts the brain and body to the daytime world. Because the period of the SCN rhythms is not exactly 24 hours, these rhythms must be reset periodically so that the internal clock remains in phase with the external light-dark cycles. In other words, subjective day (or night) needs to be synchronized, or “entrained,” with the environmental light cycle (Fig. 26.13). Such entrainment is accomplished mainly by the phase-shifting effects of light on the SCN, mediated by its direct input from the retina. If the SCN clock is too fast,

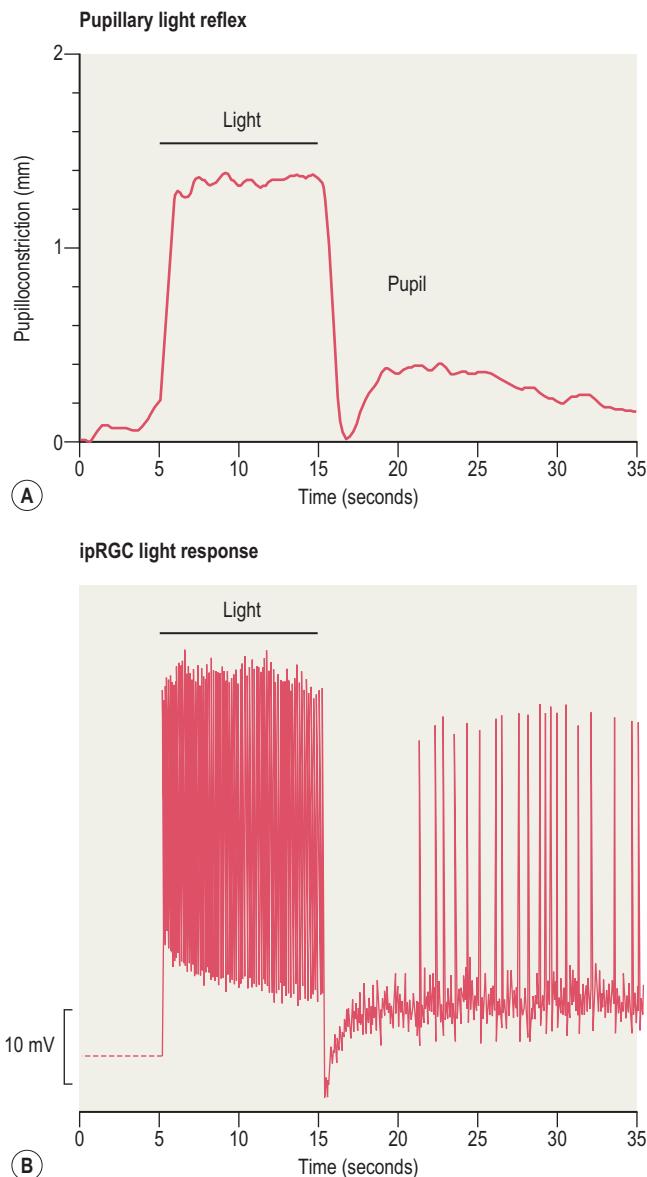

Figure 26.12 Similarity between the ipRGC photoreponse and the pupillary light reflex in macaque. The time course of the macaque pupillary light reflex closely follows that of the ipRGC light response. In both cases, a fast component that is mediated mainly by rods and cones is detected during the light stimulus, whereas a more sluggish, melanopsin-based component is evident after light off. (From Gamlin PD, McDougal DH, Pokorny J, Smith VC, Yau KW, Dacey DM. Human and macaque pupil responses driven by melanopsin-containing retinal ganglion cells. *Vision Res.* 2007 Mar;47(7):946–54. Copyright Elsevier 2007.¹³³) This temporal separation of rod/cone- and melanopsin-driven components may allow the pupillary light reflex to serve as a diagnostic test to reveal rod/cone versus ganglion cell defects in patients (See Box 26.5).

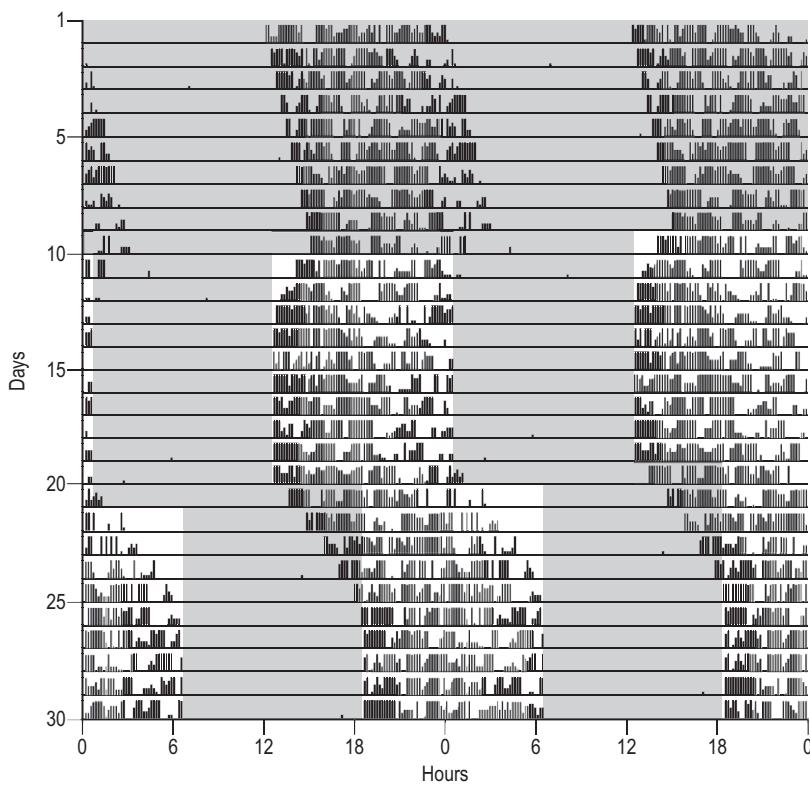

subjective night starts too early, so the organism is exposed to environmental light during early subjective night, which delays the clock. On the other hand, if the clock is too slow, subjective night starts and ends too late, so the SCN gets photic input during late subjective night, which advances the clock.^{41,43,44} The same mechanism is responsible for the recovery from jet lag when traveling across time zones. While both classical and ganglion-cell photoreceptors can mediate photoentrainment, all light signals are channeled through

Box 26.5 The Pupillary Light Reflex as a Diagnostic Test

The PLR has potential utility as a diagnostic tool to differentiate between outer retinal disorders affecting rod or cone circuits and inner retinal diseases affecting ganglion cells.¹⁶¹ As illustrated in Fig. 26.12, components of the PLR mediated by the rod and cone photoreceptors are temporally separable from those mediated by melanopsin. The earliest component of the light-driven constriction is mediated almost exclusively by rods and/or cones. By contrast, the slowly decaying post-stimulus constriction is driven by melanopsin; this presumably reflects the persistent depolarizing after-potential in ipRGCs that, in turn, is thought to be supported by a slowly depleting pool of photoactivated (meta) melanopsin (see “Melanopsin chromophore and pigment bistability” in the main text above). It should also be possible to tease out specific photoreceptor contributions by exploiting differences among them in threshold and saturating intensities and in spectral sensitivity. Red light may be presented under rod-saturating photopic conditions to selectively evoke a cone-driven PLR, whereas bright blue light is most effective for inducing a melanopsin-mediated response that persists beyond stimulus termination. To elicit a response driven mainly by the rods, a dim green light presented under a dark-adapted condition is ideal.

ipRGCs. These reach the circadian pacemaker through a monosynaptic pathway called the retinohypothalamic tract, and also through an indirect pathway involving the IGL.¹³⁵ Because a diurnal organism is typically exposed to daylight for 8–16 hours per day but light can phase-shift a misaligned clock only at the transitions between the light and dark phases, it is crucial that the retinal signal to SCN is sustained throughout those 8–16 hours so that it is still active near the end of the light phase. Therefore, the sustainedness of the melanopsin photoresponse is important for entraining diurnal animals like humans. Indeed, melanopsin-driven light responses recorded from the SCN retain the sustained nature of the ipRGC intrinsic photoresponse.^{136,137} Melanopsin is sufficient for photoentrainment not only in rodents, but also in primates including humans.^{30,31,138} Rods and cones, on the other hand, generate relatively transient light responses, and are therefore somewhat less effective in mediating entrainment.²¹

The SCN sends several output signals to drive circadian rhythms throughout the organism. One of the primary outputs is a polysynaptic circuit that leads to the pineal gland, which releases the hormone melatonin. Under the influence of the SCN clock, melatonin release is lowest at subjective day and highest at subjective night. This hormone induces a range of physiological responses throughout the body that are suitable to nighttime, such as sleepiness for diurnal animals.¹³⁹ In addition to entraining the circadian rhythm of melatonin secretion, light can acutely suppress secretion of this molecule during the subjective night. This may be associated with significant adverse health consequences. For example, there is a high correlation between the amount of light exposure at night and the incidence of breast cancer.^{140–142} This may be attributable in part to the photic suppression of nocturnal melatonin, which has been shown to exert various oncostatic and antitoxic effects.¹⁴³ Melatonin suppression by light at night may therefore be one risk factor responsible for the higher incidence of breast

**Figure 26.13 Photoentrainment of a diurnal animal.**

In this simulated actogram, the locomotor activity of a diurnal animal is plotted as vertical black bars for about a month. This diagram is double-plotted, with each row displaying two consecutive 24-hour periods and each 24-hour period plotted twice. During the first 10 days, the animal is kept in constant darkness, allowing its circadian pacemaker to "free run". Since this animal's circadian clock has a period that is slightly longer than 24 hours, its locomotor activity starts slightly later each day, as reflected in the gradual rightward shift of the period of activity. On days 11 through 20, on the other hand, a 12-hour light:12-hour dark lighting schedule is presented, and the animal's active period becomes synchronized or "entrained" to the light-dark cycle. On day 21, the light-dark cycle is abruptly delayed by 6 hours, mimicking the consequences of a westward flight that crosses 6 time zones. It takes the circadian clock several days to re-entrain the animal to this new cycle.

cancer in industrialized countries. Thus, it is important to minimize light exposure at subjective night, especially for night-shift workers whose subjective night is during the daylight hours. It has been shown that in humans, melatonin release is most effectively suppressed by blue light close to the best wavelength for melanopsin phototransduction.^{60,144} Therefore, if exposure to light at subjective night is unavoidable, red light would presumably be less harmful than broad-spectrum light (See also Box 26.6.).

Acute regulation of activity and sleep

Melanopsin RGCs project to the ventrolateral preoptic nucleus (VLPO), a brain region implicated in the regulation of sleep.^{71,127} Indeed, besides influencing the sleep-wake cycle through entrainment of the circadian system, melanopsin-mediated photoreception has been shown to acutely modulate sleep and alertness. The polarity of this effect is apparently species-dependent and related to diurnal or nocturnal lifestyle. In humans, these ipRGC outputs increase alertness and vigilance,^{31,145} whereas in nocturnal rodents they induce sleep.^{146,147}

A related acute effect of light, termed "negative masking," has emerged from studies of circadian activity rhythms in nocturnal rodents.¹⁴⁸ Bright light presented at subjective night rapidly suppresses wheel-running and other locomotor activity that would otherwise occur at this circadian time (Fig. 26.14). Both classical and ganglion-cell photoreceptors contribute to this photic response, but in different ways. In rodless-coneless mice (as in wild-type animals), steady illumination by bright light continuously suppresses activity for at least 3 hours. In contrast, in melanopsin-knockout animals, in which rods and cones are the only functional

Box 26.6 Inner-retinal Photoreception, Seasonal Affective Disorder and Sleep in the Blind

In seasonal affective disorder (SAD), patients suffer recurring bouts of depression, fatigue, and lethargy in fall and winter, when days are short.¹⁶⁷ Though the etiology of the disease is unknown, several observations, including the effectiveness of phototherapy,^{168,169} point to a possible defect in NIF photoreception and prolonged periods of nocturnal melatonin release in winter.¹⁷⁰ The efficacy of phototherapy is probably at least partly attributable to its ability to suppress melatonin release. While single-wavelength studies have shown that blue light is more effective than longer wavelengths due to the peak sensitivity of melanopsin at ~480 nm,⁶⁰ certain polychromatic stimuli have been reported to be even more potent by strongly activating not only melanopsin but also the rod and cone photopigments.¹⁷¹ A recent study found that a specific missense variant of the melanopsin gene occurred at higher frequency in SAD patients than in healthy control subjects.¹⁷² The functional consequences of this variation for melanopsin photochemistry or the intrinsic photosensitivity of ipRGCs are unknown.

Another melatonin-related clinical application concerns the treatment of sleep disorders in blind people. While some blind people retain inner retinal photosensitivity and hence NIF visual functions despite the total loss of functional rods and cones,^{29–31} others suffer more serious retinal degenerations and do not have any capacity to support NIF vision. One of the major problems experienced by this latter group is their complete lack of photoentrainment, causing their sleep-wake cycle to be uncoupled from the solar cycle. An often effective treatment is the daily administration of melatonin, to mimic the SCN output signal that normally occurs once every 24 hours in properly entrained sighted individuals.^{160,173}

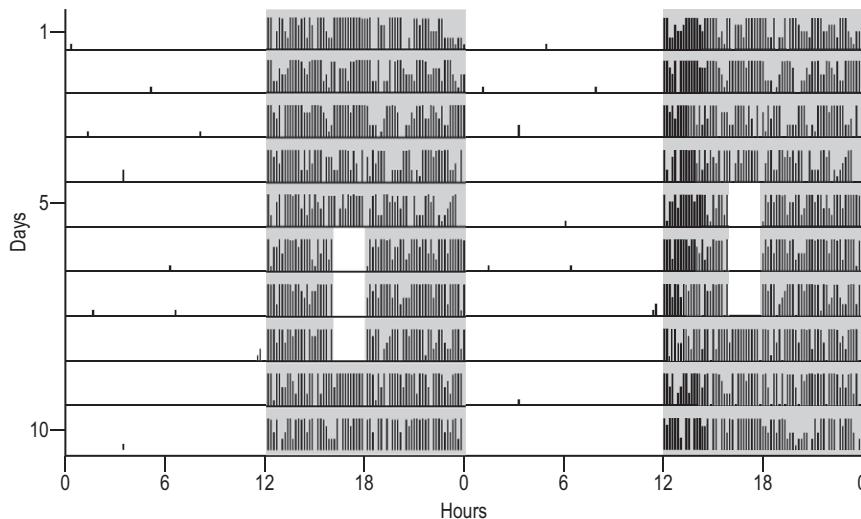

Figure 26.14 Negative masking of a nocturnal animal. This simulated actogram of an entrained nocturnal animal shows that a 2-hour light pulse delivered during the night phase acutely suppresses locomotor activity. This non-image-forming visual response is known as "negative masking".

photoreceptors, the suppression of activity by light is less effective, decays gradually and has largely dissipated by 1.5 hours.¹⁴⁹ This indicates that the sustained melanopsin photoreponse of the ipRGCs is necessary for normal negative masking, especially when triggered by prolonged light pulses. Furthermore, ipRGCs appear to be an essential relay for rod and cone influence over the masking mechanism, because killing these ganglion cells eliminates the acute photic suppression of wheel running activity.^{114–116} It remains unclear which brain regions are involved in negative masking. Lesions of image-forming visual centers such as the visual cortex, lateral geniculate nucleus and superior colliculus do not abolish negative masking, and there is conflicting evidence on a possible role for the SCN.¹³⁵ Interestingly, negative masking appears to be driven by neuronal pathways distinct from those mediating acute photic regulation of sleep.¹⁴⁶

Lateral geniculate nucleus and conscious light perception

In primates and rodents, melanopsin RGCs make substantial projections to the dorsal lateral geniculate nucleus (dLGN), the thalamic relay of retinal signals in the image-forming visual pathway.^{53,90} In a recent study, a blind woman evidently lacking functional rods and cones reported conscious perception of light, with peak sensitivity near 480 nm, as expected for a melanopsin-based mechanism.³¹ Thus, whereas the sluggish light responses and large dendritic fields of ipRGCs make them ill-suited for the analysis of fine details or motion in the retinal image, they may nevertheless contribute to conscious appreciation of ambient illumination, presumably through their projection to the dLGN. As mentioned above, synaptic input to ipRGCs in primates is color-opponent.⁵³ Thus, it is conceivable that ipRGCs contribute in some way to conscious discrimination of color, although there is presently no evidence for this. There are also weak projections from ipRGCs to the superior colliculus,⁷¹ a midbrain center involved in redirecting gaze to visual targets. Photic effects on collicular activity have been detected in mice with very advanced outer retinal degeneration.¹² Thus, ipRGCs may play some role in spatial vision.

Development

Studies in rodents clearly demonstrate that ipRGCs are the first photoreceptors to become fully functional in the developing retina.^{51,150,151} This is likely to be true also in the human eye. Melanopsin is expressed in human fetuses by 9 weeks post-conception,¹⁵² many weeks before the appearance of rod and cone opsins.^{153,154} Though outgrowing retinofugal axons reach their brain targets at around the onset of melanopsin expression,¹⁵⁵ it is unlikely that any environmental light can reach the fetal eye at intensities sufficient to drive melanopsin phototransduction. Thus, the functional significance of such early emergence of melanopsin expression is unknown. Neither deletion of melanopsin nor killing of ipRGCs early in development result in any gross alteration in retinal structure.^{113–115}

Overview of the Central Visual Pathways

Joanne A. Matsubara & Jamie D. Boyd

The role of the central visual pathways is to process and integrate visual information that travels to the brain by means of the optic nerves. Although the eye is responsible for transducing patterns of light energy into neuronal signals, it is the brain that is ultimately responsible for visual perception and cognition. Vision at the level of the central nervous system is perhaps the best understood of all the sensory systems, partly because there is a wealth of information on its neuroanatomic and functional organization. In this chapter, an overview of the central visual pathways is given, beginning with a brief description of the retinal projections and their putative functional roles and ending with an overview of the consequences of lesions along the visual pathway. Schematic views of the central nuclei that receive a retinal projection are shown in Figures 27.1 and 27.2. The most significant, in terms of the number of optic nerve fibers, is the projection to the lateral geniculate nucleus (LGN) in the thalamus. The LGN, described in detail in Chapter 29, is an important relay in the visual pathway involved with form vision. The precision and specificity of the retinogeniculate connections are crucial to form vision. From the LGN, the visual pathway proceeds to the primary visual cortex, V1. It is at the level of V1 that visual signals undergo complex processing, which is detailed in Chapter 30. Visual processing of a combination of stimulus features such as form, color, contrast, motion, texture, depth and is further enhanced by over 30 extrastriate cortical areas, some of which are described in Chapter 31. Finally, we discuss in detail the role of experience and visual deprivation on the development of the central visual pathways in Section II.

Targets of the retinal projections

The major targets of the retinal ganglion cell axons are the LGN, superior colliculus (SC), pretectum, and pulvinar. There is a weaker projection to several small hypothalamic nuclei (including suprachiasmatic, supraoptic, paraventricular nuclei) and the accessory optic system (AOS) (including the nucleus of the optic tract (NOT) and the dorsal, medial, and terminal nuclei) (Box 27.1, Fig. 27.2 and see Fig. 9.8).

The LGN of the thalamus is the major termination site of the retinal ganglion cells, and plays an important role in the visual pathway leading to the primary visual cortex.

Approximately 90 percent of all retinal ganglion cells project to the LGN, which is laminated and displays retinotopic organization. Each LGN layer receives input from a specific eye and class of ganglion cell. While electrophysiological studies have determined that the neuronal signals coming into and leaving the LGN are not appreciably different, the processing that takes place in the LGN appears to be involved in regulating the flow of information to the primary visual cortex (V1), the major projection target of the LGN (see Chapter 29).

The SC is a midbrain structure which, in conjunction with the cortical frontal eye fields and the brainstem reticular formation, is involved in the generation of visually guided saccadic eye movements^{1,2} (see Chapter 9). The SC is a laminated, retinotopically organized nucleus, and as seen in the LGN, the retinal projection retains eye segregation with alternating columns of left and right eye terminals forming a banded pattern throughout the superficial layers. Approximately 10 percent of all retinal ganglion cells project to the SC. The majority of retinal axons that terminate in the SC are small caliber, originate from ganglion cells with small dendritic fields, and do not project to other retinal targets.³

The pretectal complex, a group of small midbrain nuclei, is just rostral to the SC. It receives signals from a group of small-diameter retinal ganglion cells with large receptive fields and is involved with the control of the pupillary light reflex (see Chapter 25) by means of a projection to the Edinger-Westphal nucleus of the oculomotor complex. The pupillary light reflex demonstrates a consensual response primarily resulting from crossed and uncrossed optic nerve fibers that enter each pretectal complex which in turn sends a bilateral projection to the Edinger-Westphal nucleus (see Chapter 9).

Retinal ganglion cells also project to three of four major subdivisions of the pulvinar nucleus of the thalamus.^{4,5} The pulvinar is the largest nuclear mass in the primate thalamus and receives a projection from the small-caliber fibers from the optic nerve and the SC. It projects to several visual cortical areas, including V1, and extrastriate, parietal areas. Thus, the pulvinar represents a pathway that can bypass the LGN to get to V1 and may play a role in processing form vision. More recent studies point to a role for the pulvinar in the coding of the "importance" of visual stimuli (i.e. visual salience or "attention").⁶ It has been shown that the

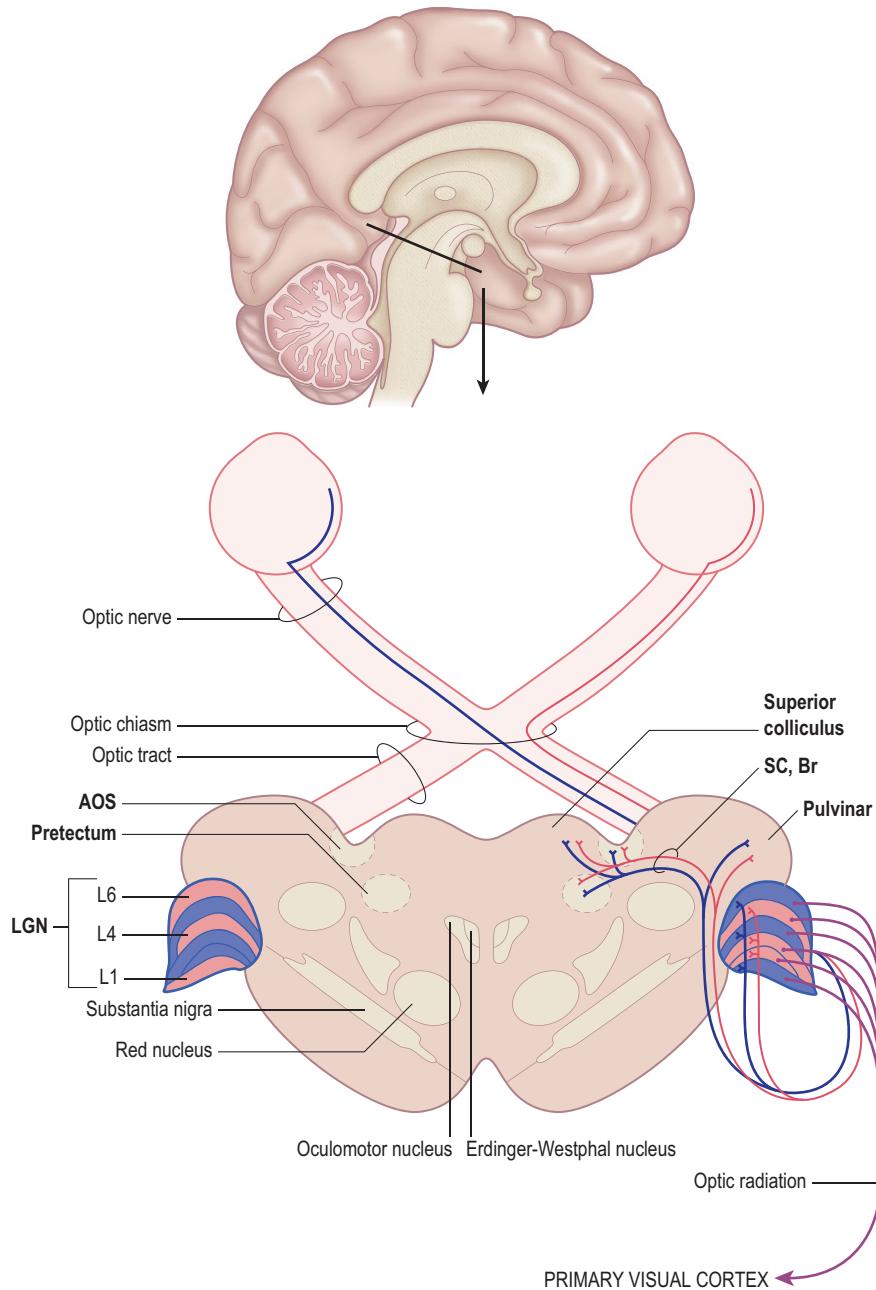

Figure 27.1 Schematic drawing of a section through the human brain at the level of the midbrain-diencephalon transition. Several of the target sites of the retinal projection are present at this level, and labeled in bold on the right: the superior colliculus, pretectum, accessory optic system (AOS), pulvinar and lateral geniculate nucleus (LGN). Optic nerve fibers originating from ganglion cells of the contralateral nasal retina cross at the optic chiasm and join the uncrossed optic nerve fibers from the ipsilateral temporal retina to form the optic tract. The layers of the LGN, the major termination site of the optic nerve fibers, receive contralateral eye (layers 1,4,6; blue) or ipsilateral eye (layers 2,3,5; red) inputs. Cells in all six layers of the LGN project to the primary visual cortex via the optic radiation. SC, Br, Brachium of the superior colliculus.

- AOS

pulvinar integrates neural signals associated with eye and hand and arm movements and may receive signals associated with saccadic eye movements, which suggests its role is also one of formulating reference frames for hand-eye coordination.⁷⁻⁹

Several small hypothalamic nuclei receive a direct retinal projection. The suprachiasmatic nucleus receives a sparse projection from fibers that leave the dorsal surface of the optic chiasma and has been implicated in the synchronization of circadian rhythms.¹⁰ The paraventricular and supraoptic nuclei are likely also involved with the regulation of the light-dark cycle for neuroendocrine functions.

The AOS consists of several small nuclei, the lateral terminal nucleus (LTN), the medial terminal nucleus (MTN), and the dorsal terminal nucleus (DTN), as well as the NOT in the midbrain.¹¹ The AOS plays an important role in optokinetic nystagmus (OKN) in which slow compensatory and pursuit-type eye movements alternate with fast saccadic-type eye movements in response to viewing prolonged large field motion (see Chapter 9). In primates, lesions of the NOT and

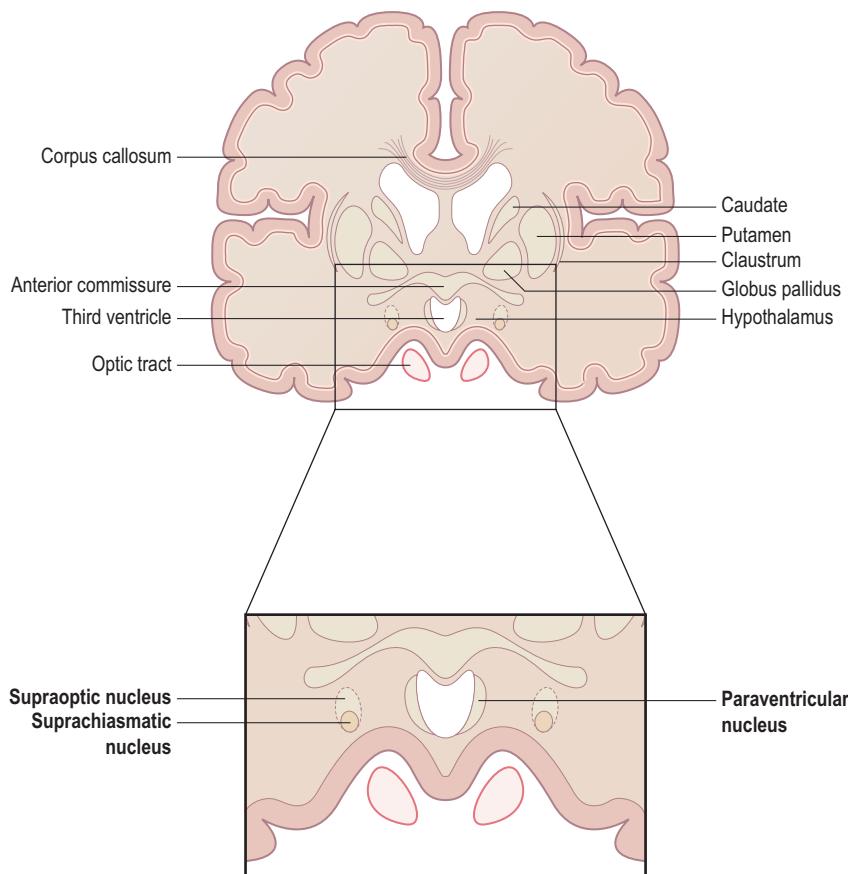

Figure 27.2 Schematic drawing of a section through the human brain at the level of the anterior commissure. Retinal target in the hypothalamic area are labeled in bold (bottom enlargement). A small number of fibers branch off the optic tract, forming the retinohypothalamic tract, and terminate in the supraoptic, suprachiasmatic and paraventricular nuclei of the hypothalamus. Visual input to the hypothalamus drives the light–dark entrainment of neuroendocrine function and other circadian rhythms.

the DTN have been shown to modify the OKN and reduce or abolish optokinetic after-nystagmus (OKAN).¹²

Visual field lesions

Much of our knowledge of the retinotopic organization of the central visual nuclei arises from the visual field defects associated with lesions along the major pathway leading to form vision, the retinogeniculocortical pathway (Box 27.2). Figure 27.3 illustrates several known anatomical lesions, from the retina to the occipital lobes, and their subsequent effect on the visual fields. In the example shown in Figure 27.3A complete interruption of one optic nerve, which may occur with severe degenerative disease or injury, results in permanent blindness in the affected eye. Partial interruption of the nerve fibers results in a partial loss of the visual field and can occur with glaucoma, optic disc drusen, pits, infarcts, or optic neuritis.

Slightly further along the visual pathway, interruption of the decussating optic nerve fibers in the optic chiasm (Fig. 27.3B) results in loss of vision in the temporal visual hemifields of both eyes called bitemporal hemianopia. Damage of this type commonly occurs with pituitary tumors as they grow and compress the overlying optic chiasm. Rarely, pressure is exerted on the lateral edge of the optic chiasm (Fig. 27.3C) – damage arises primarily in the uncrossed fibers,

Box 27.2 Visual field lesions

- A. Monocular blindness is caused by a lesion of the optic nerve or nerve fiber layer and may vary from complete blindness to various sizes of scotoma, depending on the extent of the lesion.
- B. Bitemporal hemianopia results from a lesion at the level of the optic chiasm affecting the decussating optic nerve fibers.
- C. Nasal hemianopia results from a lesion of the uncrossed fibers in the optic nerve at the level of the optic chiasm. Nasal visual field defects not necessarily respecting the vertical meridian are common with optic nerve head disease.
- D. Homonymous hemianopia with an afferent pupillary defect in the contralateral eye results from a complete interruption at the level of the optic tract.
- E. Normal visual fields may accompany an afferent pupillary defect caused by a lesion that is specific to the brachium of the superior colliculus, sparing the retinogeniculate fibers.
- F. Homonymous hemianopia may also result from a lesion at the level of the LGN, which can be distinguished from (D) by the absence of an afferent pupillary defect.
- G. Homonymous hemianopia with sparing of the macular field results from a lesion at the level of the optic radiation and is usually seen after vascular lesions of the occipital lobes. Several hypotheses exist for the macular sparing, including overlapping vascular fields of the middle and posterior cerebral arteries in the occipital lobes where the macula is represented.

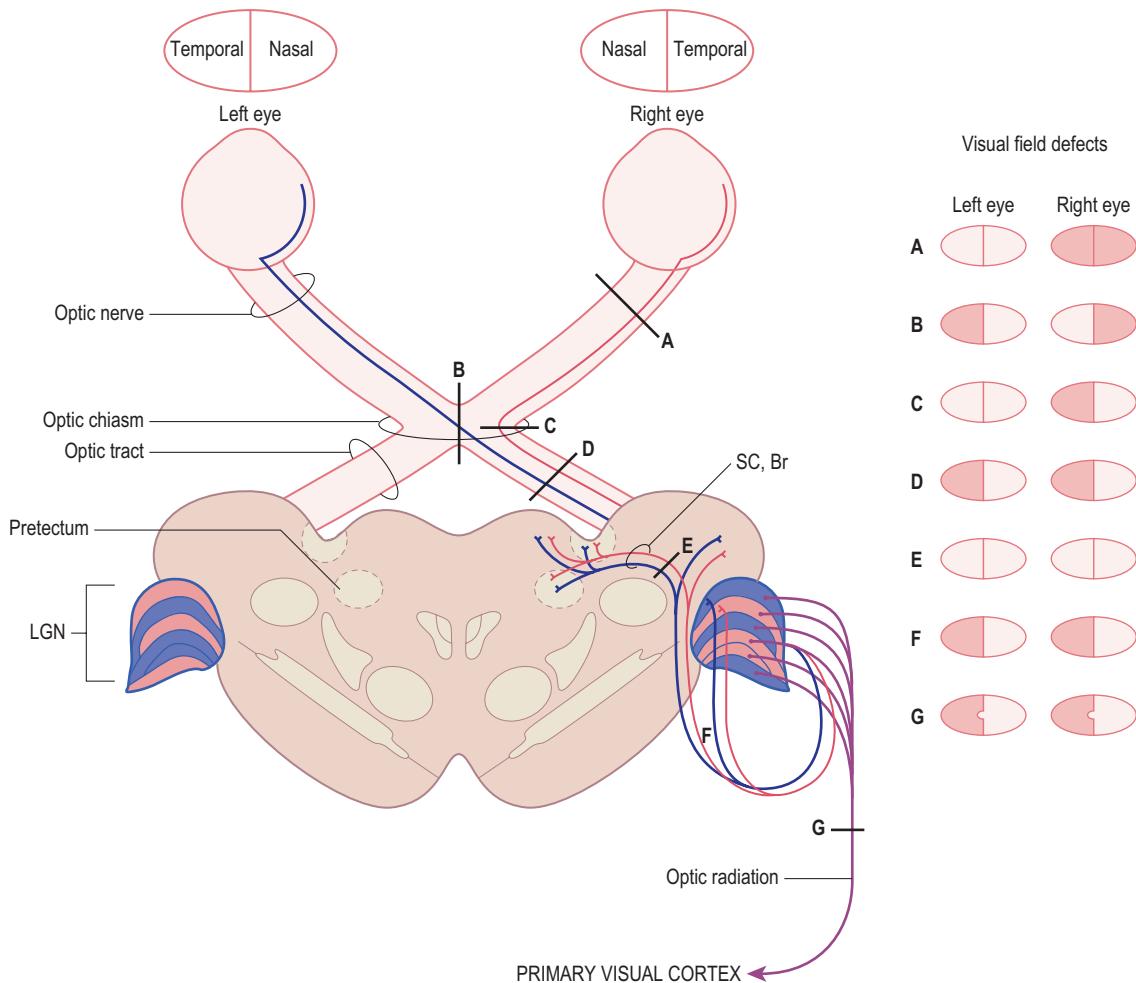

Figure 27.3 Visual field defects associated with lesions of the visual pathway. The bars (A–G) depict the location of lesions, and the associated visual field defect is shown at the right (shaded area represents visual field loss). A: Lesion of the right optic nerve causes blindness in the right eye. B: Optic chiasm lesion results in a bitemporal hemianopia, a loss of vision in the temporal visual field of both eyes. C: Lesion affecting only the uncrossed fibers of the optic chiasm results in a loss of vision in the nasal field of the ipsilateral eye. D: Lesion of the optic tract causes homonymous hemianopia, or complete loss of vision in the contralateral visual field. An afferent pupillary defect also arises from a lesion at this level. E: Lesion affecting the fibers in the brachium of the superior colliculus (SC, Br) results in an afferent pupillary defect, but with intact visual fields because the projection to the lateral geniculate nucleus (LGN) remains intact. F: Lesions at the level of the LGN are similar to lesions at D and result in homonymous hemianopia, but with an intact, normal pupillary reflex. G: Lesions at the level of the optic radiation also result in a homonymous hemianopia, but with sparing of macular vision.

resulting in loss of vision in the nasal hemifield, or nasal hemianopia, ipsilateral to the compression.

Lesions that occur after the chiasm are characterized by visual field defects that involve the temporal hemifield of the contralateral eye and the nasal hemifield of the ipsilateral eye; this is because of the partial decussation of optic nerve fibers at the optic chiasm. In this type of lesion, visual field loss occurs on the side contralateral to the lesion. Complete interruption at the level of the optic tract (Fig. 27.3D) or beyond results in loss of vision in the contralateral visual field, i.e. homonymous hemianopia. It is usually difficult to determine whether the site of the lesion is at the level of the optic tract, LGN, or visual cortex for most homonymous hemianopias. In cases in which the lesion is in the optic tract, the homonymous hemianopia may be accompanied by an afferent pupillary defect in the contralateral eye. The reason for this is likely because ganglion cells in the nasal retina outnumber those in the temporal retina, thus causing

a greater loss of fibers for the pupillary response of the contralateral eye¹⁴ (however, also see reference 3). Lesions at the level of the brachium of the SC (Fig. 27.3E), may result in an afferent pupillary defect in the contralateral eye, but with intact, normal visual fields because lesions at this level spare the retinogeniculate fibers.

Lesions involving the LGN (Fig. 27.3F) are often difficult to distinguish from other optic tract lesions, but usually present with a visual field defect and an intact contralateral afferent pupillary reflex because lesions at this level normally spare the retinal fibers terminating in the pretectum responsible for the afferent pupillary reflex.

Lesions involving the optic radiation (Fig. 27.3G) or the visual cortex result in homonymous hemianopia (Box 27.3), but with sparing of the central, macular field. Several hypotheses have been put forward to explain macular sparing, but in many patients, macular sparing is likely more apparent than real because it is likely an artifact of visual

Box 27.3 Blindsight

Blindsight is a phenomenon in which people with lesions of primary visual cortex and hemifield defects are unconsciously aware of visual stimuli presented in their blind hemifield. Methodology used to obtain these results may be responsible for the apparent visual awareness and thus the concept of blindsight is heavily surrounded by controversy. However, when methodology can be ruled out, blindsight may be explained by the existence of retinal inputs to central targets other than the LGN, specifically the superior colliculus and pulvinar, and their projections to extrastriate cortical areas.¹⁵

field testing caused by poor foveal fixation or eye movements. In other patients in whom macular sparing is not artifactual, the most likely explanation is the immense areal dimension of the cortical representation of the retinal fovea. The posterior cerebral artery supplies the occipital poles, but in some individuals they are supplied by both the posterior and middle cerebral arteries. Thus infarcts of the posterior cerebral artery would affect only part of the occipital poles, sparing portions of the foveal representation and sparing macular vision.

Optic Nerve

Jeffrey L. Goldberg

Introduction

The two optic nerves carry the axons of retinal ganglion cells (RGCs), and along these axons transmit all of the visual information from the inner retina (Chapter 23) to the brain (Chapters 29–31). Thus, diseases that affect the optic nerve commonly cause vision loss. The retina and optic nerve are developmentally an outgrowth of the forebrain, and, like other white matter tracts of the central nervous system (CNS), the optic nerve does not repair itself after most types of injury. Thus, blindness from optic nerve injury or degenerative disease is typically irreversible. This chapter reviews the principal aspects of optic nerve anatomy, development, and physiology, and discusses the pathologic changes at the molecular and cellular levels in the context of clinical disease.

Optic nerve anatomy

Retinal ganglion cell axons within the nerve fiber layer

RGC axons begin at the RGC bodies in the inner layer of the retina. Although most neurons in this layer are RGCs and the layer is commonly referred to as the *ganglion cell layer*, in humans approximately 3 percent of cells in the central retina and up to 80 percent in the peripheral retina may be other cell types, primarily displaced amacrine cells.¹ In addition, studies in mammals have demonstrated a few displaced RGCs located in the inner nuclear layer.² As discussed in Chapter 23, the RGCs receive input from bipolar cells and amacrine cells, and project their axon towards the vitreous, whereupon they turn approximately 90° and project towards the optic nerve head in the *nerve fiber layer*. The nerve fiber layer is not quite radially arranged around the optic nerve head (optic disk), as axons near the center of our visual field course away from the fovea, and then towards the optic disk, entering in the superior and inferior portions of the disk (Fig. 28.1). This interesting anatomy prevents axons from crossing the high-sensitivity fovea, where they might otherwise scatter light and degrade visual acuity. The axons from more peripheral RGCs are more superficial (vitread) to those arising from less peripheral ganglion cells³ (Fig. 28.2). In addition, there is strict segregation of those fibers arising

from RGCs located superior to the temporal horizontal meridian (raphe) and those fibers arising from RGCs located inferior to the horizontal raphe. Because of this segregation, visual field defects corresponding to injury to RGC axons typically have stereotyped patterns, e.g. superior or inferior nasal steps, temporal wedges, or arcuate scotomas. These are called nerve fiber bundle defects, and with other visual field defects are covered in more detail in Chapter 35. The nerve fiber layer can be measured using various modalities in human eyes (Box 28.1).

Intrascleral optic nerve

The optic nerve itself is considered to begin at the optic nerve head which, when viewed through the front of the eye, is observed as the *optic disk*. There is an approximately 1-mm component of optic nerve within the intrascleral part of the globe, which includes the lamina cribrosa (Fig. 28.3). Once at the optic disk, ganglion cell axons turn away from the vitreous and dive into the optic disk towards the brain. Axons arising from more peripheral RGCs are peripheral within the optic nerve head.⁴ The optic disk contains the nerve fibers around its edge, the *neuroretinal rim*, and the central *cup* which does not contain RGC axons. The *cup-to-disk ratio* may range from 0 to 1.0, depending on natural variation in the size of the disk, and whether there is less than a full complement of axon fibers, for example as a result of damage from glaucomatous optic neuropathy (see below).

Intraorbital optic nerve

The optic nerve extends approximately 30 mm from the globe to the optic canal.⁵ The straight-line distance from the back of the globe to the optic canal is much less (the exact amount depending on individual orbital depth), with the excess optic nerve laxity allowing for free movement of the globe during eye movements. Excessive proptosis stretches the optic nerve tautly, resulting in some cases in direct injury to or even avulsion of the nerve itself. Beginning behind the globe, the nerve is ensheathed by the layered meninges extending from the brain, bathing the optic nerve in cerebrospinal fluid and providing vascular support along the length of the nerve (see below).

The retinotopic segregation of RGC axons (topographic correspondence of optic nerve fibers to retinal location),

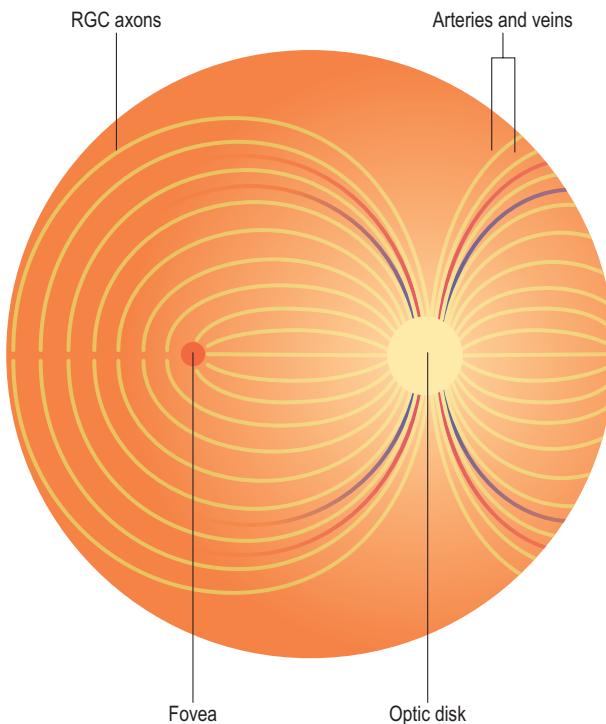

Figure 28.1 Axons of retinal ganglion cells take a specific course through the retina, such that fibers more temporal to the fovea skirt around the edge of the macula and enter the optic nerve head closer to the superior or inferior poles. Neither the axons nor the blood vessels typically cross the horizontal meridian of the retina.

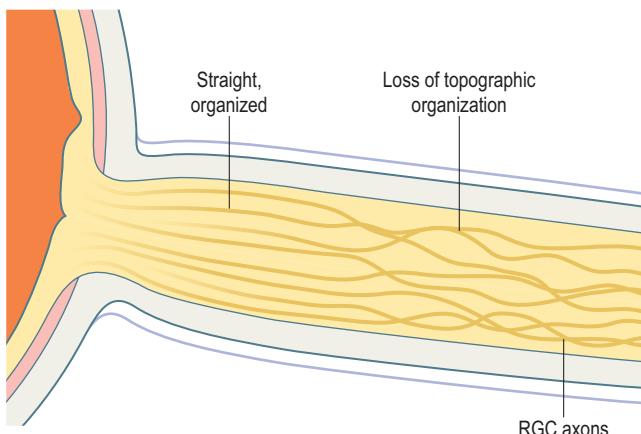

Figure 28.2 Retinal ganglion cell axons enter the optic nerve head with specific retinotopic organization (as in Fig. 28.1). With increasing distance from the optic nerve head, however, the axons become increasingly jumbled, losing their topographic organization. Thus focal damage to nerve at the nerve head will produce specific retinotopic defects, while focal damage to axons further posterior to the eye will produce scotomas that lack retinotopic organization.

particularly the segregation between axons arising from the superior and inferior retina, is gradually lost as the axons course through the nerve (Fig. 28.3). There is only moderate retinotopy in the initial segment of the optic nerve.⁶ The retinotopy decreases distally,^{7,8} and then becomes ordered vertically for eventual nasal decussation near the chiasm.⁹

Box 28.1

The number of RGC axons in the optic nerve is, in most cases, probably well-approximated by the number of RGC axons in the nerve fiber layer of the retina immediately adjacent to the optic nerve. The peripapillary nerve fiber layer can be measured quantitatively using a variety of modalities including coherence tomography (OCT), which measures layer thickness based on reflectance of light from the interfaces between layers, and by scanning laser polarimetry (SLP), which estimates nerve fiber layer thickness based on the interaction of polarized light with organized bundles of microtubules inside axons. Each of these technologies may face limitations. OCT estimation of RGC axons may be complicated by the presence of retinal astrocytes, which accompany RGC axons through the nerve fiber layer and contribute to nerve fiber layer thickness. SLP estimation of axon integrity may be limited by degradation or disorganization of RGC microtubules that may precede axon loss. All such technologies are limited by their inability to measure optic nerve axons specifically, and rather substitute peripapillary axon measurements.

The loss of retinotopy is not absolute, because the fibers from the nasal (but not temporal) macula continue to be located centrally within the nerve over a considerable distance.¹⁰ Fibers from large RGCs are less retinotopically organized than those from smaller ganglion cells.¹⁰ Although studies in humans are difficult to do ante-mortem, post-mortem studies of nerves with specific visual field defects demonstrate similar findings, while post-mortem studies of developing fetuses and adult eyes also show loss of retinotopy within the transition from the optic nerve head to the nerve.^{6,11} Within the orbit, the optic nerve travels within the muscle cone formed by the superior rectus, lateral rectus, inferior rectus, and medial rectus muscles. Tumors within the cone are common sources of compression of the optic nerve, or *compressive optic neuropathy*. Examples of these tumors include cavernous hemangioma, hemangiopericytoma, fibrous histiocytoma, lymphoma, and schwannoma. In addition, enlargement of the muscles themselves, particularly the inferior rectus and/or the medial rectus in Grave's ophthalmopathy, may also compress the optic nerve.

The optic canal

The optic nerve enters the cranium via the optic canal, a 5–12 mm passage which lies immediately superonasal to the superior orbital fissure.¹² The optic canal contains some axons of sympathetic neurons destined for the orbit, as well as the ophthalmic artery. The latter lies immediately inferolateral to the optic nerve itself, covered in dura. At the distal end of the canal, there is a half-moon-shaped segment of dura which overhangs the optic nerve superiorly, and thereby lengthens the canal by a few millimeters. As in the intraorbital portion of the optic nerve, within the canal, and immediately posterior to the optic canal, meningeal tissue ensheathes the optic nerve. Benign tumors of the meninges, or meningiomas, are frequent causes of compressive optic neuropathies in these locations. Small tumors within the canal itself, where there is very little free space, may lead to compressive optic neuropathy without a radiographically visible tumor.

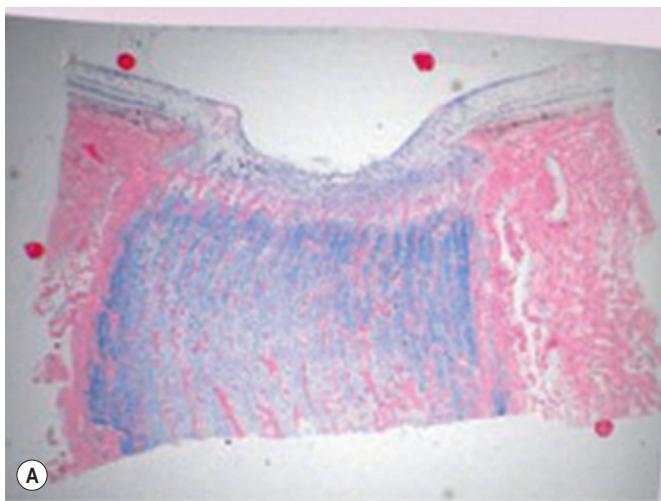

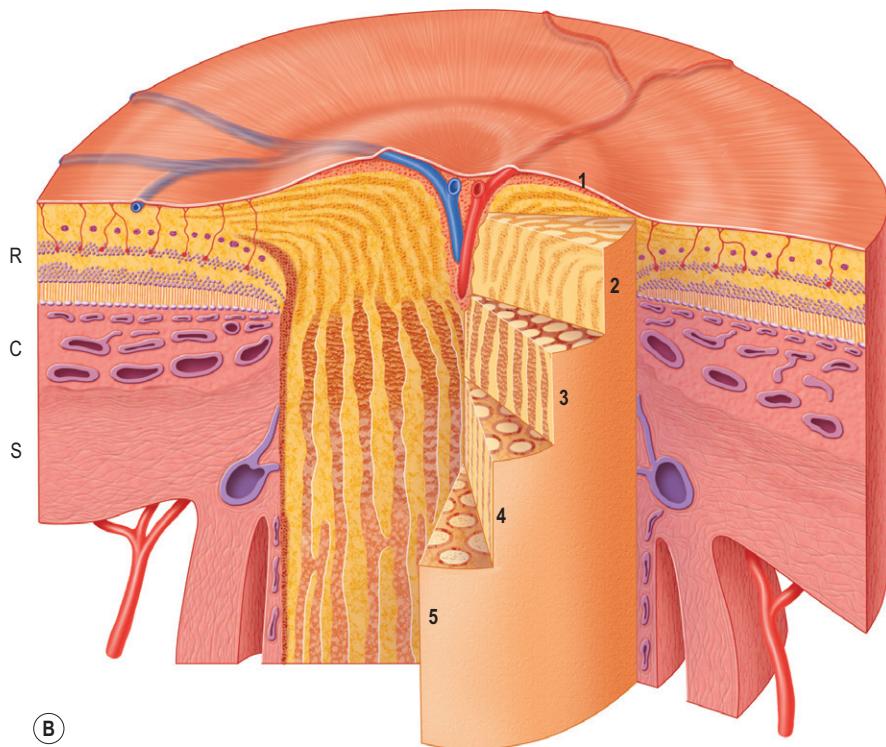

Figure 28.3 (A) Histochemical staining of the human optic nerve head. **(B)** The optic nerve head is at various points adjacent to retina (R), choroid (C), and sclera (S), and demonstrates a varied cellular morphology along this distance. (1) Superficial nerve fiber layer; (2) Anterior prelaminar region; (3) Posterior prelaminar region; (4) Laminar region; (5) Retrolaminar region. (A from Figure 1 in: Sigal et al, *Exp Eye Res* 2009; 90(1):70–80; B from Scheme 1 in: Trivino et al, *Vision Res* 1996; 36(14):2015–28.)

Intracranial optic nerve and the optic chiasm

Once the nerve has entered the cranium, there is a highly variable (8–19 mm, mean of 12 mm) length of nerve until the chiasm is reached.¹³ The length of the chiasm itself is approximately 8 mm. The intracranial optic nerve and chiasm are immediately above the planum sphenoidale and sella turcica, the latter of which contains pituitary gland. There is approximately 10 mm between the inferior part of the nerve and the superior part of the pituitary. Tumors of the pituitary which increase in size enough to compress the chiasm may therefore cause compressive optic neuropathy.

At the optic chiasm, RGC axons from the temporal retina remain ipsilateral, and those from the nasal retina cross the chiasm and course towards the contralateral brain. The ratio

of fibers which cross versus those which do not cross is anatomically 53:47¹⁴ and functionally 52:48.¹⁵ This small difference between the number of crossing and non-crossing fibers is commonly reported to be responsible for the relative afferent pupillary defect seen in disorders of the optic tract, in which an afferent pupillary defect is seen contralateral to the injured tract (see Chapter 25), but could also reflect the fact that some fibers from specialized cells within the retina responsible for the pupillary reflex may cross from the temporal retina into the contralateral optic tract.¹⁵

The optic tract and lateral geniculate nucleus

Although the optic nerve anatomically ends at the chiasm, RGC axons continue within the optic tract until the lateral

geniculate nucleus, superior colliculus, pretectal nuclei, or hypothalamus (see below). Circuitry and processing by these targets are discussed in Chapters 25 and 29.

Optic nerve axon counts and dimensions

In the normal adult human optic nerve, manual techniques have demonstrated an estimated 1,200,000 RGC axons per nerve;¹⁶ automated counting algorithms give figures between 700,000¹⁶ and 1,400,000^{17,18} axons. There is a strong correlation between the size of the neuroretinal rim and the number of axons,^{18,19} and between the number of axons and the size of the scleral canal in primates,²⁰ although the degree of correlation is controversial.^{18,21}

Many factors affect the number of axons within the optic nerve, from inherited differences to damage from disease, i.e. optic neuropathy (see below). In addition, there is a gradual loss of RGCs during normal human aging, with an approximate 5000 axon loss per year of life.^{16,17,22,23} For unclear reasons, there is a smaller degree of loss of macular RGCs with age, compared to peripheral RGCs, and this may reflect contraction of the macula with time.²⁴

Although the number of RGC axons entering the optic nerve is fairly constant, the diameter of the optic nerve varies widely. At the disk itself, where the fibers are completely unmyelinated, the mean vertical diameter of the disk is 1.9 mm (range 1.0–3.0 mm) and the mean horizontal diameter is 1.7–1.8 mm (range 0.9–2.6 mm).^{19,25} The mean area of the disk is 2.7 mm² (range 0.8–5.5 mm²). The mean area of the neuroretinal rim (not including the cup) is 2.0 mm² (range 0.8–4.7 mm²). Because the axonal tissue entering the optic disk varies much less than the size of the optic disk itself, the optic cup in the center of the disk can vary greatly without necessarily reflecting any underlying deficit in the number of ganglion cell axons. The diameter of the optic nerve approximately doubles posterior to the globe as a result of myelination of the axons.

Microscopic anatomy and cytology

Axons

There are no other neuronal cell bodies within the optic nerve, making it a pure white matter tract of the central nervous system. Although the optic nerve itself may contain other small nerves, particularly tiny peripheral nerves (branches of the trigeminal system) which carry pain sensation or control vascular tone, the vast majority of the optic nerve is composed of the approximately 1,200,000 axons of the retinal ganglion cells. Optic nerve axons are collected in fascicles, which are separated by pia-derived septa. The number of fascicles ranges from approximately 50 to 300, being maximal immediately retrobulbar and at the optic canal.²⁶ The mean axon diameter is slightly less than 1 µm, with a unimodal distribution skewed to the left. The mean diameter may decrease during aging, either through loss of large-diameter axons,²⁷ or from a general, aging-induced

atrophy. Compared with the optic tract, there is relatively little segregation of axons by size within the optic nerve, except for a tendency for finer axons to be located inferocentrally.^{7,28}

There is variability of axonal diameter and myelin thickness from the retina to the brain. Studies in the ferret show that the diameters of the largest axons increase as the distance from the retina increases.²⁹ The diameter of individual axons is regulated by multiple factors, including oligodendrocytes³⁰ and activity,³¹ increases during development, and correlates with local accumulation of specifically phosphorylated neurofilament proteins.³²

Oligodendrocytes and myelin

Conduction of nerve impulses down the axons in the optic nerve depends on the presence of myelin, a fatty multilaminated structure which insulates each axon and greatly increases the speed and efficiency of conduction (discussed below). The retrobulbar optic nerve is completely myelinated under non-pathological circumstances (Fig. 28.4). There are non-myelinated axons of the peripheral nervous systems within the adventitia of the central retinal artery³³ and non-myelinated and myelinated Schwann cells around peripheral axons of the outer dura.³⁴ Each axon is myelinated with several lamellae of myelin bilayers, with the number of lamellae varying from axon to axon³⁵ but in strict proportion to the diameter of the axon. Individual oligodendrocytes elaborate an average of 20–30 processes per cell, each of which myelinates 150–200 µm of axon length.³⁶

Oligodendrocytes and axons regulate each other during development and throughout adulthood. Oligodendrocytes depend on the presence of axons for their survival,³⁷ and for production of myelin proteins.³⁸ Axons regulate oligodendrocyte survival and proliferation, and thus their number, through expression of specific signaling proteins³⁹ and through axonal electrical activity,⁴⁰ controlling oligodendrocyte number to match the number of axons.⁴¹ Conversely, axons are signaled by oligodendrocytes to regulate axon number and diameter, and to prevent axon sprouting or branching in the optic nerve.^{30,42} Later, in the adult, oligodendrocytes and myelin are partially responsible for inhibition of axon regeneration after optic nerve damage or degeneration (see below).^{43,44}

Astrocytes

Astrocytes, named for their stellate appearance, are ubiquitous glial components of the central nervous system, and function in white matter tracts like the optic nerve to regulate ionic and energy homeostasis. Astrocytes are highly efficient at transporting potassium, and increases in the level of extracellular potassium as a result of repolarization are buffered by astrocytes. Their ability to accumulate glycogen may allow them to serve as an energy source for the optic nerve in the absence of glucose (e.g. ischemia), by shuttling lactate to adjacent axons.⁴⁵ Astrocytes form the glial-limiting membrane,⁴⁶ and their processes are concentrated at the nodes of Ranvier and in contact with nearby capillaries. This positions the astrocyte to play a role in transportation of substances between the local circulation and the axons; in inducing

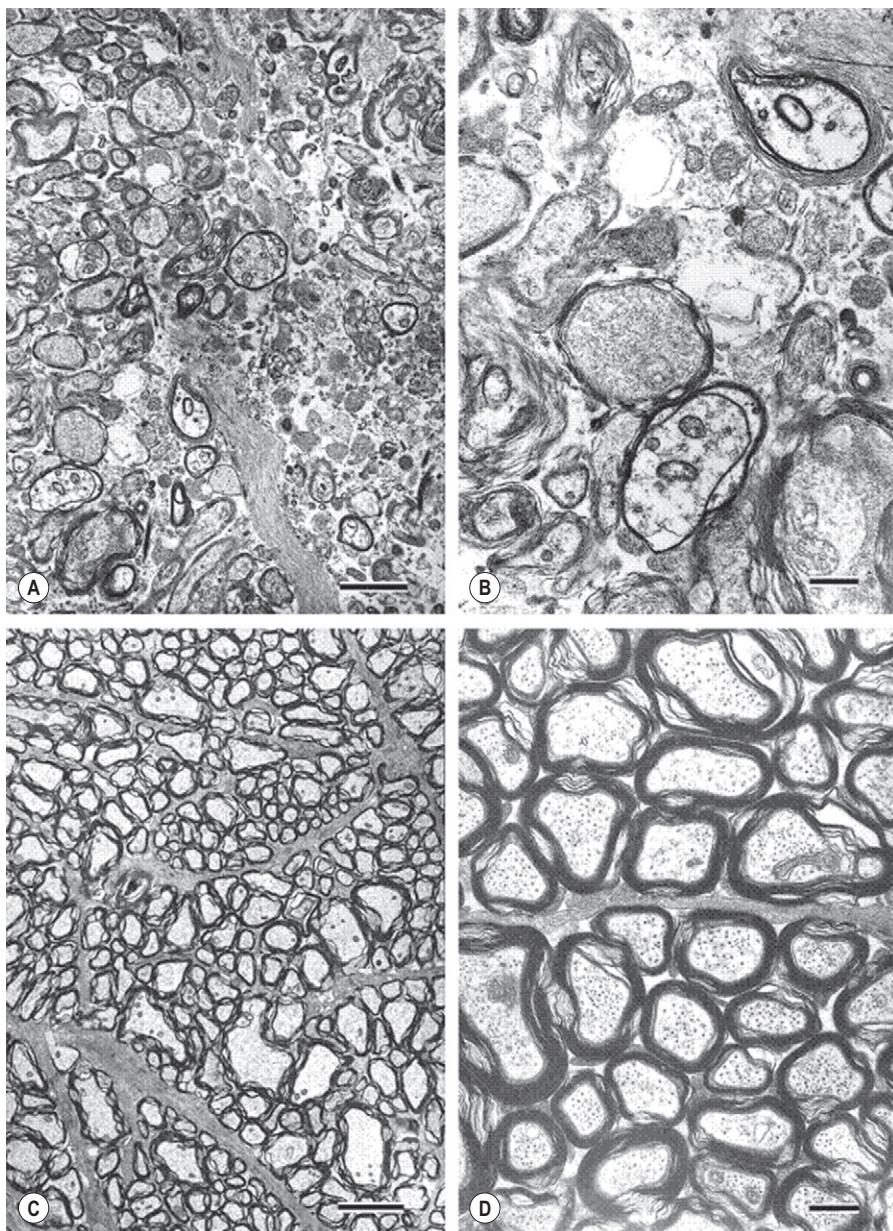

Figure 28.4 Transverse sections through the adult rat optic nerve demonstrate typical profiles of myelinated axons and the fibrous glial septae that separate bundles of axons. Scale bars are 4 mm in the left panel, 500 nm in the right. (From Figure 3 in, Gong & Amemiya, *Exp Eye Res* 2001; 72:363–9.)

endothelial cells to form the blood–brain barrier,⁴⁷ and perhaps in signaling blood vessels to dilate or constrict according to local metabolic needs. Astrocytes also mediate connectivity between optic nerve axons and the adjacent connective tissues, such as the pial septa, the adventitia of the central retinal artery and vein, and the pia in a layer named the glial mantle of Fuchs.³³

Interestingly, the most common intrinsic tumor of the optic nerve is an astrocytoma, or optic nerve glioma. This is usually a low-grade tumor of well-differentiated astrocytic cells that appear hair-like, or “pilocytic.” Pilocytic astrocytomas are usually seen in childhood, and have a favorable prognosis. They are also commonly seen in association with neurofibromatosis. Rarely, more malignant neoplasms of astrocytic origin develop in adults. These resemble the higher-grade astrocytic neoplasms found elsewhere in the central nervous system, and are usually fatal.

Microglia

Microglia, a type of resident macrophage, are an important cellular component of the optic nerve. Although their origin was debated for decades, they have been shown experimentally to be of peripheral, bone marrow origin, and are not derived from the neuroectoderm that yields neurons, astrocytes, and oligodendrocytes.^{48,49} Microglia share several markers with macrophages, with both having Fc receptors (for immunoglobulin), C3 receptors (for complement), binding of Griffonia isolectin B4, and antigenicity for F4/80 and ED1 monoclonal antibodies.⁵⁰ In the human optic nerve, microglia can be seen at 8 weeks after conception, when they are relatively undifferentiated. Microglia become more differentiated during fetal development, going from tuberous to amoeboid to a ramified morphology.⁵¹ They are associated with axon bundles, but not necessarily with blood

vessels, and are found in both the nerve parenchyma and its meninges. Nerve and meningeal microglia are similar ultrastructurally except for vacuoles and endoplasmic reticulum in the former. This may be due to their phagocytosis of dying axons during development.⁵² Microglia share several characteristics of immune capacities of macrophages. By phagocytosing extracellular material, degradation within intracellular compartments can occur. This may be followed by antigen presentation on the cell surface. In combination with certain histocompatibility antigens, this presented antigen can cause stimulation of T lymphocytes and subsequent immune system activation (see below).

Meninges and meningotheelial cells

The optic nerve is covered with three layers of meninges, dura, arachnoid, and pia. The meninges can also be divided up into *pachymeninges* (dura) and *leptomeninges* (arachnoid and pia). The outermost dura is a thick fibrovascular tissue, which is in immediate contiguity with the sclera, periorbita, and the dural layer of the lining of the cranial contents. The middle arachnoid layer is a loose, thin, fibrovascular tissue. The innermost pia is a thin, tightly adherent layer with extensions into the nerve itself forming the pial septae, through which the fascicles of ganglion cell axons course.²⁶ In the optic canal, there are numerous trabeculae connecting the dura through the arachnoid to the pia, which reduce the free space of the nerve sheath in this area.⁵³

The space between the dura and arachnoid is the subdural space, while the space between the arachnoid and pia is the subarachnoid space. The subdural space around the optic nerve is small, and is not in communication with the intracranial subdural space. The subarachnoid space, on the other hand, is in communication with the intracranial subarachnoid space. The optic nerve subarachnoid space ends anteriorly within a blind pouch just before the optic disk. This extension of the subarachnoid space from the brain into the orbit explains why elevated intracranial pressure may cause compression of the optic nerve via elevating the hydraulic pressure. There is an appreciable pressure within the subarachnoid space, measuring from 4 to 14 mmHg.⁵⁴

Meningotheelial cells may have several functions,⁵⁵ including wound repair and scarring, phagocytosis, and collagen production. The meningeal vessels include pericytes and endothelial cells, which form tight junctions.³⁴ Macrophages⁵⁶ and mast cells⁵⁷ are also found in the meninges. The role of these and other resident cells in meningeal inflammations is only speculative.

Blood supply

Optic nerve head

Studies of histological sections and of corrosion casting of the vessels themselves have added greatly to our understanding of the optic nerve blood supply⁵⁸ (Fig. 28.5). The ophthalmic artery provides the major vascular supply to the inner retina and optic nerve. The central retinal artery branches off of the intraorbital ophthalmic artery, and enters the optic nerve during approximately 12 mm behind the globe. In the retina, RGC bodies and the nerve fiber layer are supplied by capillary branches derived primarily from the

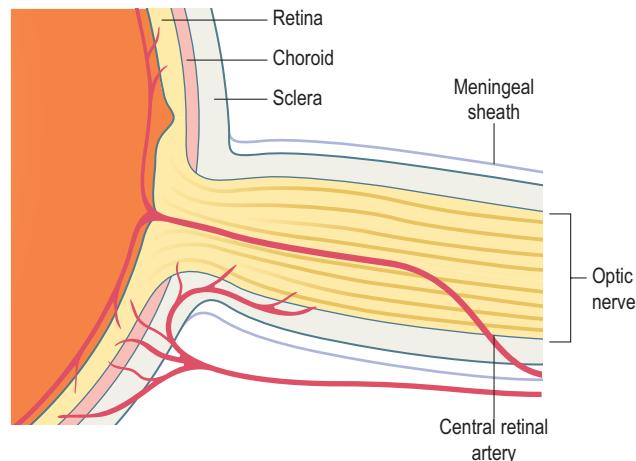

Figure 28.5 Vascular anatomy of the optic nerve head. The optic nerve is supplied by branches from the central retinal artery, from penetrating meningeal arterioles, from recurrent arterioles off of the inner retinal vasculature, and from diffusion from the fenestrated blood supply of the choroid.

central retinal artery arising out of the optic nerve head. As it branches on the optic disk into the retinal arterioles, the central retinal artery provides partial perfusion of the superficial optic disk via small capillaries. Along the optic nerve itself, however, the central retinal artery provides minimal perfusion of the nerve through which it courses.⁵⁹

In contrast, branches of the medial and lateral short posterior ciliary arteries, originating from the ophthalmic artery, provide the major blood supply to the optic nerve head, as well as the choroid. Their branches perfuse the optic nerve, both anteriorly via direct branches and posteriorly via a retrograde arteriolar investiture of the optic nerve (see below). Anastomoses of posterior ciliary artery branches^{60,61} form the circle of Zinn-Haller, which contributes significant perfusion to the optic nerve head. In addition, there are contributions from recurrent choroidal arterioles to the prelaminar and laminar optic nerve head, and contributions from recurrent pial arterioles to the laminar and retrolaminar optic nerve head. A clinical implication of the common posterior ciliary arterial source of the choroid and deep optic nerve head is that they will fluoresce simultaneously during the earliest phase of fluorescein angiography, before the retinal arterioles transit dye.

Unlike the choroidal vessels, which have fenestrated endothelial cells, optic nerve vessels have non-fenestrated endothelial cells with tight junctions, surrounded by pericytes. Optic nerve vessels therefore share the same blood-nerve barrier characteristics as the blood-brain barrier. Only a restricted number of molecules can cross the blood-nerve barrier. For example, gadolinium enhancement on magnetic resonance imaging is not seen unless there is some pathological process within the optic nerve that would disrupt the blood-nerve barrier, e.g. inflammation.^{62,63} Another major difference between choroidal and optic nerve head vessels is that only the latter can autoregulate, i.e. maintain approximately constant blood flow despite most changes in intravascular or intraocular pressure.⁶⁴⁻⁶⁶ Thus there is compensation of perfusion for a wide range of intraocular pressures in normal individuals. A dysregulation in optic nerve head autoregulation, and any ischemia that would follow, may contribute to the pathophysiology of glaucoma (see below).

Intraorbital optic nerve and optic canal

The intraorbital optic nerve is perfused primarily by the pial circulation, which branches off of the ophthalmic artery either directly or indirectly via recurrent branches of the short posterior ciliary arteries. The pia sends penetrating vessels into the intraorbital optic nerve along the fibrovascular pial septae, from which a capillary network extends into neural tissue (axons and glia). Similarly, the intracanalicular optic nerve is perfused by up to three branches of the ophthalmic artery, namely a medial collateral, lateral collateral, and ventral branch,^{67,68} which perfuse the pial surface and then penetrate the nerve. An important clinical implication of the pial supply relates to optic nerve sheath meningiomas. If a surgeon strips the meningioma away from the nerve, then the pia will be removed as well, resulting in loss of the blood supply to the nerve, and possible infarction and blindness. Another clinical correlation is related to the small amount of free space within the canal, when occupied by blood from shearing of the delicate vessels there, this may result in a sight-threatening compressive hematoma⁶⁸ (and see below).

Intracranial optic nerve, chiasm, and optic tract

The intracranial optic nerve and chiasm are perfused by the internal carotid artery and its branches, primarily the anterior cerebral, anterior communicating, and the superior hypophyseal artery. The posterior chiasm may also be perfused by branches of the posterior communicating artery. The optic tract is predominantly perfused by branches of the posterior communicating and anterior choroidal arteries. Similar to the intraorbital and intracanalicular optic nerve, the blood supply occurs via small pial penetrating vessels. However, there is no dura or arachnoid surrounding the optic nerve posterior to the optic canal, and thus the risk of infarction is not from stripping a tumor off the nerve, but from inadvertent detachment of the fine vessels during surgical manipulation.

Vascular biology

Vessels of the human optic nerve contain endothelial cells separated from pericytes by a basement membrane, with endfeet of astrocytes surrounding the two.⁶⁹ The tight junctions between endothelial cells contribute to the blood–nerve barrier, which is present in normal optic nerve throughout its length. The anterior part of the optic nerve, however, shares a distinctive feature with the area postrema, choroid plexus, and median eminence, in that there is local disturbance of this blood–brain barrier. Although the optic nerve capillary endothelial cells in the anterior optic nerve have tight junctions, leakage can occur from adjacent choriocapillaris through the border tissue of Elschnig at the level of the lamina choroidalis.^{70,71} Further leakage from this area into the subretinal space may be prevented by tight junctions between the glia making up the intermediary tissue of Kuhnt.^{70,72} The blood–nerve barrier may be incompetent in focal inflammatory disorders, such as optic neuritis.⁷³

The optic nerve differs from almost all other areas of the CNS in that there is connective tissue around vessels.³³ The vessels are closely surrounded by morphologically

specialized collagen⁷⁴ and pial fibroblasts, beyond which are astrocytic foot processes.^{33,69,75} These pial septae are not a constant feature of mammalian optic nerves; rats, for example, do not have septae.

The vessels within the nerve have their own innervation. These nervi vasorum contain multiple neurotransmitters⁷⁶ including adrenergic, cholinergic, and calcitonin gene-related peptide; neuropeptide Y; substance P; and vasoactive intestinal peptide.⁷⁷ Human posterior ciliary arteries respond to the potent vasoconstrictor angiotensin II.⁷⁸

Optic nerve development

Generation of optic nerve oligodendrocytes and myelination

Oligodendrocytes develop from oligodendrocyte precursor cells (OPCs). OPCs migrate from the brain into the optic nerve, perhaps from the base of the preoptic recess, and this migration may continue during adult life.⁷⁹ The OPC has a complex regulatory mechanism, with *in vitro* and animal studies implicating platelet-derived growth factor (PDGF), basic fibroblast growth factor (bFGF), ciliary neurotrophic factor (CNTF), and other factors in the control of differentiation, division, and renewal of the progenitor cell population.^{80,81} An intrinsic developmental clock controls the differentiation of OPCs into oligodendrocytes,⁸² after which the cell is mitotically unresponsive to PDGF.^{83–87} In normal development, some OPCs persist into the adult and may participate in remyelination after injury or in diseases like optic neuritis.⁸⁸

After oligodendrocyte differentiation from OPCs, there is typically a short delay before myelination starts, which may be regulated by inhibitory signals from axons activating the notch signaling pathway.⁸⁹ The developmental regulation of myelination of the optic nerve and tract occurs earliest at the brain end of the optic nerve, then travels distally toward the eye, i.e. proximally with respect to the ganglion cell axon. This is opposite to myelination elsewhere in the CNS, which usually occurs from the neuron cell body outward along the axon. The brain-to-eye direction of myelination correlates with animal studies demonstrating OPC migration and then differentiation outward along the optic nerve.^{90,91} In humans, oligodendrocytes are not seen in the optic nerve before 18 weeks of gestation.⁹⁰ Later, optic tract and intracranial nerve axons begin myelination at 32 weeks of gestation, with the process virtually complete at birth. The axons adjacent to the globe begin myelination only at birth; all are myelinated by about 7 months of age.⁹² Further myelination continues, however, and thickening of axonal myelin may continue past 2 years, or longer.

In longitudinal studies of rat optic nerve development,⁹³ axons that become myelinated increase in diameter. The signal for change in caliber is generated by the oligodendrocytes.^{30,94} Although unmyelinated and not yet myelinated axons can conduct electrical impulses in the developing optic nerve, there is a surprising increase in conduction velocity during development, independent of diameter or myelination status, the reasons for which are unclear.⁹⁵

Interestingly, intraretinal RGC axons are not normally myelinated in most species; indeed, there are normally no

oligodendrocytes in the retina. Studies of rat optic nerve head and anterior optic nerve demonstrate an abnormal transition zone from unmyelinated axons to myelinated axons, with varying lengths and thicknesses of myelin, unusual nodal region morphology, and few normal oligodendrocytes.⁹⁶ Studies of rat optic nerve suggest that a signal found at the lamina cribrosa blocks the migration of OPCs into the retina.⁹⁷ This barrier is possibly due to the presence of specialized optic nerve head astrocytes,⁷⁹ serum factors from a focally deficient blood–nerve barrier^{98,99} or the adhesion substrate tenascin.¹⁰⁰ In rabbits, which have no lamina cribrosa, there are axons myelinated by oligodendrocytes in the retina, and intraretinal OPCs can be identified.⁹⁷ Further, the retinal portion of the ganglion cell axon has no constitutive barrier to myelination because ganglion cell axons of retina transplanted into rat midbrain can be myelinated,⁹⁹ and OPCs injected intraretinally can differentiate and myelinate RGC axons.¹⁰¹ Myelination may also be artificially induced by injuring the retina from the scleral side. This trauma leads to migration of Schwann cells and subsequent intraretinal myelination.¹⁰² In human eyes, myelination of part of the nerve fiber layer is occasionally seen; it is assumed that this is secondary to ectopic oligodendrocytes, although there are reports of Schwann cells myelinating intraretinal axons in the cat¹⁰³ and rat.¹⁰⁴ Although oligodendrogiomas within other parts of the central nervous systems are sometimes seen, neoplasms of oligodendrocytes within the optic nerve are very rare.

Generation of optic nerve astrocytes

Astrocyte precursor cells have been considerably less well studied. Like oligodendrocytes, developmental regulation of astrocyte number is determined by the RGC.¹⁰⁵ Astrocyte precursor cells may depend on CNTF or LIF for differentiation into astrocytes,¹⁰⁶ at which point they upregulate the expression of glial fibrillary acidic protein (GFAP), an intermediate filament protein. GFAP itself is important to optic nerve development, as transgenic mice lacking GFAP demonstrate abnormal myelination and blood–brain barriers.¹⁰⁷ Astrocytes may also be critical for optic nerve development in that they may serve as the substrate over which extending ganglion cell axons grow.¹⁰⁸

Development of optic nerve meninges

The anatomy and development of the optic nerve meninges have been well described.^{34,55} All three meningeal layers are formed from fibroblast-like cells, which vary in ultrastructural appearance from typical process-bearing fibroblasts to mesothelial cells lining the subdural and subarachnoid space. The meningeal layers are particularly rich in collagen and elastin. Trabeculae between the arachnoid and pia are formed from collagen and are lined with the same mesothelial cells that line the subarachnoid space. The most rapid proliferation of human meningeal cells during development occurs within 8–18 weeks of conception, with centrally located fibroblasts and peripherally located cells containing glycogen that increase during this time.^{34,56} By 14 weeks, the three layers of the meninges can be distinguished. These glycogen-rich cells go on to produce large amounts of collagen, which is deposited in the dura after 14 or 15 weeks.

Axon number

Studies in animals suggest that approximately 50–100 percent excess RGCs are produced in the retina. During early development, the number of RGCs decreases by programmed cell death called apoptosis (discussed in the context of axon injury, below), in many cases because not all of the axons properly connect to their target regions within the brain.^{109,110} This form of programmed cell death may be adaptive if it does not release toxic intracellular components into the extracellular environment and thereby does not affect neighboring cells that are already integrated to survive. Likewise, in humans, up to two-thirds of developing RGCs die, predominantly during the second trimester.¹¹¹

Axon growth

Considerable progress has been made in recent years in our understanding of the development of the optic nerve, particularly at the level of molecular and cellular regulation. Axon growth requires specific extracellular signals – merely inhibiting cell death is not sufficient for inducing axon growth in developing RGCs.^{112,113} The most potent signals for axon growth are the same peptide trophic factors that most strongly promote RGC survival, and multiple trophic factors can often combine to induce even greater axon growth.^{113–116} The best-studied peptide trophic factors for RGC axon growth are brain derived neurotrophic factor (BDNF), ciliary neurotrophic factor (CNTF), insulin-like growth factor (IGF), basic fibroblast growth factor (bFGF), and glial cell line-derived neurotrophic factor (GDNF), although it is not clear how critical any of these are for axon growth during normal development.^{112,117,118} Other than peptide trophic factors, extracellular matrix molecules like laminin and heparin sulfate proteoglycans, and cell adhesion molecules like L1 and N-cadherin are expressed in the visual pathway^{119,120} and provide a critical substrate along which axons extend. Eliminating N-cadherin expression, for example, clearly decreases RGC axon growth *in vivo*.¹²¹ Finally, other extracellular signals as simple as purine nucleotides may be critical to induce axon growth, although the mechanism of this activity is still mysterious.¹²²

Electrical activity (discussed below) is not required for axon growth, but likely plays a role in sculpting axonal morphology. Thus, after injecting tetrodotoxin into the eye to block action potentials,¹²³ or in experimental mice in which synaptic release of neurotransmitters is essentially eliminated,¹²⁴ RGCs and other CNS neurons successfully elongate their axons to their targets in the absence of electrical activity. RGC activity may increase the rate of axon arborization in their target fields by stabilizing growing branches,^{125–127} and may influence the specificity of local connectivity and targeting of axons.^{128–130} Considerable progress has been made in understanding these molecular mechanisms for axon growth, and these have been reviewed elsewhere.¹³¹

Axon guidance

Optic nerve axon guidance is heavily influenced by the earliest pathfinding axons,¹³² which serve as a substrate and guidance cue for the growth of the axons that follow. During development, RGC axons are guided by neuronal and glial molecules that attract and repel axonal growth cones.^{133,134}

For example, embryonic RGC axons are repelled by Müller glia away from deeper retinal layers into the nerve fiber layer.^{135,136} Within the retina, the interesting course of retinal axons in the macular nerve fiber layer are likely due to a foveal repellent combined with an optic disk attractant.¹³⁷ RGC axons are directed centrally in the retina away from chondroitin sulfate proteoglycans (CSPGs)¹³⁸ and are attracted into the optic nerve head by netrins.^{139,140} A semaphorin, sema5A, may contribute to keeping the developing axons within the substance of the developing optic nerve.¹⁴¹ Ipsilateral-projecting axons are repelled at the optic chiasm by slit1 and slit2,¹⁴² ephrin-B,^{143,144} and CSPGs.¹⁴⁵ The developmental ordering of the axons as they pass through the chiasm and go on to innervate the lateral geniculate primarily reflects their time of arrival.^{146,147}

RGC axons reach four main targets: (1) the lateral geniculate nucleus of the thalamus; (2) the superior colliculus; (3) the pretectal nucleus; and (4) the suprachiasmatic nucleus. Most axons course unbranched to the lateral geniculate nucleus, but studies in many animals,¹⁴⁸ including primates,¹⁴⁹ have demonstrated the existence of axon collaterals to the other targets, suggesting that the same may be true for human optic nerves.

The lateral geniculate nucleus is the primary synaptic target for visual information processing on the way to the visual cortex (discussed at length in Chapter 29). The primate lateral geniculate nucleus has six layers: layers 1 and 2 consist of large (magnocellular) cells, and layers 3, 4, 5, and 6 consist of small (parvocellular) cells. The magnocellular layers receive input from the midget RGCs, while the parvocellular layers receive input from the parasol RGCs. Layers 2, 3, and 5 receive input from the ipsilateral retina, while layers 1, 4, and 6 receive input from the contralateral retina. In addition, there are interlaminar cells forming the koniocellular layers. These cells are smaller than those of the parvocellular layers, and receive synaptic input from blue-yellow RGCs.¹⁵⁰

A second set of optic nerve axons project to the superior colliculus, a paired structure of the dorsal midbrain. In lower animals, e.g. rodents, the majority of fibers of the optic nerve project to the superior colliculus. In primates, including humans, only a minority does so, with the majority of axons destined instead for the lateral geniculate nucleus. These fibers arise from most of the retina, except for the central 10 degrees.¹⁵¹ The superior colliculus has a laminar organization, and is retinotopically mapped.¹⁵² Most studies of superior colliculus architecture have been done in animals, although the human superior colliculus appears to have similar anatomy.¹⁵³ The function of the superior colliculus is to coordinate retinal and cortical control of saccades and fixation.¹⁵² Fibers branching to midbrain terminal nuclei stabilize the retinal image during movement of the eye, head, or body.¹⁵⁴ The role of the superior colliculus in extraocular movements is covered in Chapter 9.

The pretectal nucleus in the midbrain receives RGC fibers important for the pupillary response.^{155,156} The pretectal projection is bilateral, and in addition fibers from each pretectal nucleus project both ipsilaterally and contralaterally to the Edinger-Westphal subnuclei of the third nerve nucleus. The latter then projects parasympathetic axons along the course of the third nerve to the ciliary ganglion within the orbit, where a synapse is made. Postsynaptic parasympathetic

fibers continue to the pupilloconstrictor muscle, constriction of which is visible as the pupillary light reflex. The combined ipsilateral and contralateral projections from the retina to the pretectal nuclei, and from the pretectal nuclei to the Edinger-Westphal subnuclei necessitate that a light stimulus causing impulses along either optic nerve will cause equal constriction of both pupils. This is the physiological basis for detecting an afferent pupillary defect (also called a Marcus Gunn pupil). If there is a functional difference in the number of optic nerve axons carrying impulses from each retina, then light shined into the eye with fewer axons will cause a lesser amount of (bilaterally symmetric) pupillary constriction than light shined into the other eye. By alternating the light between the two eyes and observing the difference in pupil size dependent on which eye the light is shined into, one can detect which optic nerve is functionally conducting less than the other. This measure is highly correlated with differences in the number of surviving RGCs or RGC axons.¹⁵⁷ It has been proposed that there are differences between the myelin surrounding axons destined for the lateral geniculate nucleus and those responsible for the pupillomotor reflex because of the existence, albeit rare, of patients with demyelinative optic neuropathies and monocular blindness with preserved pupillary reflexes.¹⁵⁸ These patients do not have apparent conduction toward the lateral geniculate nucleus but do have conduction toward the pretectal areas responsible for the pupillary reflex. Detection of the afferent pupillary defect is discussed at length in Chapter 25.

A fourth projection of optic nerve axons is via the retinohypothalamic tract to the suprachiasmatic nucleus and the paraventricular nucleus^{159–161} within the hypothalamus. These fibers are responsible for circadian control of the sleep-wake cycle, temperature, and other systemic functions.

Retrograde labeling studies in pigeons¹⁶² and rats¹⁶³ indicate that only a few percent of RGC axons project to the pretectal and suprachiasmatic nuclei. Recently, a population of intrinsically photosensitive RGCs has been identified,¹⁶⁴ that express the photopigment melanopsin,^{165–167} and project to the subthalamic nuclei to mediate circadian rhythm and pupillary light response.^{168,169} Thus, even if all rod and cone photoreceptors are lost (as in retinitis pigmentosa, for example), these intrinsically photosensitive RGCs can continue to collect light for circadian rhythm entrainment, for example.

Optic nerve physiology

Retinal ganglion cell electrophysiology and synaptic transmission

In the retina, RGCs receive synaptic input from bipolar and amacrine cells, which primarily use glutamate as the major excitatory neurotransmitter. RGCs have both NMDA and non-NMDA ionotropic glutamate receptors, as well as metabotropic receptors.^{170–175} Other neurotransmitters modulating RGC activity include GABA,¹⁷⁴ acetylcholine,^{176,177} and aspartate (acting on NMDA receptors), as well as serotonin and dopamine.¹⁷⁸ Within the retina itself the levels of glutamate are modulated by Müller cells, which

have glutamate transporters, and which contain the enzyme glutamine synthetase, converting glutamate to the amino acid glutamine. Glutamate reuptake within the retina is necessary for maintaining appropriate RGC function.^{179–182} The electrophysiology of RGCs is complex,^{183–188} and is discussed at length in Chapter 23 and elsewhere.¹⁸⁹ RGCs themselves are glutamatergic, but they also use other neurotransmitters, including substance P and serotonin.^{190–194}

Axonal conduction

Action potentials

RGC axons transmit information via action potentials, which are all-or-nothing spikes of electrical activity. This is in contrast to most intercellular communication within the retina, where *graded potentials* are used to transmit information. With action potentials, the actual amount of voltage change, i.e. depolarization, is the same, while the number of impulses per second and the distribution of impulses within various axons is the mechanism by which visual information is carried down the optic nerve. Conduction down individual axons occurs via the same biophysical mechanisms which occur in any myelinated axon (see section on myelin, below). Variations in conduction velocity of individual axons may help coordinate conduction time between RGCs located at differing distances between their retinal location and the optic nerve.¹⁹⁵

The mechanism of axonal conduction is straightforward. At rest, the inside of an axon is at a negative voltage with respect to the outside of the axon. This negative *resting potential* primarily results from the higher concentration of potassium within the axon compared to its extracellular concentration. As a small number of potassium ions flow down their concentration gradient from the inside of the axon to the outside, this *leak current* out of the axon results in a negative potential within the axon. Outward flux of potassium continues until the charge separation becomes too great, and can no longer be driven by the concentration difference between inside and outside the axon. The point at which the gradient for potassium concentration is balanced by the gradient for separation of charge results in an equilibrium potential for potassium. While the resting potential is primarily determined by potassium, there is also a smaller contribution from sodium flowing down its concentration gradient. In the case of sodium, the concentration in the extracellular space is high, compared with a low concentration within the axon. This concentration gradient would induce sodium to enter the axon, and movement of a small number of sodium ions results in a positive sodium equilibrium potential. However, in a resting (non-depolarizing) axon the conductance for sodium is much smaller than that for potassium, and therefore the final resting potential is weighted much more by the equilibrium potential for potassium than for sodium.

The situation changes during axonal conduction. Partial axon depolarization (resulting from an adjacent section of membrane that is already depolarized) induces opening of voltage-sensitive sodium channels located within the membrane. These allow much greater amounts of sodium to enter the axon, and the positive sodium ions cause the axon to become more positive, i.e. *depolarized*. In this case, the potential across the membrane is now weighted far more by

the sodium equilibrium potential than by the potassium equilibrium potential. Why do the sodium channels open? These channels are voltage-sensitive, and a relatively small depolarization of the membrane will cause them to open transiently. Increased potential within the axon rapidly affects adjacent sections of the axon, and causes sodium channels in these adjacent areas of axonal membrane to likewise become partially depolarized. These then completely open, and cause a compete depolarization. This chain of events continues down the axon, resulting in a transmission of action potential.

Repolarization is the return of the axonal membrane potential to the original (negative resting potential) state, and is necessary for more than a single action potential to be transmitted down the axon. Repolarization is due to the closure of the voltage-sensitive sodium channels and a transient opening of voltage-sensitive potassium channels. Once the latter occurs, the membrane resting potential is weighted more by the potassium equilibrium potential than by the sodium equilibrium potential. This results in a restoration of membrane potential to the resting state.

In the process of transmission of an action potential there is movement of sodium and potassium ions along their concentration gradients. If action potentials continued indefinitely, the sodium and potassium concentrations would reach equilibrium across the axonal membrane, resulting in loss of their concentration gradients and conduction block. In order to re-establish these concentration gradients, there is a relatively slow redistribution process of these ions via the Na⁺-K⁺-ATPase. This is a highly energy-dependent process, and will fail to happen if axonal metabolism is disturbed.

Role of oligodendrocytes and myelin

Myelin confers two electrophysiological functions. First, it decreases capacitance, meaning less sodium ion-positive charge needs to enter the axon in order to depolarize the membrane. Second, it increases resistance, meaning that there is less leakage of charge across the membrane. Together, these properties decrease the amount of ionic flux needed to achieve changes in voltage across the membrane, saving on the Na⁺-K⁺-ATPase activity and thus energy needed to maintain ionic homeostasis after conduction.

Oligodendrocytes and myelin confer other critical properties for axonal conduction. Neonatal unmyelinated axons have a low density of sodium channels spread along the length of the axon, which allows a measure of axon conduction. In the adult, however, ion channels are not distributed uniformly along a myelinated axon. Instead, the channels are segregated into patches located within the small areas where the axon is unmyelinated, called nodes of Ranvier.¹⁹⁶ Conduction in a myelinated axon, called *saltatory conduction*, becomes much faster, as depolarization “jumps” from one node to the next. The clustering of sodium channels into nodes, as well as an important developmental switch in sodium channel isoforms, are also induced by oligodendrocytes.^{197–199}

Role of astrocytes

Although neurons are classically considered the only electrically active cell population in the CNS, astrocytes also have ion channels. For example, multiple voltage-sensitive

sodium channels have been demonstrated in rat optic nerve astrocytes.^{196,200,201} Both sodium and potassium channels have been studied electrophysiologically in cultured astrocytes.^{202,203} Within the intact optic nerve, non-vesicularly released glutamate from the axon may inducing glial cell spiking²⁰⁴ and possibly other effects.²⁰⁵ Whether ion channels or neurotransmitter receptors on optic nerve glia are physiologically important *in vivo* has yet to be demonstrated, but their presence suggests that optic nerve astrocytes may be more functionally specialized than previously recognized.

Axonal transport

The entire length of the RGC axon must be maintained by transporting proteins and other subcellular constituents many centimeters from the cell body, where the nucleus and most of the protein synthetic machinery resides. Axonal transport occurs in two directions, orthograde (away from the cell body and towards the brain), and retrograde (towards the cell body and away from the brain). By injecting radioactive, fluorescent, or enzymatically active macromolecular tracers into either the eye or the terminal fields of the axons, the course and timing of orthograde and retrograde transport can be determined. Studies have generally been performed in experimental mammals, with findings generally consistent across species.²⁰⁶ The rates of transport of specific moieties may vary as a function of stage of optic nerve development, suggesting a developmental regulation of axonal transport.²⁰⁷ Different rates of axonal transport may be related to differences in the motor proteins interacting with microtubules, e.g. kinesin²⁰⁸ for fast transport and dynein²⁰⁹ for slow transport.

Fast axonal transport, at 90–350 mm/day,^{210,211} carries several subcellular organelles, such as the vesicles of neurotransmitter used in synaptic transmission, towards the axon terminal.²¹² This class of transport continues despite transection of the axon distal to the cell body, suggesting that intra-axonal components are sufficient for the process to occur. Slow axonal transport is divided into two classes, a slower class at 0.2–1 mm/day that carries cytoskeletal proteins, such as neurofilament proteins and the tubulins that make up microtubules,²¹³ and a more rapid class at 2–8 mm/day, which carries proteins such as actin and myosin, metabolic enzymes, and mitochondria.^{214–216} Slow axonal transport does not continue after transection of the axon distal to the cell body, unlike fast axonal transport.²¹⁷

Retrograde transport occurs at about half the velocity of fast orthograde transport. Retrograde transport of neurotrophic molecules during development may signal the cell body that the axon is reaching its targets in the brain. How do growth signals at the axon get passed along to the distant cell body, where gene transcription and translation are induced to support survival and axon growth? Neurotrophin-mediated activation of Trk receptors leads to endocytosis of activated, ligand-bound receptors into clathrin-coated vesicles. These signaling endosomes carry with them the machinery of the ras-raf-MAP kinase signaling cascades, and can continue to activate these pathways once inside the cell.²¹⁸ Neurotrophin signaling endosomes may then be retrogradely transported back to the cell body along microtubules, where they can activate transcriptional regulators and induce new gene expression.^{219–221} The relationship between

vesicle localization and signaling effects remains a largely unanswered question, but is clearly important for the maintenance of normal axon physiology.

Optic nerve injury

Clinical implications

The optic nerve is commonly involved in disease, resulting in optic neuropathy and visual loss. Glaucoma is the most common optic neuropathy; others include inflammatory optic neuropathies such as optic neuritis associated with the demyelinating disease multiple sclerosis; ischemic optic neuropathy usually affecting older adults; and compressive optic neuropathy, commonly associated with a tumor or aneurysm. Although not proven, some researchers believe that Leber's hereditary optic neuropathy and some of the toxic optic neuropathies may reflect damage to the RGC body within the retina. Except for these, most optic neuropathies are due to damage directly to the optic nerve. Therefore, the vast majority of optic neuropathies involve axonal injury. Importantly, in all forms of axon injury, there is typically no capacity of RGC axons to regrow in the adult optic nerve, and thus little endogenous repair.

Types of optic nerve injury

Traumatic optic neuropathy

Although traumatic optic neuropathy, particularly optic nerve transection, is one of the least common human scenarios in which RGC axons are injured, it has been the best studied animal model by far. In humans, concussive injury can indirectly traumatize the optic nerve and injure axons, as might happen after a car accident or other blunt injury. Direct transection, though more rare, might result from a bullet, or fragment of broken orbital bone, or by optic nerve avulsion. In animal models, typically, the optic nerve is surgically cut or crushed within the orbit behind the eye, although experiments crushing the nerve intracranially have also been studied. Regenerative response is assayed by labeling RGC axons and determining whether any extend past the lesion site.²²² Interestingly, although injuring the optic nerve at increasing distances from the eye delays the onset of RGC death,²²³ there may be less regenerative response with more distal injury.²²⁴

Ischemic optic neuropathy

Because the vascular supply to the optic nerve is complex and varies qualitatively along its course, a variety of clinical syndromes may result from ischemia or infarction at each location. Arteritic and non-arteritic anterior ischemic optic neuropathies are associated with histopathologically verifiable occlusion of posterior ciliary arteries. An infarction of the central retinal artery or one of its branches will result in RGC axon loss, with a pale disk and loss of axons within the optic nerve itself. Ischemia may also result from hypotension or severe blood loss, although the resulting pathophysiology may vary.^{225,226} Finally, there is a tremendous controversy as to whether the effects of intraocular pressure causing axonal damage in glaucomatous optic neuropathy is an ischemic or compressive process.

The pathophysiology of myelinated axonal ischemia is complex.^{227,228} The presence of myelination affects the metabolism of the axon. Because less current is necessary for depolarization to occur, less ATP is needed for transmission of action potentials. At the same time, the myelinated axon is more sensitive to anoxic damage. Although neonatal optic nerve, which is not myelinated, does not easily suffer irreversible damage from anoxia, more mature nerves from animals that have just undergone myelination are highly sensitive to anoxia. Similarly, optic nerves from *md* rats, a myelin-deficient rat strain, are sensitive to anoxia.²²⁹ Finally, myelinated axons (white matter) are relatively less sensitive to ischemia than neuronal cell bodies (gray matter).²³⁰

Ischemic optic nerve injury can be modeled in experimental animals via a variety of approaches. A powerful method is to occlude the posterior ciliary arteries, best done in primates, but which has the disadvantage of also affecting the choroidal circulation.^{231,232} Infusion of the vasoconstrictor endothelin-1 into the perineural space is a good model of subacute to chronic ischemia, and can be performed in a variety of species.^{233–239} More recently, direct vascular damage, tissue edema, and vascular compromise have been modeled at the optic disk^{240,241} and at the retrobulbar optic nerve.²⁴²

Optic neuritis and inflammation

Inflammation of the optic nerve, or optic neuritis, is the most common form of acute optic neuropathy in young and middle-aged adults, and is a frequent harbinger of multiple sclerosis.^{243,244} Demyelination is the most common pathological accompaniment of optic nerve inflammation, and conduction block due to this or other effects of inflammation²⁴⁵ is responsible for the usually temporary loss of visual function seen in patients with optic neuritis. Demyelination itself would not necessarily cause loss of RGCs, and as in multiple sclerosis, multiple rounds of demyelination and associated inflammation may be required for axonal loss.^{246–248} Axonal loss in optic neuritis has been long appreciated clinically as optic atrophy and loss of the nerve fiber layer,²⁴⁹ and experimental models of optic nerve inflammation can be used to elucidate how this axonal damage occurs.^{250–252} It is likely that one major effect of inflammation is on the axonal cytoskeleton, as witnessed by changes in microtubule and neurofilament organization,²⁵² and by changes in axonal transport.^{253–255}

In cases of acquired loss of myelin, for example in idiopathic optic neuritis, there is abnormal conduction because of the changes in resistive and capacitive properties of the membrane brought about by demyelination. This can happen via loss of the compact morphology of the myelin alone, i.e. without frank demyelination.²⁵⁶ A low density of internodal sodium channels in adult optic nerve may allow some conduction after demyelination, as in optic neuritis.²⁵⁷ Axonal conduction becomes slowed, however, and in some cases may be blocked ("conduction block"), both resulting in decreased visual function. Even in a completely demyelinated axon, a low density of internodal sodium channels in demyelinated optic nerve may still allow conduction.²⁵⁷ Another phenomenon peculiar to demyelination is worsening of vision with heat or exercise, or *Uhthoff's phenomenon*. Increased temperature and exercise are thought to decrease the sodium channel open-time during depolarization, resulting in less charge entering the axon, and a decreased

likelihood that an adjacent section of demyelinated axon will be able to depolarize enough to cause opening of its own voltage-sensitive sodium channels. This leads to temperature-sensitive conduction block.

Optic neuritis has been modeled in rat and mouse models of experimental autoimmune encephalomyelitis, in which rodents' immune systems are stimulated to react against myelin-associated proteins. Immunization against myelin-oligodendrocyte glycoprotein (MOG) induces multiple sclerosis-like demyelination throughout the brain including in the optic nerve,²⁵⁸ but creating transgenic mice with T cells directed against MOG, or passively transferring anti-MOG T cells in rats, creates demyelinating disease largely confined to the optic nerve, mimicking optic neuritis.^{259,260} In such models, RGC axons are incidentally severed and fail to regenerate, and as after optic nerve trauma, RGCs die with a 1–2 week delay.²⁶¹

Compressive optic neuropathy

Compression of the optic nerve is a common clinical correlate of a large number of optic neuropathies. Besides the obvious causes such as neoplasms and aneurysms, the optic nerve can also be compressed by enlarged extraocular muscles (as in Grave's ophthalmopathy), edema (as seen with indirect traumatic optic neuropathy, where the nerve is contused within the optic canal), or optic disk drusen. Compression intrinsic to the nerve itself may occur in some forms of glaucomatous optic neuropathy, where increased intraocular pressure may cause bowing out and shifting of the lamina cribrosa, constricting the bundles of optic nerve axons within the cribriform pores.²⁶² Although all three layers of meninges are present in the intraorbital and intracanalicular optic nerve, only the pia continues along the intracranial optic nerve. The clinical relevance of this is that a tumor arising from the optic nerve meninges themselves, i.e. an optic nerve sheath meningioma, will normally continue through the optic canal, but then extend along the sphenoid bone, and not along the course of the intracranial optic nerve or optic chiasm. This means that it is extremely rare for an optic nerve sheath tumor to extend towards the chiasm, and thereby affect the other side. The more common way for optic nerve sheath meningiomas to become bilateral is by directly extending along the sphenoid bone meninges.

The effects of chronic experimental compression of the intraorbital optic nerve have been delineated at the microscopic and ultrastructural level.^{263,264} Demyelination occurs initially, followed by remyelination, even while the axons are still compressed, with relatively little axonal loss. Demyelinated axons or the direct effects of pressure might be expected to lead to conduction block, which would be reversible. This could therefore explain the remarkable return of visual function after removal of tumors compressing the optic nerve.²⁶⁵

Glaucoma

The most common optic neuropathy is glaucomatous optic neuropathy, distinguished by a distinct morphology of progressive excavation of the nerve head without significant pallor of the remaining neuroretinal rim. Within the retina, there are decreased numbers of RGC bodies in glaucoma,^{266–268} and this likely reflects death by apoptosis.^{269–272}

The number of RGCs lost correlates with the visual field deficit.²⁷³ In addition to the RGC cell body loss, there is loss of the ganglion cell axons, manifested by segmental loss of the nerve fiber layer,^{274–278} increased cup-to-disk ratio, thinning of the optic nerve²⁷⁹ and chiasm,²⁸⁰ changes in post-synaptic cell counts within the lateral geniculate nucleus^{281–284} (the main target of RGC axons in higher animals), and in the cerebral cortex.^{285,286}

That the site of primary injury is likely at the optic disk is consistent with a wide variety of evidence demonstrating pathology at that level,^{268,287} particularly at the lamina cribrosa.^{262,288–299} The focal areas of optic nerve axonal injury correlate with the focal areas of cell body loss in the retina and visual field defects.^{22,23} Thus the most typical glaucomatous visual field defects spread in an arcuate pattern but stop at the horizontal meridian in the nasal field. This site in the visual field corresponds to the temporal raphe of the nerve fibers within the retina. Although there is a small distance between adjacent RGCs across the temporal raphe, the axons that correspond to these RGCs are separated by a large distance at the optic disk (Fig. 28.1). In those cases when defects are seen on both sides of the horizontal meridian, it can be seen that spread has occurred in both the superior and inferior visual fields, but not directly across the meridian. Thus the spread of visual field loss in glaucoma reflects the spread of pathology at the optic nerve head, followed later by RGC cell body loss in the retina.

What mechanisms induce RGC death in glaucoma? Glaucoma has been extensively modeled in animals (see reviews^{300,301}). Studies of tissue from human patients with glaucoma and non-human primates and other mammals with experimental glaucoma confirm changes at the optic nerve head, such as with respect to bowing out of the lamina cribrosa, intra-axonal accumulation of organelles (consistent with blocked axonal transport; Fig. 28.6), and Wallerian degeneration distal to the lamina cribrosa.^{262,302,303} Whether due to mechanical trauma of axons,^{223,304–306} ischemia,²³⁸ generation of nitric oxide,^{307,308} or other causes, axonal injury causes changes in RGCs, eventually resulting in death. Increased intraocular pressure perturbs rapid anterograde and retrograde axonal transport at the lamina cribrosa.^{309–312} This may cause RGCs to be deprived of neurotrophic factors or other survival signals produced by brain targets. Studies in experimental animals have shown that injury to the optic nerve, for example from increased intraocular pressure in experimental glaucoma, blocks the retrograde transport of the neurotrophic factor brain-derived neurotrophic factor (BDNF) along with its associated receptor, TrkB.^{313–315} Interestingly, one of the genes associated with a hereditary form of glaucoma, optineurin,³¹⁶ may in its mutated form contribute to RGC sensitivity to optic nerve insults by failing to adequately participate in retrograde transport of neurotrophin signaling complexes, or by oxidative dysregulation.^{317–320}

Papilledema

Papilledema is defined as optic disk edema secondary to elevated intracranial pressure, and should not be used non-specifically to denote disk edema. Pathological examination of optic nerve heads with papilledema reveals intra-axonal edema, consistent with abnormalities of axonal transport. However, the pathogenesis of papilledema is controversial. While primate experiments show definite abnormalities of

Figure 28.6 Failure of axoplasmic flow in the optic nerve injury associated with elevated intraocular pressure. The radiographs capture the optic nerve through the prelaminar region (**A**), the lamina cribrosa (**B**), and the post-laminar orbital optic nerve (**C**). Optic nerves were harvested after tritiated leucine was injected into the eyes of normal monkeys (left), or eyes of monkeys with moderately (center) or more severely (right) experimentally elevated intraocular pressure. With increasing IOP, increasing accumulation of radioactive label is appreciated at the lamina cribrosa, with an associated decrease in grains transported posterior to this point. (From Figures 2–4 of Anderson & Hendrickson, Invest Ophthalmol 1974; 13(10):771. Reproduced with permission from Association of Research in Vision and Ophthalmology.)

slow axonal transport,^{321,322} evidence for abnormalities of fast axonal transport (which would include retrograde transport) is less clear,^{322,323} and in part depends on experimental paradigms where papilledema is simulated by ocular hypotony.^{324,325} It is also unclear whether the visual loss associated with chronic papilledema results from disturbances of axonal transport, or from ischemia due to congestion of the optic nerve head.

Retinal ganglion cell death after optic nerve injury

Death of RGCs is the final common pathway underlying virtually all diseases of the optic nerve, including glaucomatous optic neuropathy, anterior ischemic optic neuropathy, optic neuritis, and compressive optic neuropathy. In many diseases affecting the RGC axons (e.g. glaucoma or arteritic ischemia), visual loss is permanent, reflecting the fact that RGC loss is irreversible. In some cases (e.g. chronic compressive optic neuropathy, acute optic neuritis, or papilledema) visual loss can be reversed when the axonal damage is

relieved, presumably because RGC death has not yet occurred. Even in glaucoma, there is now evidence that there is some period of RGC electrophysiological dysfunction and visual field deficit, that precedes frank cell death.^{326–328} However, if allowed to continue, these disorders eventually can result in permanent RGC death.

Time course

The rate and timing of RGC death after optic nerve injury depends on the species, age, RGC cell body size, and the distance from the site of injury to the RGC. For example, after optic nerve injury in goldfish and frogs, ganglion cells do not die, but hypertrophy and regenerate axons within 1–2 months.^{329–331} Conversely, in adult rodents, optic nerve injury leads to initiation of cell death within 5–7 days, and 50–90 percent cell death taking weeks to sometimes months.^{304–306,332–335} Similarly, ganglion cells from squirrel and owl monkeys die approximately 4–6 weeks after axotomy.^{336,337} In humans with chiasmal compression for at least 6 months, there is extensive loss of ganglion cells from the nasal hemiretinas; yet even 35 days after transection of the ipsilateral optic tract there is sparing of some temporal ganglion cells.³³⁸ In contrast, neonatal RGCs are far more sensitive to axotomy than adults,^{304,339,340} perhaps because naturally occurring developmental cell death is taking place at the same time. As an example, in postnatal rodents, 90 percent of RGCs die within 48 hours of optic nerve crush.

It is controversial whether the response of ganglion cells to axotomy depends on the distance between the lesion and the cell body. Some studies have shown that the shorter that distance, the more rapid the degeneration^{332,333} and the more severe the effect.^{341–344} This could be due to lack of a trophic signaling along a length of residual axon, or more rapid transmission of a signal mediating cell death, either mechanism possibly mediated through retrograde axonal transport.^{306,337,345} Others have suggested that the timing of ganglion cell degeneration is not correlated with the distance to the lesion.^{336,337} Axotomized fibers from the macula degenerate later than those more peripheral, suggesting that the distance from the site of axotomy to the retina does not affect timing of RGC death.³³⁷ Differences in ganglion cell survival also depend on the site of optic nerve transection in relation to the vascular supply of the retina. If the ophthalmic or central retinal arteries are transected, then the inner retina, including the ganglion cell layer, will be infarcted,³⁴⁶ rapidly speeding RGC death.

Apoptosis

A variety of techniques have been used to show that the death of RGCs after axotomy occurs by apoptosis.^{223,269,347–350} Pathological studies show condensation of the nucleus and cytoplasm, budding of the cytoplasmic membrane, cleavage of DNA into 180–200-bp fragments, fragmentation of the cell into membrane-bound bodies, and heterophagy of these bodies.^{351,352} The apoptosis program is an intricate and sequential activation of multiple intracellular enzymes, including cysteine-dependent aspartate-directed proteases (caspases), and endonucleases, regulated from the mitochondrial membrane by the Bcl-2 family of proteins. Pro-apoptotic family members such as Bax, Bak, and Bok are held in check by antiapoptotic members such as Bcl-2 and Bcl-xL. A third group in this family, including Bim and Bad,

cannot activate apoptosis by themselves, but can facilitate apoptosis by interfering with Bcl-2 or Bcl-xL's ability to regulate Bax, for example. If anti-apoptotic proteins are unable to balance the proapoptotic family members, either because they are sequestered by Bim-like proteins, or are in short supply due to inadequate production, the anti-apoptotic proteins will increase mitochondrial membrane permeability, and enhance release of cytochrome c into the cytoplasm. Cytochrome c binds to an adaptor protein Apaf-1, forming a complex that can initiate a cascade of enzymatic degradation of cellular components by a family of enzymes called caspases, beginning with the activation of procaspase-9. Also released from the mitochondria, a protein called Smac/Diablo binds to and inactivates an anti-apoptotic protein called Inhibitor of Apoptosis (IAP), which normally represses activation of procaspases. Thus by at least two mechanisms, mitochondrial permeabilization by Bax inclines the balance towards apoptosis. Once the *apoptosome* is formed from the factors released from the mitochondria, the activation of caspases takes place. These in turn activate other caspases, and this cascade of events results in the activation of other enzymes within the cell which results in the breakdown of DNA and other macromolecules, membrane-bound compartmentalization of cell components, and then phagocytosis by adjacent cells.

Besides axonal injury, several other modes of cell death may induce apoptosis. For example, the binding of tumor necrosis factor to tumor necrosis factor receptors may induce apoptosis via death domain signaling and subsequent activation of caspase-8, initially bypassing the caspase-9 activation by the mitochondria. Glutamate excitotoxicity may also induce apoptosis,³⁵³ and RGCs are particularly susceptible to high levels of glutamate in the extracellular space.^{175,354–356} It has been proposed that excitotoxic RGC death may explain pathological conditions, such as glaucoma.³⁵⁷ The evidence supporting this is that antagonists of glutamate excitotoxicity mediated by NMDA receptors generally decrease RGC death after optic nerve injury,^{358,359} and that there may be elevations of glutamate levels within the eye after optic nerve injury,³⁶⁰ or experimental or human glaucoma.³⁶¹ Changes in NMDA receptor subunit expression follow axonal injury,³⁶² and may underlie changes in susceptibility to excitotoxicity. Variability in the sensitivity of RGCs to excitotoxicity in animal models,³⁶³ and the failure of clinical efficacy of NMDA receptor inhibition for prevention of progression in glaucoma, however, raises significant questions about this mechanism.³⁶⁴

Signaling of axonal injury

How does axonal injury result in induction of apoptosis? RGC death after optic nerve injury or target removal appears to take place through several mechanisms, including lack of neurotrophic factors from the target tissue, excitotoxicity from physiological or pathological levels of glutamate, free radical formation, leakage of cellular constituents out the end of the axon, proliferation of macroglia, activation of microglia, build-up of excess retrogradely transported macromolecules, and breakdown of the blood-brain barrier.^{117,332,341,343,359,365–367} Even the contralateral retina may be affected by a unilateral optic nerve injury, suggesting the involvement of intrachiasmal signaling or axon fibers that run towards the retina.³⁶⁸

RGCs are highly dependent on neurotrophic factors during development and in the adult for their survival. Support for the role of neurotrophin dependence comes from experiments using identified neurotrophic factors to rescue injured neurons, including RGCs after axotomy in adult animals.^{117,118,335,369–375} The survival of ganglion cells in adult animals is facilitated by BDNF, FGF, GDNF, CNTF, and conditioned medium from transected sciatic nerves.^{118,376–380} Purified neonatal RGCs (which are axotomized during dissociation) can be kept alive for significant periods beyond the normal time of developmental death with a cocktail of factors, including BDNF, CNTF, forskolin, and insulin.³⁸¹ Supplying neurotrophin alone is insufficient, as responsiveness to neurotrophin also appears to require cAMP elevation^{382,383} or physiological levels of electrical activity.¹¹³ Microglia may play a role in ganglion cell death, based on experiments using macrophage inhibitory factor (MIF) to inhibit microglial activation and enhance ganglion cell survival after axotomy.³⁸⁴

Our understanding of how neurotrophic factor deprivation causes neuronal cell death derives from understanding how these factors normally maintain neuronal survival. For example, TrkB functions as a receptor for BDNF, and both TrkB and BDNF are expressed in RGCs during postnatal development.³⁸⁵ TrkB itself is regulated by activity or cAMP levels.³⁸³ TrkB binding by BDNF causes autophosphorylation, inducing binding of specific adapter proteins, and activation of a cascade of GTP-binding proteins and kinases called the Ras-Raf-MAP kinase cascade.³⁸⁶ Ras activity also leads to activation of PI3-kinase, which transduces a separate set of signals through activation of Akt (protein kinase B).^{387,388}

If the optic nerve is injured, BDNF or other neurotrophins introduced into the vitreous or retina increases survival of RGCs.^{117,118,335,369–371} However, there is no direct evidence that adult RGCs are normally dependent on BDNF or other neurotrophic factors, and it is possible that the increased survival seen after neurotrophin administration is not a *specific* rescue from neurotrophin deprivation, but rather a generalized pro-survival effect. Furthermore, retrograde axonal transport is rapid, and the subacute time-course by which RGCs die after axonal injury does not reflect the time-course of interrupted retrograde axonal transport. This probably explains why damage to the RGC axon in several different places results in similar rates of death after axonal injury.

Phagocytosis and immune activation

Optic nerve injury also leads to activation of local glial cells and recruitment of immune cells. For example, during Wallerian degeneration, resident microglia as well as circulating monocytes phagocytose myelin debris,⁷² and there may also be a contribution from oligodendrocytes and astrocytes.^{77,104,389–391} Probably most phagocytes in the degenerating optic nerve are derived from the circulation, although not all studies are in agreement.^{392,393} A partial answer to the contradictory reports of phagocytic cells after optic nerve injury may come from a study in which several zones of the monkey nerve were examined after transection behind the globe.³⁹⁴ Under these conditions, phagocytosis by macrophages of presumed hematogenous origin were seen focally, whereas endogenous cells, perhaps

oligodendrocytes, phagocytosed at distant sites of Wallerian degeneration. This is supported by the findings of ED1-positive macrophages in regions of GFAP-negative crushed optic nerve.³⁹⁵ Microglia can be observed to invade the myelin sheath and disrupt the myelin lamellae, the fragments of which are then phagocytosed.³⁹⁶ Deficiencies in the activation of microglia may lead to decreased clearance of myelin debris, and subsequent inhibition of axonal regeneration;³⁹⁷ conversely, increasing macrophage-mediated clearance of debris can increase regeneration.³⁹⁸

Gliosis

The role of optic nerve astrocytes in the pathologic processes of gliosis is complex.^{399,400} As a reaction either to local injury or to remote death of adjacent axons, astrocytes hypertrophy and extend processes, partly as a type of scar formation, but likely also as part of the process of recruiting or modulating other cell types. Astrocyte activation after injury may explain in part the failure of ganglion cell axons to regenerate after injury⁴⁴ (see below).

Failure of axon regeneration

In adult mammals, there is essentially no axon regenerative response after optic nerve injury. This contrasts with lower vertebrates – for example, not only do goldfish RGCs survive after their axons are transected,⁴⁰¹ but they are also able to extend neurites and ultimately establish correct connections with their targets.⁴⁰² Research in the early 20th century showed that mammalian RGCs, like other centrally projecting neurons, make only abortive attempts to regenerate their axons. Even when conditions permit axonal extension, only a small minority of RGCs eventually extend their axons. For example, severed rodent RGC axons approach the optic nerve head but then reverse and meander in another direction.⁴⁰³ Analysis of the proximal stump of the transected optic nerve just posterior to the optic nerve head shows early sprouting termed *abortive regeneration*, which then fails to continue and dies back.⁴⁰⁴

Thus in most cases, optic nerve injury and axon loss leads to permanent vision loss. Our understanding of the mechanisms preventing axon regeneration in adult mammals continues to advance, particularly with respect to the role of inflammation, discussed above, of glial-associated inhibitory signals, and of neuron-intrinsic limitations to axon repair, discussed below.

Glial inhibition of neurite extension

Since the early experiments of Aguayo and colleagues, it has long been known that RGCs and other central nervous system (CNS) neurons regenerate axons into peripheral nervous system (PNS) grafts (e.g. sciatic nerve), but not into CNS tissue.^{222,405} Since RGCs do not extend axons in the absence of specific extracellular signals (discussed above), regenerative failure might be explained in part by a relative inability of mature CNS astrocytes and oligodendrocytes to secrete trophic signals after injury. Evidence has supported this hypothesis, but it turns out that astrocytes and oligodendrocytes also actively inhibit axons from regenerating. The non-permissive nature of the CNS (but not PNS) substrate for axonal elongation is therefore of great interest,

and has resulted in a large number of candidate molecules. The most studied inhibitory molecules are components of oligodendrocyte myelin and proteoglycans expressed by astrocytes, and these molecules and their signaling mechanisms have recently been reviewed in detail.⁴⁰⁶

Resident microglia and/or macrophages recruited to the site of injury may also inhibit or fail to support axon growth. Although macrophages/microglia do increase in number at the site of injury,^{395,407} they may not be appropriately activated for support of axonal extension,^{398,408} and may differ from other macrophages in fundamental ways.⁴⁰⁹ If activated macrophages/microglia are poorly able to phagocytose degraded myelin, then the inhibitory signals found in myelin may prevent axonal regeneration.³⁹⁷

Neuron-intrinsic limitations to axon regeneration

Interest has also focused on the possibility that failure of regeneration reflects a specific inability of an adult RGC to extend its axon, since embryonic axons are able to do so when transplanted into adult tissue. Recent research has focused on determining whether the rate and extent of axon growth depends purely on extracellular signals and substrates, as discussed above in regards to optic nerve development, or also on the intrinsic state of the neuron. Elsewhere in the CNS, embryonic neurons can regenerate their axons quite readily, but they lose their capacity to regenerate with age.⁴¹⁰⁻⁴¹² This developmental loss of regenerative ability has generally been attributed to the maturation of astrocytes and oligodendrocytes, and to the production of myelin, all of which strongly inhibit axon growth after injury. In experiments in which the inhibitory environment is removed or molecularly blocked, however, only a few percent of axons regenerate, and functional recovery typically proceeds remarkably slowly (discussed further below). For example, RGCs may take two months to regenerate through a peripheral nerve graft.^{413,414}

These experiments indicate that the neurons themselves are partly responsible for regenerative failure. For example, axons from postnatal day 2 or older hamster retinas lose the ability to reinnervate even embryonic tectal explants.⁴¹⁵ When cultured in the complete absence of CNS glia, embryonic RGCs extend their axons 10 times faster than postnatal or adult RGCs.⁴¹⁶ Interestingly, the decrease in axon growth ability of RGCs occurs sharply at birth during the period of target innervation, but target contact may not be responsible for this change. Rather, retinal maturation, and possibly a membrane-associated signal from retinal amacrine cells, may be sufficient to induce the developmental decrease in RGC axon growth ability.⁴¹⁶ Once this signal is sent, the loss is permanent – removal of the amacrine cells does not allow the RGCs to speed up again. This may explain the failure of RGC regeneration, at least in part – even in a perfect environment, RGCs may lack the intrinsic capacity to rapidly grow their axons again, after they have done it once during development.

What molecular changes underlie the developmental loss in rapid axon growth ability? RGCs could gradually increase expression of genes that limit axon growth or decrease expression of genes necessary for faster axonal elongation, or both. For instance, in the developing chick, RGCs lose axon growth responsiveness to laminin either by down-regulating specific integrins (laminin receptors),⁴¹⁷⁻⁴¹⁹ or by

down-regulating the activation of such integrins,⁴²⁰ although they continue to respond to laminin-2 (merosin).⁴²¹ Enhancing integrin signaling enhances regeneration in animal models.⁴²² Similarly, a difference in trophic receptor levels or responsiveness to trophic signals could explain these differences. For example, depolarization rapidly elevates TrkB receptors on the surface of CNS neurons.^{381,423}

Indeed, almost any molecule in the cell could be crucial to determining axon growth.¹³¹ It is attractive to first consider transcription factors that could activate the expression of whole programs of axon growth, and recent data have pointed to a family of transcription factors that may regulate axon regenerative ability in RGCs.^{424,425} Transcription factors are not the only master regulators in a cell, however. Levels of specific complements of proteins can be regulated post-translationally by ubiquitination and degradation; the ubiquitin ligase anaphase-promoting complex (APC) has a significant role in regulating the axon growth rate of cerebellar granule neurons.⁴²⁶ Cytoplasmic kinases or phosphatases such as Ca²⁺-dependent signaling kinases, calmodulin kinases (CaMKs), may provide a downstream mechanism for axon growth control as well.⁴²⁷ Second messengers such as cAMP and cGMP have also been implicated in the RGC's intrinsic axon regenerative control, perhaps by modulating responsiveness to positive neurotrophic factors¹¹³ or to myelin-associated axon growth inhibitors.⁴²⁸ Finding the molecules that, when modified, truly enhance functional regenerative repair remains a major ongoing goal in optic nerve research today.

Optic nerve repair

The major goal of any optic nerve repair strategy must be to protect or regenerate the connections of RGC axons to their targets in the brain, as these connections are ultimately what serve vision.

Optic nerve remyelination

In the case of optic neuritis, where the primary defect in RGC function is attributable to oligodendrocyte demyelination, strategies to enhance remyelination are paramount. Currently, the major approach involves treating patients with steroids, which presumably interferes with an ongoing inflammatory insult and allows a faster re-wrapping of optic nerve axons and return to baseline vision. In the presence of demyelination, oligodendrocytes may reconstitute themselves and remyelinate axons,⁴²⁹ although the nature of the inducing chemical signals has not been well characterized.⁴³⁰ Similarly, chronic treatment with immune modulators decreases the risk of subsequent demyelinating events.

Neuroprotection and retinal ganglion cell survival

A first step to protecting optic nerve axons from a degenerative process is preventing RGC death. Neuroprotection, first proposed for other central nervous system diseases, has been considered in recent years as a possible treatment for optic neuropathies.^{431,432} Neuroprotective strategies include blocking retinal excitotoxicity mediated by

glutamate (which binds to N-methyl-D-aspartate [NMDA] receptors and induces RGC death),⁴³³ activation of small molecule receptors, which may enhance neuronal resistance to insult;^{434,435} inhibition of nitric oxide synthases, which may prevent axonal injury at the lamina cribrosa;⁴³⁶ and immunization with certain synthetic polypeptides.⁴³⁷ Furthermore, as was seen for RGCs in vitro,¹¹³ elevation of cAMP levels in RGCs enhances their regenerative ability after optic nerve injury in vivo.^{438–440} None of these strategies has yet been successfully proven in randomized controlled clinical trials in human patients with glaucoma. However, there is a variety of laboratory evidence using cell culture or animal models of optic nerve disease to suggest that one or more neuroprotective methodologies eventually may be successful in clinical disease.

Most promising may be administration of neurotrophic factors which maintain RGC survival.^{117,335,370} Indeed, ample evidence exists to support a role for neurotrophins in stimulating RGC survival in vivo. The same peptide trophic factors that stimulate RGC axon growth in vitro enhance survival and axon regeneration in vivo. GDNF,^{441–443} BDNF,^{444–446} and CNTF⁴⁴⁷ strongly promote RGC survival. Generally, these neurotrophic factors tend to work on any optic neuropathy model. For example, CNTF has a potent effect in enhancing RGC survival after optic nerve transection in the adult rat,^{118,438,448–450} in the adult mouse,^{451,452} and in the adult cat.^{440,453} Sustained delivery with viral vectors may be as or more effective.^{452,454,455} Similarly, peptide trophic factors have proven neuroprotective in multiple animal models for ocular hypertension or glaucoma.^{447,456,457} Thus neurotrophic factors provide a potent approach for RGC neuroprotection in multiple optic neuropathies.

Similarly, the convergence of many cell death signals onto the common pathways of apoptosis (discussed above) provides another avenue for therapeutic intervention and neuroprotection. Interfering with the apoptosis cascade at any of these points may provide a mechanism to protect RGCs from death after optic nerve injury. Inhibitors of cytochrome c, mitochondrial membrane depolarization, caspase activation, and IAP signaling are all in development for neuroprotection in the eye, brain, or elsewhere in the body.

Regeneration of RGC axons

The same neurotrophic factors that strongly promote retinal ganglion cell survival also tend to strongly promote RGC axon regeneration in vitro¹¹³ and in vivo.⁴⁵² Recent evidence has extended the list of neurotrophic signaling molecules beyond these traditional families. For example, a small, macrophage-derived, calcium-binding protein named oncomodulin binds RGCs and strongly promotes RGC axon growth in vitro and in vivo.⁴⁵⁸

Furthermore, our understanding of the mechanisms of axon growth has generated much progress in understanding regenerative failure. For example, understanding that the regulation of both repulsion and collapse of growth cones by inhibitory molecules rely on the same intracellular signaling pathways suggests that manipulating these common regulators can increase regeneration. Thus, blocking the growth cone collapsing activity of the small GTPase rho increases RGC regeneration in the inhibitory environment of the optic nerve in vivo.⁴⁵⁹ Such manipulations may be

combined with cAMP elevation and trophic factor delivery to enhance regeneration even further.⁴⁶⁰

Does the loss of intrinsic axon growth ability by RGCs⁴¹⁶ contribute to their failure to regenerate after injury in the adult? As mentioned above, a loss of intrinsic axon growth ability could explain why in many animal models of optic nerve injury, regeneration proceeds remarkably slowly, even when glial inhibitory cues have been removed. For example, most RGCs take 2–3 months to regenerate through peripheral nerve grafts to the superior colliculus.^{413,414} This is far slower than the 10 days they would take if they elongated their axons at an embryonic growth rate of 10 mm/day. It is not clear whether this developmental switch will be reversible, either: soluble signals from optic nerve glia or peripheral nerve glia, or from retinal or superior collicular cells were not able to reverse the loss of rapid axon growth ability in RGCs in vitro, suggesting that the developmental switch may normally be permanent.⁴¹⁶ There remains the possibility, however, that other signals, or the discovery and manipulation of genes involved in this transition, may revert the postnatal neurons to their embryonic axon growth ability, and that this may be critical to increase regeneration in the CNS. Thus a combinatorial approach may be required – both the intrinsic neuronal growth state and the extrinsic environment may have to be optimized for successful regeneration after injury.

"Neuroenhancement" of retinal ganglion cell function

Before RGCs have died, and even before their axons are fully damaged in the optic nerve and would require a pro-regenerative therapy, RGCs may be partially inhibited in the optic nerve from their full functional capacity. For example, glaucoma causes dysfunction and then death of RGCs, but the window between dysfunction and death in humans is not currently known. Acute studies of IOP raising and lowering in humans, and chronic studies of IOP raising and lowering in animal models, both suggest that a window between dysfunction and death exists in this degenerative disease.^{326–328} Thus, factors known to enhance RGC health and, ultimately, survival, could be applied to intervene before death and potentially reverse dysfunction, an approach termed "neuroenhancement". These remain major goals for the biomedical community for patients with glaucoma.

Neuroenhancement has been used in the literature either generically to refer to improvement of axon regeneration, or more specifically to improvement of cognitive function in degenerative brain disease.^{461–463} Compared to the many years it would take a glaucoma trial to demonstrate neuroprotection (e.g. one would ideally demonstrate that progression of visual field losses is slowed or halted), it may be possible to measure an enhancement of RGC structure or function acutely. A potential "neuroenhancement" therapy would target RGCs that are dysfunctional and/or atrophic. With the same neurotrophic factors that stimulate neuroprotection in the long term, such dysfunctional RGCs could hypertrophy to their normal size, or resume normal electrical responsiveness or optic nerve transmission of visual information, or both. It is likely that the same neurotrophic factors that stimulate RGC survival, such as GDNF,^{441–443}

BDNF^{444–446} or CNTF⁴⁴⁷ will also stimulate measurable neuroenhancement in these cells.

Conclusions

The optic nerve is the critical conduit from the eye to the brain. The past decade has seen dramatic increases in our fundamental understanding of optic nerve physiology and pathophysiology, particularly at the cellular and molecular levels, but much remains to address the many optic neuropathies that lead to vision loss and blindness. The next decade will likely prove even more exciting, as advances in regenerative medicine begin to transition from the bench to the clinic.

Processing in the Lateral Geniculate Nucleus (LGN)

Vivien Casagrande & Jennifer Ichida

The lateral geniculate nucleus: the gateway to conscious visual perception

Conscious perception requires the visual information that passes through the dorsal lateral geniculate nucleus (LGN) in primates. Although the retina sends axons to many subcortical nuclei, only the pathway from the retina to LGN to cortex is critical to visual awareness.

The LGN is a distinctively layered structure and is located at the posterior lateral margin of the dorsal thalamus (Fig. 29.1). Although there is agreement that the LGN provides the key visual gateway to cortex, there is less agreement over LGN function.^{1,2} The main reason is that receptive field properties of LGN cells are so similar to those of their retinal ganglion cell inputs. Given that visual signals are transformed in other visual areas it is puzzling that a similar transformation can not be identified in the LGN. The most reasonable explanation is that the main role of the LGN is to regulate the flow and strength of visual signals sent to V1. Evidence indicates that this regulation is much more complex than simply opening and closing a single gate. The LGN and visual cortex, working together, form part of a dynamic system designed to rapidly and efficiently process the most useful visual signals for survival. The parallel processing of visual information, elaborate circuitry and many extraretinal inputs, including the massive visual cortical feedback to the LGN, all suggest that visual signals are regulated in a variety of specific and general ways within the LGN.

The purpose of this chapter is to illuminate the structure and function of the LGN by first reviewing LGN anatomy and physiology and then current controversies over signal processing. The field has moved from static descriptions of LGN cell receptive field properties to dynamic descriptions that take into account eye movements, motor planning, arousal level, attention and possibly even more complex information concerning visual memories. In the following two sections, we describe the basic architecture, connections and neurochemistry of the LGN. The next four sections consider the LGN in a functional context beginning with the

basics of signal processing in section four. Then we consider the potential functional impact of attention, motor planning, and binocular rivalry. The final section summarizes key points.

Overview of lateral geniculate anatomy

Layers and maps

The LGN is an elongate layered structure with each layer representing the opposite visual hemifield (Fig. 29.2). Within each layer the opposite hemifield is represented such that the superior and inferior visual fields are located toward the lateral and medial zones of the layer, respectively, and the central (toward the fovea) and peripheral visual fields are located, respectively, at the posterior and anterior zones of each layer. Each layer receives monocular input from the retina and only those layers receiving input from the contralateral eye (nasal retina) represent the entire contralateral visual hemifield since LGN layers receiving input from the ipsilateral eye (temporal retina) cannot represent the monocular portion of the hemifield. This means that the ipsilateral layers are always shorter in all dimensions than the corresponding contralateral layers (Fig. 29.2). The maps in each layer are retinotopically aligned such that each point in visual space is represented along a line perpendicular to the layers. The alignment of the maps is so precise that a cell-free gap, representing the optic disk (see arrows in Figs 29.1B and 29.2), exists in all contralaterally innervated layers in order to maintain retinotopic alignment with the ipsilaterally innervated layers. This is because the optic disk contains no receptors and is located in the nasal retina.

There are three types of cell layers, those with large cells (the magnocellular or M layers), those with medium size cells (the parvocellular or P layers) and those with very small cells (the koniocellular or K layers). All primates have at least two P and two M layers with K layers lying below each M and P layer. In humans and some other primates, each P layer can split into two or more layers in the portion of the

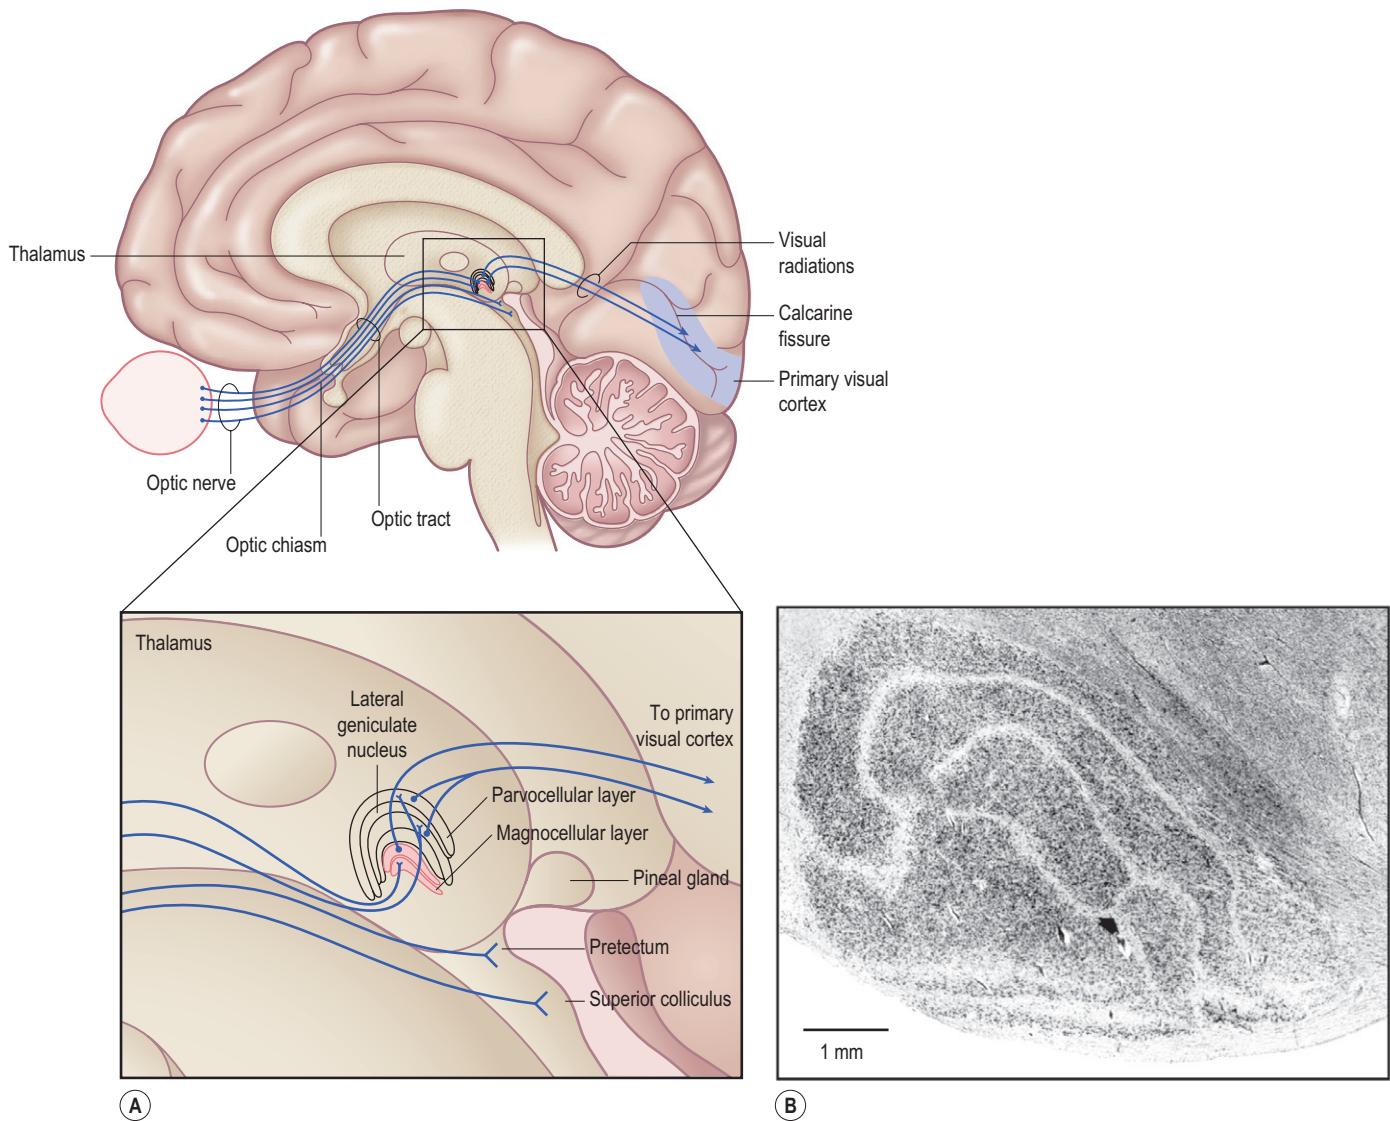

Figure 29.1 (A) Schematic diagram showing the location of the human LGN in relationship to the rest of the brain, with a magnified diagram of the LGN. (Modified from Kandel et al.⁴⁸) (B) Nissl (cell) stained coronal section through the human LGN showing the laminar organization. LGN that represents central vision (~2–17 degrees). The normal human LGN can contain as few as two or as many as six P layers.³

Among primates, the laminar organization and topography of the LGN has been studied in the most detail in the macaque monkey. Malpeli and colleagues^{4,5} performed careful reconstructions of the entire LGN documenting the retinotopic organization and number of M and P cells in each LGN layer (K cells were not counted). These studies have shown that in macaque monkeys the representation of the central visual field is magnified in the LGN (Fig. 29.2 and see Fig. 29.5 below). The magnified representation of the central few degrees in the LGN is easy to understand given that each LGN cell receives input from approximately one to three retinal ganglion cells and ganglion cell density is much higher in central retina.

Only within the portion of the nucleus representing eccentricities from 2 to 17 degrees do the two P layers split to represent four or more P layers, an arrangement which may reflect an increase in the diversity of retinal ganglion cells representing this portion of visual space. Classical textbook sections of the LGN typically are taken from this region of the LGN which shows four P layers and two M layers; as mentioned, we now know that K layers lie below each P and M layer as depicted for the macaque monkey in Figure 29.3.

Cell classes

All LGN cells can be grouped into two principal cell classes, *relay cells* that send an axon to visual cortex and *interneurons* whose axons remain within the LGN. LGN relay cells use

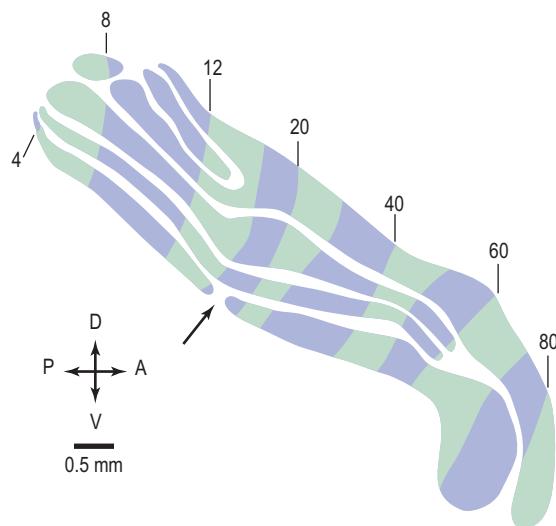

Figure 29.2 A reconstructed parasagittal section through the LGN of a macaque monkey. Light and dark bands represent eccentricity hemizones that have been mapped onto the LGN layers. Numbers refer to the eccentricity at the border between two adjacent eccentric hemizones. The gap in magnocellular layer 1 (M1) represents the optic disk (arrow). The cluster of arrows indicates anatomical orientation (D, dorsal; V, ventral; P, posterior; A, anterior). (Reproduced with permission from Malpeli et al.⁵)

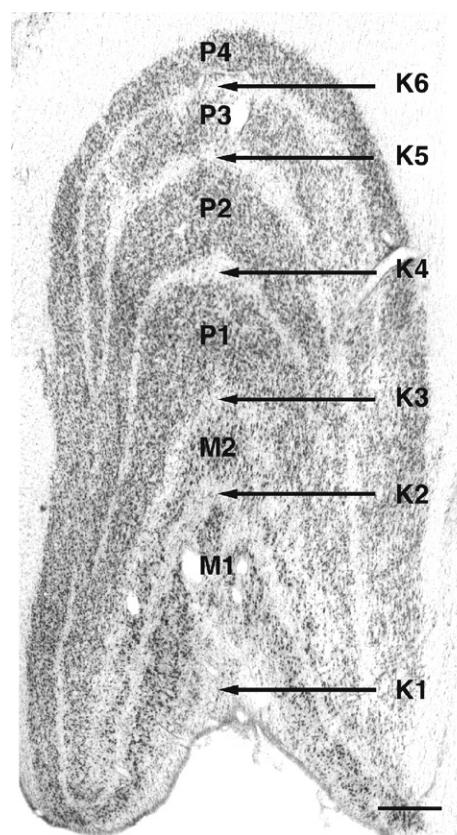

Figure 29.3 A coronal Nissl (cell) stained section through the LGN of a macaque monkey showing the parvocellular (P), magnocellular (M), and koniocellular (K) layers. At this cross-sectional level of the nucleus there are four P layers, two M layers, and six K layers. Scale bar = 500 μ m.

the transmitter glutamic acid (glutamate) and interneurons use the transmitter gamma-amino butyric acid (GABA). Relay cells and interneurons occur in a ratio of approximately 4:1 throughout the LGN and exhibit distinct dendritic morphologies. The LGN contains several classes of interneurons⁶ whose general role is to regulate signals that will ultimately pass to cortex from the retina via relay cells. The M, P, and K cells mentioned previously are all classes of relay cells and, in addition to size, can be distinguished based on dendritic morphology, calcium binding protein content, physiological properties, and axonal projection patterns to cortex.^{1,7–9} P and M LGN cells play a major role in setting up the properties of V1 cells, but it remains controversial as to whether P and M cells belong to just two classes. Evidence from retinal inputs, axon projection patterns and physiology indicate that there are subclasses of P and M cells that perform somewhat different functions in V1¹⁰ (see also below). It is even more likely that K cells are not a single LGN cell class given the diversity of their connections to cortex⁸ (see also below).

Inputs: the retina

Classically it was argued that there were two pathways from the retina to the LGN, the P and the M pathways; all other retinal ganglion cells were presumed to project to other subcortical nuclei.¹¹ Evidence from more recent studies has shown that 10 or more different types of retinal ganglion cells send axons to the LGN based primarily on morphology¹² (Fig. 29.4). This finding complicates the picture because it becomes unclear whether K, M, and P LGN cells, as described above, receive unique inputs from only one class of ganglion cell or more than one class. It is evident from projection patterns of LGN axons in V1 that at least 10 axon classes have been identified that could support the argument that each retinal ganglion cell class has a unique conduit to cortex via a labeled line through the LGN⁸ (see also Fig. 29.6 below).

Inputs: extraretinal sources and cortical feedback

In addition to retinal input, LGN cells receive input from a variety of both visual and non-visual extraretinal sources. These extraretinal afferent sources provide a much larger input to the LGN, in terms of synapse number, than does the retina (see review²). These extraretinal inputs also regulate the flow of information in the LGN in a variety of ways given the different transmitters they contain and the number of transmitter receptors that exist on LGN neurons¹³ (Fig. 29.5). Input from extraretinal visual sources maintains retinotopic fidelity, meaning, regions representing a common point in visual space are connected. Extraretinal visual input to the LGN has been documented from the following areas in primates with their transmitter type in parentheses: primary visual cortex (glutamate), some extrastriate areas (likely glutamate), superior colliculus (glutamate), pretectum (GABA), parabigeminal nucleus (acetylcholine or ACh), and the visual sector of the thalamic

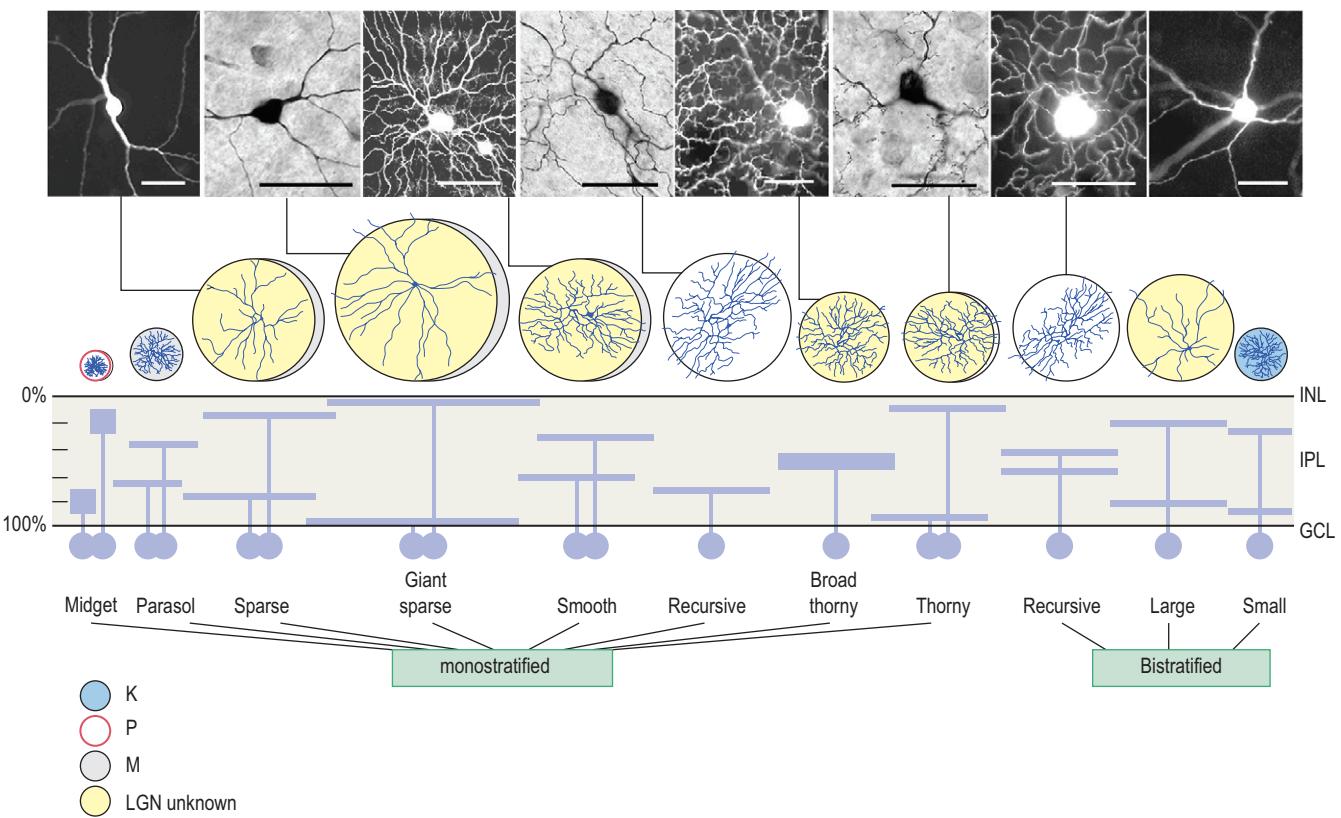

Figure 29.4 Many different types of retinal ganglion cells project to the LGN. Photomicrographs show details of cell morphology (scale bars = 50 μm) and the cell drawings and disks show the relative dendritic field sizes. The midget (red circle) and parasol (gray) cells are known to project to the P and M layers, respectively. The small bistratified cells (blue) are known to project to the K layers. Several other types of retinal ganglion cells (yellow) are also known to project to the LGN, but the layer specificity of their projection is currently unknown. The other cell types shown do not project to the LGN. (Modified from Dacey.¹² © 2004 Massachusetts Institute of Technology, by permission of the MIT Press.)

reticular nucleus (GABA). Of these extraretinal visual sources the two major sources, in terms of synapse number, come from the thalamic reticular nucleus and the primary visual cortex. The input from the thalamic reticular nucleus has been studied in great detail, and together with the primary visual cortex, provide retinotopically localized regulation of LGN signals to cortex. The massive cortical feedback pathway is highly specific in that cells in different subdivisions of layer VI of V1 send axons to either the P or M LGN layers but not both. This feedback also targets the K LGN layers and the thalamic reticular nucleus but only via axon collaterals destined for either the P or M LGN layers at least in owl monkeys.¹⁴

Extraretinal input to the LGN also arrives from several non-visual sources. The most well studied of these afferents are the cholinergic afferents from the pons that innervate all LGN layers and also contain the transmitter nitric oxide at least in the cat.¹⁵ Other afferent sources include a serotonergic input from the dorsal raphe nucleus and a histaminergic input from the hypothalamus.¹⁶⁻¹⁹

Outputs: projections to V1 and beyond

In primates the bulk of the efferent axonal output from the LGN terminates within the primary visual cortex and the visual sector of the thalamic reticular nucleus (TRN). Although not documented in primates, in cats the projection to the equivalent of the visual sector of the TRN comes from collateral branches of LGN relay cell axons not from a separate projection that goes solely to this thalamic nucleus. A smaller efferent projection from the LGN also has been reported to terminate in several extrastriate visual areas. The most well documented of these projections is to the middle temporal area (MT). This projection appears to originate from K LGN cells, based upon double labeling studies using retrograde tracers and immunocytochemistry for calbindin, and arises from K cells that do not send collateral projections to V1.²⁰ Although this projection involves only about 1 percent of LGN cells, it has been implicated in the residual vision referred to as "blindsight" in patients that have lost their primary visual cortex²¹ (Box 29.1).

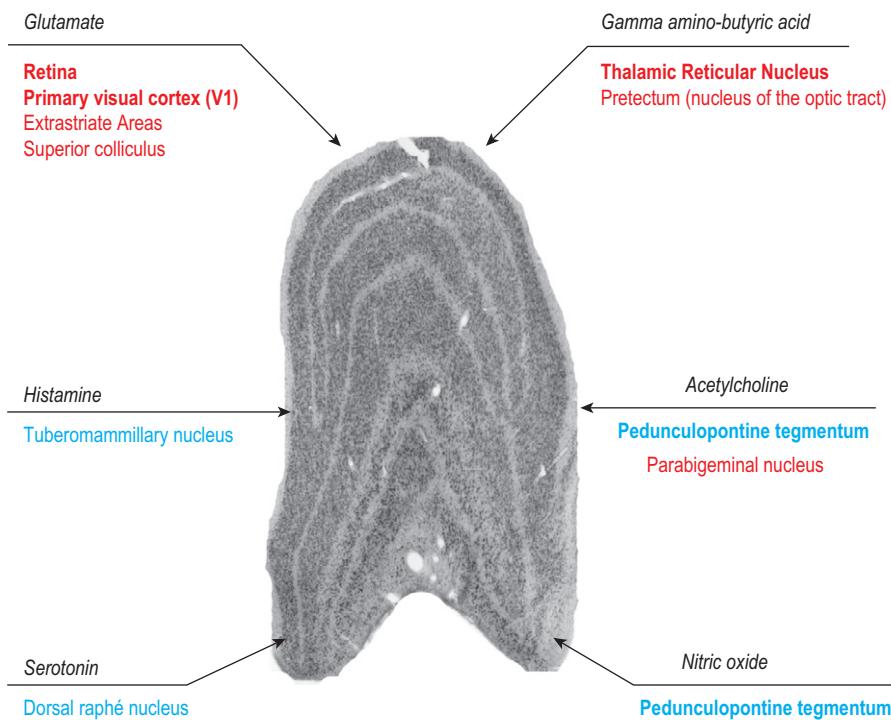

Figure 29.5 Diagram illustrating the brain areas connected directly with the macaque LGN and their chemical messages. Input from visual sources is indicated in red, input from non-visual sources is in blue. Bold text indicates areas that provide the heaviest input to the LGN in terms of synapse number. (Modified from Casagrande et al.³⁸)

In primates, studies have shown that P cells send axons principally to the middle and lower tier of layer IVC of V1 (using the nomenclature of Brodmann²²). In addition, some P cells in macaque monkeys may send axons to IVA. The projection to layer IVA appears to be a specialization of only certain primates since it is absent in chimpanzees and likely also humans. M cells send their efferent axons to the middle and upper tier of layer IVC of primary visual cortex. Finally, K cells send their axons to cortical layers IVA (in macaque monkeys) and IIIB/IIIA where they terminate in patches of cells whose mitochondria contain high amounts of cytochrome oxidase (CO), the “CO blobs” and to layer I (see review²³). Some M and P cells also have sparse projections to layer VI in V1. The pathways to V1 are summarized in Figure 29.6.

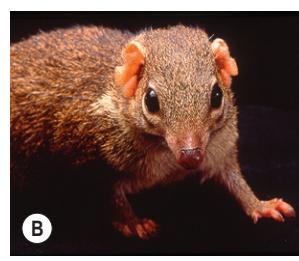

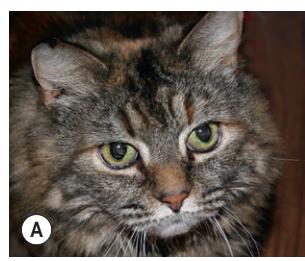

LGN circuits: How are visual signals regulated?

Feedback and feedforward pathways

Visual signals within the LGN are regulated by circuits involving two groups of inhibitory neurons, local inhibitory neurons and TRN inhibitory neurons. These inhibitory neurons are connected in feedforward and feedback circuits to LGN relay cells involving, respectively, retinal input to local inhibitory cells and relay cell input to TRN neurons as shown schematically in Figure 29.7A. The feedforward pathway involves a unique synaptic arrangement referred to as a triad in which a retinal terminal synapses upon a relay cell dendrite and the dendrite of an inhibitory interneuron

Box 29.1 The “blindsight” controversy

Cats (A; courtesy of Julie Mavity-Hudson) show only a slight loss in visual acuity following bilateral removal of primary visual cortex⁴⁹ and tree shrews (B; courtesy of Robert Strawn) (the closest living relatives of primates) show no deficit in acuity following similar lesions.⁵⁰ In both of these species it has been argued that vision is preserved via alternative subcortical routes to extrastriate cortex. Humans, however, appear to be completely blind following similar damage to V1. Nevertheless, it has been argued by some investigators that residual vision within the “blind” field (so called “blindsight”) exists even in patients with damage or complete loss of V1. Controversy persists, however, over whether such vision simply reflects small remaining pieces of V1 that are functional or is really the result of a separate functional pathway to extrastriate cortex as has been demonstrated in cats and tree shrews. Even among those who believe that a functional retinal route exists in humans and other primates that bypasses V1 there is debate as to whether this route passes through the LGN via direct projections from koniocellular (K) cells to extrastriate cortex²¹ or involves a pathway from the retina to the superior colliculus to the pulvinar to extrastriate cortex as has been demonstrated in tree shrews.⁵¹

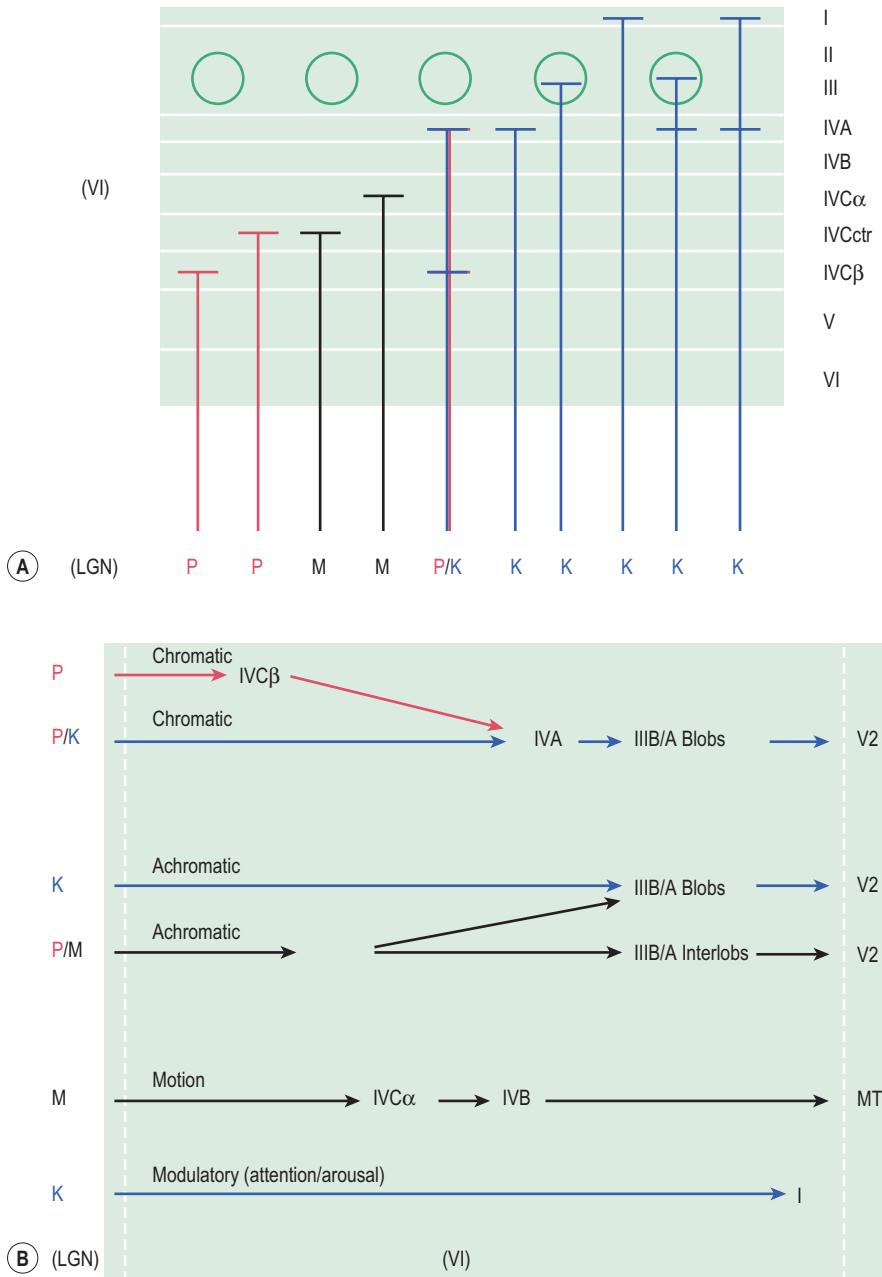

Figure 29.6 **(A)** Simplified schematic diagram of the efferent projections of LGN cells. Parvocellular (P, red), magnocellular (M, black), and koniocellular (K, blue) LGN cells have different projections to primary visual cortex (V1). P cells mainly terminate in lower and central layer IVC with some projections to layer IVB. M cells have the bulk of their terminations in upper and central layer IVC. K cells in the cytochrome oxidase blobs in layer III, layer IVA and layer I. K cell projections to layer I and the blobs in layer III usually arise from populations of K cells that lie in different LGN layers. (Modified from Casagrande & Xu.²³) **(B)** Connections and possible functions of the eight parallel pathways within V1. In this diagram the ventral to dorsal sequence of layers in V1 is laid out from left to right. V1 projects directly to different compartments within the secondary visual area (V2) and to the middle temporal visual area (MT). Not shown: V1 also sends axons to the dorsal medial visual area (DM) also called V3a which exit from CO blob columns, to the third area (V3), and very sparsely to the fourth visual area (V4). See text for details.

(Fig. 29.7B). The dendrite of the inhibitory interneuron, in turn, makes a dendro-dendritic synapse on the same relay cell dendrite. In contrast, in feedback inhibition the relay cell synapses on the dendrite of a TRN neuron that then sends an inhibitory connection back to terminate on the dendrite of the same relay cell (Fig. 29.7A). Given that feedforward and feedback circuits can influence how retinal input is modulated, further documentation of ultrastructural differences in the circuits within the different layers of the primate LGN will become critical to the development of accurate physiological models.

Circuit neurochemistry

Although the feedback and feedforward circuits to LGN relay cells form the basic architecture for controlling visual signals, the final information that is sent on to the visual cortex is dependent in complex ways on all of the inputs that can impinge upon this circuitry and the variety of transmitter receptors that are activated by these inputs. Given space limitations we can only give a few examples here. Many of the same inputs that contact LGN relay cells are known to also contact inhibitory interneurons within

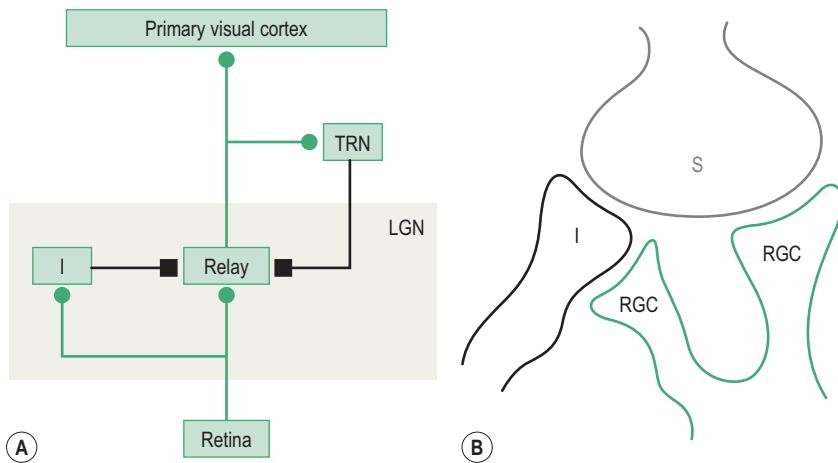

Figure 29.7 Simplified diagram of visual thalamic circuitry. **(A)** Diagram of feedforward and feedback inhibitory pathways that influence LGN relay cells. Excitatory inputs are indicated in green. Inhibitory inputs are indicated in black. TRN: thalamic reticular nucleus; LGN: lateral geniculate nucleus; I: LGN interneuron. (Modified from Casagrande & Xu²³ with permission of publisher.) **(B)** Schematic diagram showing the spine triad circuit within the LGN. Within a triad, a retinal afferent (RGC) synapses on a relay cell dendrite (S) and an interneuron dendrite (I), which, in turn, synapses onto the same relay cell dendrite.

the LGN or within the TRN although the transmitter receptors in some cases differ. The visual cortex is known to provide the most massive extraretinal input to the LGN. This glutamatergic input arriving from cells in layer VI of cortex activates both ionotropic and a specific class (group 1) of metabotropic glutamate receptors, both of which can directly depolarize relay cells although (importantly) with very different time courses and potentially different effects on the firing pattern of LGN relay cells²⁴ (see also²). Since cortical axons also synapse with inhibitory interneurons and TRN neurons that themselves have both types of receptors, the net output from the relay cell can not easily be predicted even from a simple circuit involving feedback from visual cortex.

A second major input to the LGN comes from cholinergic neurons in the pons (the parabrachial region in the cat). These cholinergic fibers innervating the interneurons and relay cells of the LGN and the TRN also are capable of releasing a second transmitter, nitric oxide. The impact of this input on the output of visual signals to cortex is complicated by the fact that ACh can activate both fast ionotropic nicotinic receptors and slower metabotropic M1 receptors on relay cells; both result in relay cell depolarization. These same ACh-containing pontine axons activate M2 receptors on interneurons and TRN cells resulting in hyperpolarization of these cells. The net impact of this ACh input on LGN relay cells, therefore, is generally excitatory since relay cells are directly depolarized and feedback and feedforward inhibition blocked. Under this condition one would predict an increased transfer ratio of retinal signals to cortex. In contrast, activation of the inhibitory circuitry would lower the transfer ratio and, under some circumstances, could change the temporal structure of signals arriving from the retina. The cortical and pontine inputs and their receptors in the LGN just described are only two examples that have been worked out for the cat LGN. The number of axonal inputs to the LGN and the variety of effects that each can have depending upon which receptor is activated argues strongly that LGN gating is not equivalent to simply opening or closing a connection between the retina to the cortex.

Signal processing in the LGN

Receptive field properties and parallel processing

With some exceptions the receptive field properties of LGN cells are inherited from retinal ganglion cells even though the synaptic inputs from other sources outnumber those of retinal axons within the LGN. It has been argued that retinal axons, therefore, are "drivers" for LGN cells and the other inputs are "modulators" based upon the impact that each source has on LGN relay cell output. The impact of retinal axons is mirrored in their anatomy given that these axons terminate closer than other excitatory inputs to the axon hillock of relay cells, have much larger terminals, and signal through fast ionotropic glutamate channels located at these synaptic sites on LGN relay cell dendrites.²⁵

As in the retina, the majority of primate LGN cells have receptive fields defined as ON or OFF center with opposing surrounds. Some K LGN relay cells, however, appear to have non-standard visual receptive fields that have been difficult to characterize. Included in this category are cells with large diffuse fields, cells with no clear surround, and cells with more complex properties such as direction selectivity. Since some non-standard cells have also been identified in the primate retina, these unusual LGN cells also may reflect their retinal inputs (see reviews^{12,26}).

When the input from the retina is measured within an LGN relay cell in the form of synaptic or S-potentials and these S-potentials are compared to the output of that same cell recorded as action potentials, the *ratio* of S potentials that result in action potentials (the *transfer ratio*) is less than 1.0, typically around 0.3–0.5 in an anesthetized preparation²⁷. This would seem, ostensibly, to be a wasteful loss of important visual information. Kaplan et al²⁷ however, argued that such a decrease in the transfer ratio of signals between retina and LGN is non-linear and is largest when higher stimulus contrasts are used. They argue that this non-linear transfer of signals from retina to LGN serves, in part, to protect the cortex from response saturation under

conditions of high stimulus contrast and thus preserves the dynamic range of cortical cells. Others have argued that relevant visual signals, such as information about stimulus contrast, also may be enhanced at the level of the LGN. For example, Hubel & Wiesel²⁸ suggested that LGN cells recorded in the cat exhibit a stronger surround mechanism than their retinal inputs and concluded from these data that the role of the LGN was to sharpen contrast differences and reduce responses to diffuse illumination (see also²⁹). Although other interpretations of Hubel & Wiesel's original data exist,¹ it is evident that the LGN can act as both a spatial and temporal filter for the visual signals that it receives from the retina. We will have more to say about these filtering mechanisms below, but in order to appreciate how the LGN can filter or gate retinal signals, it is first necessary to describe more about the basic LGN signaling properties.

Physiology of M, P, and K cells

Numerous studies have investigated the detailed physiology of LGN P and M cells in different primate species (see reviews^{1,2}). Typically, studies of M, P, or K cells have assumed that information is coded in the rate of production of action potentials over some period of time in relationship to the stimulus. There also is evidence that information is contained in the pattern of action potentials. For example, in sleeping cats, cells within the LGN can exhibit a regular bursting pattern of action potentials. Bursting has been observed in awake monkeys, but whether it is capable of transmitting information in awake animals has been the subject of some debate.³⁰ Sherman and his colleagues have argued that bursting performs a non-linear amplification of the visual signal, sacrificing signal discrimination for signal detectability in the awake animal (see review²). According to this hypothesis bursting is more efficient at alerting an animal to novel stimuli while tonic firing is more efficient for transferring information about stimulus quality. Thus far, this hypothesis has not been confirmed.³⁰

In general, using firing rate as a criterion, P LGN cells can be distinguished from other cell classes, as a group, by their sensitivity to higher spatial and lower temporal frequencies measured using high contrast gratings to stimulate their receptive field centers. M cells, as a group, have the highest temporal frequency sensitivity and have the lowest thresholds for contrast measured in their receptive field centers at their preferred spatial and temporal frequency. M cells excel at temporal resolution, in part, because they signal the entrance or withdrawal of a stimulus in their receptive fields whereas P cells give a sustained response to the presence of a stimulus. Many K cells fall between the two other classes in terms of spatial and temporal resolution suggesting that the visual resolution of the whole system may reflect a combined contribution of all of these cell classes under some conditions. In terms of wavelength selectivity, there is evidence that both P and K cells contribute in some diurnal primates. In primates that have trichromatic vision, such as humans and macaque monkeys, there is evidence that many P cells transmit information about red and green in the same manner as their ganglion cell inputs. Similarly, some LGN K cells transmit information about blue/yellow based on their retinal inputs. Since the majority of primates are actually dichromats (meaning that they only

have two cones), however, indicates that the P pathway is color blind in most primates. This is because primates with two cone types always have one S cone and one other longer wavelength cone for chromatic comparison. If S cone information is transmitted exclusively by K cells, as most investigators believe, and not P cells, then this condition renders P cells color blind since P cells would only get input from a single cone.³¹ Although it has been popular to link the physiological properties of LGN cell classes to complex behaviors such as P = form, M = motion, and K = color there is unlikely to be a direct link between the behavior of single cells and the behavior of the whole organism (Box 29.2).

The influence of the “extra-classical” surround

Although the receptive fields of most primate LGN cells are pictured classically as concentric ON center/OFF surround fields or the reverse, it is known that stimuli presented well beyond the classical receptive fields of LGN cells could influence the behavior of these cells.^{32,33} It is currently accepted that LGN cells do respond to direct stimulation of their extra-classical surrounds and that these surrounds overlap the classical receptive field and extend beyond its borders. This suppressive surround is often referred to as the non-linear surround or suppressive surround, as stimuli of either sign (ON or OFF) reduce the driven responsiveness of neurons.^{34,35} This form of suppression likely plays an important role in adjusting the gain of LGN responses to visual stimuli. Some investigators have suggested that this cryptic surround could contribute to the phenomenon known as visual pop-out where highly salient stimuli, such as a red ball against a field of blue balls, pops out from the background. Studies designed to manipulate the extraclassical surround of LGN cells also indicate that M cells show greater extra-classical surround suppression than P cells and that this suppression likely originates in the retina, as suggested by much earlier studies of the periphery effect.³⁶

The impact of feedback

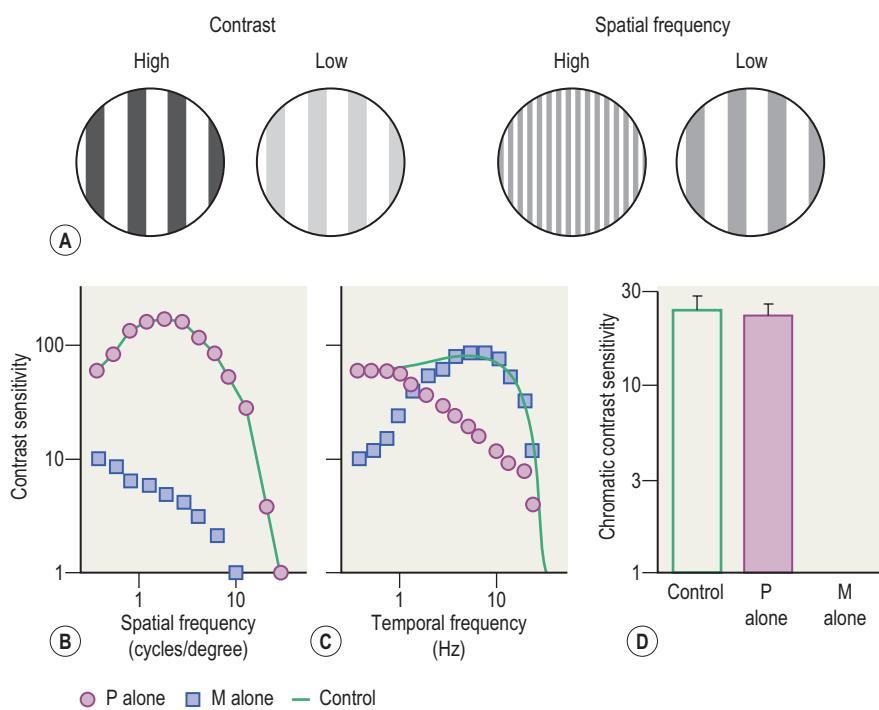

As mentioned above, cortical feedback from V1 to the LGN forms the largest modulatory pathway impacting the responses of LGN cells. Feedback from V1 influences circuits in LGN both directly and indirectly via the TRN. Cells in layer VI of V1 send axons to both the TRN and LGN (as described above) and extend their axons to a larger area of the LGN since V1 receptive fields view a larger area of visual space. Additionally, V1 cells get feedback of their own from higher visual cortical areas such as the area MT. Given that feedback pathways in cortex are quite fast this means that slower messages arriving from the LGN will intersect continually with feedback messages. This dynamic interplay means that every message from the retina can be modified in the LGN based on information received from higher-order visual areas. Such a system can be highly efficient because messages of key interest can be allotted a higher transfer ratio than messages of lower relevance. For example, Sillito and colleagues³⁴ demonstrated that manipulations of the activity in primate area MT can significantly change the activity in the LGN. Sillito and colleagues increased the activity in a localized region of MT by injecting a small amount of a GABA antagonist. Simultaneous to this injection in MT, they recorded from cells in the LGN and found that the increase in activity in

Box 29.2 Linking physiology to behavior: lesions in M and P layers

It has been popular to link the properties of cells in specific visual pathways to complex behaviors. For example, it is common to hear that P cells are for form and red/green color discrimination, K cells are for blue/yellow color discrimination and M cells are for discriminating motion. We know, however, from physiology that the majority of cells in all LGN classes respond to high contrast moving gratings of the correct temporal and spatial frequency. So, of course, they “see” motion and form. We also know that we can discriminate a huge variety of colors. Clearly if retinal ganglion cells were already dedicated to a particular complex visual behavior the brain would not waste synaptic time sending the information first to the LGN, then to V1, etc.

Direct tests of the contributions of P and M cells to visual behavior have been attempted by examining visual losses after making lesions within either the P layers or the M layers of the LGN in macaque monkeys. The monkeys were then trained to look at a fixation spot with one eye only (the other eye was covered). Stimuli to be discriminated were presented in various locations including the part of the visual field corresponding to the damaged portion of the M or P layers. Each lesion extended into adjacent

layers and therefore included some of the K layers. The behavioral tests demonstrated that monkeys *can discriminate form and motion with either pathway* assuming that the stimuli are high enough contrast and are presented in the spatial and temporal frequency range of the remaining pathway. Therefore, it is incorrect to say that P cells are necessary for form discrimination while M cells are necessary for motion discrimination. Instead, the behavioral tests revealed that after P layer lesions (including the associated K layers 4–6) monkeys lost the ability to discriminate high spatial frequencies (**B**, below) and any forms made up solely of these frequencies and colors, whereas after M and associated K layer lesions the monkeys lost the ability to discriminate high temporal frequencies (and any movements that were very fast) (**C**). The monkeys also suffered a major unpredicted deficit in contrast sensitivity following a loss of P cells (**B**). Taken together, these results suggest that the properties that distinguish cell classes at the retina and LGN provide basic information about contrast, size, wavelength, and speed and that higher level analysis, such as that necessary for the discrimination of complex shapes and the movement of these shapes in space, is performed in cortex.

Visual losses after selective ablation of the M, P, and associated K layers of the LGN in macaque monkeys. Contrast sensitivity for all spatial frequencies is reduced when only the M and K layers 1 through 3 remain intact after lesioning the P layers and the K layers 4 through 6. The solid green line in (**B**) and (**C**) shows sensitivity of the normal monkey; circles show the contribution of

the P pathway (after M lesions), and squares the contribution of the M pathway (after P lesions). (**C**) Contrast sensitivity to a grating with low spatial frequency is reduced at lower temporal frequencies when only P cells remain. (**D**) Color contrast sensitivities are lost when only the M cells remain. (Reproduced with permission from Kandel et al.⁴⁸)

MT can both increase and decrease responses of LGN cells. This example shows that the flow of information through the LGN can be modulated by high-level cortical feedback.

The LGN and arousal, attention and conscious vision

Given the diversity of non-retinal LGN connections and the diversity of connections that each of these input sources has with the rest of the brain, it stands to reason that LGN cells must be modulated by many different sensory, motor, and cognitive messages. Closer inspection of the types of circuits that impact the LGN suggests that signals leaving this nucleus are mainly influenced by four types of information. The most well-accepted impact of these non-retinal sources on the LGN concerns changes with the state of an animal. Numerous investigations, beginning more than 50 years ago, have shown that LGN cells change their firing patterns depending on whether animals are awake or asleep. During sleep LGN cells exhibit burst firing which has been interpreted as a disconnection between the thalamus and cortex.³⁷ During the waking state the LGN is dominated by tonic firing which modulates in relationship to visual stimulation. Whether the infrequent bursting of LGN cells during wakefulness conveys special visual meaning (perhaps alerting animals to something unusual) remains a subject of debate² (see above and also³⁰). Regardless, there is little doubt that the LGN changes its message to cortex depending on the level of arousal.

The second source of information that likely impacts the LGN is visual attention. The influence of attention on the LGN, however, is controversial for two reasons:

- (1) there exists an historic bias against the idea that sensory thalamic relay nuclei should do more than stably relay their messages in a feedforward manner to cortex and
- (2) there has been difficulty demonstrating an impact of attention on individual LGN cells (see review³⁸).

Demonstrating the impact of attention in LGN poses a problem mainly because the classical receptive fields of individual LGN cells in primates are quite small. Additionally, recording from single LGN cells in awake, behaving monkeys is challenging since monkeys cannot hold their eyes completely stationary. This means that stimuli must be presented over areas larger than an individual LGN cell's receptive field center in order to avoid artifactual stimulation of the edges of a receptive field during experiments. The result is that LGN cells respond poorly because the inhibitory surrounds of their receptive fields are being stimulated at the same time as their excitatory centers are being stimulated. In extrastriate cortex (see Chapter 31) receptive fields are quite large and, as a result, it has been much easier to demonstrate that changes in visual attention impact the responses of individual cells because stimulation can be confined to individual receptive fields. The other issue is that many LGN cells drive one V1 cell so that effects of attention on any one individual LGN cell could be minute but add up to a large impact when one considers the number of LGN cells that synapse with any one V1 cell. Therefore, it is not surprising that one of the first demonstrations of the impact of visual attention on the LGN used functional imaging (fMRI) in

human subjects and compared activation patterns seen in each LGN when subjects were asked to shift spatial attention to different locations.

Looking at measures of neural activity at the population level with fMRI, O'Connor et al,³⁹ using flickering checkerboard stimuli of high and low contrast, showed that responses in LGN were reduced to unattended stimuli and enhanced to attended stimuli and that the shift between the baseline activation of the left and right LGN could be seen in anticipation of where the stimulus would come on even without retinal input. Surprisingly, O'Connor et al³⁹ also showed that the changes in activation relative to attention were stronger in LGN than in primary visual cortex (V1). This result is surprising because one might predict that the attentional shifts in LGN are a result of feedback from V1. Alternatively, it may be that both arousal and more specific spatial attentional effects are conveyed to the LGN through direct or indirect pathways involving either the large cholinergic pathway from the pons (pedunculopontine tegmental nucleus, PPT) or the GABAergic pathway from the thalamic reticular nucleus (TRN) or both. The latter pathway is of particular interest given the original proposal by Crick⁴⁰ that the TRN acts as an "attentional searchlight". In support of this proposal, McAlonan et al⁴¹ showed that increases in visual attention in monkeys reduced the responses of individual visual TRN neurons (whose main output is to the LGN). In the LGN both McAlonan et al⁴¹ and Royal et al⁴² were able to show, recording from single P and M LGN neurons in monkeys, that attention modulates their responses rapidly at latencies that occur before signals can reach cortex (Fig. 29.8).

The LGN and motor planning

The third modulatory input to LGN responses comes from eye movements. Visual signals from the retina can only be processed usefully in the context of action. In other words, as human beings we use vision to interact with the world so our visual world is in constant motion. To maintain stability we need to know where our head, eyes, limbs, etc. are in relationship to the objects around us. It is known that auditory and visual maps in the superior colliculus of the mid-brain are converted to common motor maps so that congruence between head-centered auditory space and eye-centered visual space exists in motor output neurons from this structure.⁴³ The question is, do LGN cells modulate their activity in relationship to motor activity? Again, because of technical challenges it has been difficult to test this idea. General support for the idea that LGN cells modulate in relationship to motor commands comes from studies of saccadic suppression. The brain suppresses signals related to our eye movements presumably to remove potential retinal blur and allow efficient processing between fixations.

There is now good evidence that such suppression occurs at the level of the LGN (see reviews^{38,44}). Recording from single LGN cells in awake, behaving monkeys Royal et al⁴⁴ were able to show that all LGN cell classes (K, M, and P) modulate their activity in relationship to saccadic eye movements. What was especially interesting in the latter study was that LGN cells modulated their activity in complete darkness in anticipation of the pending eye movements. Activity in

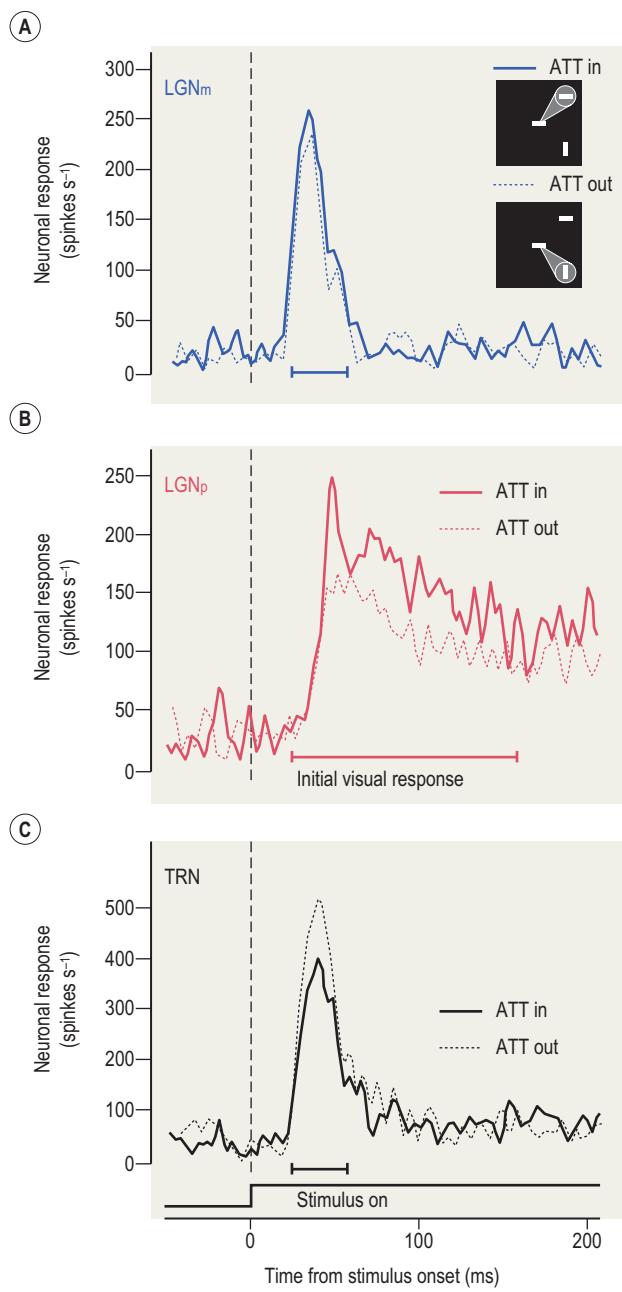

Figure 29.8 Attentional modulation of cells in the LGN. Spike density plots of a cell's response to an attended stimulus (ATTin, solid traces) and an unattended stimulus (ATTout, dashed traces). The inset illustrates the "spotlight" of attention that is directed to the circle representing the receptive field. Responses are aligned to stimulus onset (the dashed vertical line). **(A)** Responses of sample magnocellular LGN cell (LGNm). **(B)** Responses of sample parvocellular LGN cell (LGNp). **(C)** Responses of sample TRN cell. (Reproduced with permission from McAlonan et al.⁴¹ Reproduced by kind permission of Springer Science + Business Media.)

LGN cells were suppressed as much as 100 ms prior to a "motor plan" to move the eyes to a new location. Once the eyes landed at their new location, activity significantly increased (Fig. 29.9). This pattern of changes in LGN activity could account for the perceptual phenomenon of saccadic suppression and help facilitate efficient transmission of relevant signals during fixation. It is noteworthy that many investigators have argued that attention and planning

saccadic eye movements are intimately related. Perhaps the cholinergic PPT-LGN pathway conveys information about both shifts in attention and the anticipated saccadic eye movements that accompany these attentional shifts.³⁸

The LGN and binocular rivalry and visual awareness

The fourth source of information that can modulate LGN activity is interocular. Although LGN cells are activated only by one eye, in the 1970s Sanderson et al³³ showed that cat LGN cell responses can be suppressed by stimulation of the other eye. These results were subsequently replicated in primate LGN. A number of investigators have argued that binocular interactions in the LGN might account for binocular rivalry. When two stimuli are presented that cannot be fused into a coherent picture by the two eyes (say a face presented to one eye and a house presented to the other eye), rivalry is induced such that one sees first the face and then the house and so forth, alternately. This means that we are only "aware" or conscious of one image at a time. Is the LGN modulated by such changes in awareness? Recently, at least two groups have demonstrated positive results using functional imaging with fMRI.^{45,46} These groups clearly showed that signals in both LGNs and V1 fluctuated while subjects viewed rivalrous stimuli. These results argue that the LGN is perceptually "aware" or conscious. Where do these signals come from? There is anatomical evidence that they could exist within the circuitry of the LGN itself⁴⁷ or arrive via feedback connections from V1, either directly or indirectly via the TRN. Since fMRI signals have poor temporal resolution it will take further study with single electrodes to dissect these pathways in more detail.

Conclusions

The primate LGN relays all retinal signals necessary for conscious visual perception to cortex. Each LGN cell receives monocular input from only a few ganglion cells of a given class. Since the LGN receives input from as many as 10 different morphological classes of ganglion cells, however, it follows that multiple relay cell classes exist in each morphologically defined layer. K LGN cells are the most diverse relay cell class based on morphology and physiology. Some K cells transmit yellow/blue chromatic signals but the function of the majority of K LGN cells remains unknown. M cells likely transmit signals important to low resolution form and motion, while P cells transmit detail and some P cells transmit red/green chromatic information. The LGN also contains several classes of interneurons that regulate the flow of information from the retina through feedforward and feedback inhibitory circuitry. In addition to the retina, the LGN receives input from a variety of other sources including a major feedback projection from V1. These inputs dynamically regulate the signals that the LGN receives from the retina, depending on planned action, eye movements, and attention. Thus, visual signals arriving from the retina immediately become part of a dynamic circuit in the LGN that is designed to process that information for the most efficient use.

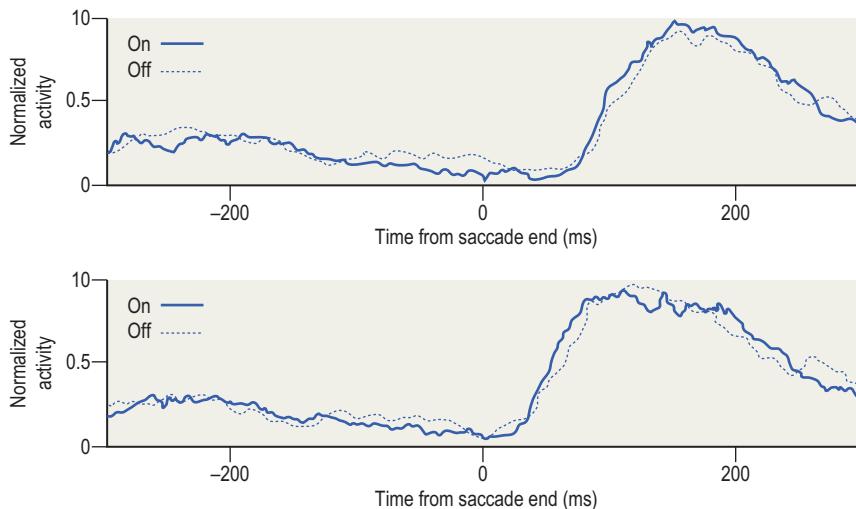

Figure 29.9 LGN cell activity during saccades. Activity of LGN ON-center and OFF-center cells that demonstrate significant perisaccadic modulations during spontaneous saccades. **(A)** Spike density functions for 25 LGN cells (10 ON-center, 15 OFF-center; 5M, 19P, 1K) that demonstrated significant saccadic suppression and postsaccadic facilitation during spontaneous saccades. Trials are aligned on saccade start (0 ms). **(B)** Spike density functions for the same 25 LGN cells with trials aligned on saccade end (0 ms) to demonstrate the time course of the postsaccadic facilitation. Spike density functions were normalized to the highest peak-firing rate observed in the two curves. Processing in the Primary Visual Cortex

Vivien Casagrande & Roan Marion

Overview: The primary visual cortex constructs local image features

The visual system provides a description of the location and identification of objects that have survival value to the species. This description must be made in a dynamic world in which our gaze is constantly shifting and in which objects move. To be useful, the description must select items of importance depending on context and memory; in essence the visual system is designed to make useful predictions about visual reality, not to actually represent reality. Implicit in the architecture of the visual system reside mechanisms tuned by evolution and development to optimize useful vision. Beginning in the retina, the visual system selects what is needed to accomplish this goal. The retina contributes to this selection process by eliminating information about absolute light intensity, emphasizing local image contours, and compressing the visual signal information into a manageable size during a manageable time window to be transmitted to the lateral geniculate nucleus (LGN, see Chapter 29). The LGN contributes by regulating the flow of visual signals. Primary visual cortex (V1), as we will learn, contributes by coding aspects of local image features including their size, orientation, local direction of movement, and binocular disparity. All of these local descriptions of stimulus quality are critical for the more global and complex identification of objects ("what") and spatial relations ("where").

Classically, V1 is described as an area where information provided by the separate LGN channels is combined in different ways before it is sent to extrastriate visual areas for further processing. In order to do its job, V1 must solve the geometry puzzle of representing all stimulus qualities necessary for the subsequent steps of analyses within tissue that maps the outside world, i.e. responds to different parts of the visual field. V1 accomplishes this goal by a division of labor between different layers and different iterated modules within each layer. In this classic view, V1 is pictured as the beginning stage for several sets of serial processes that take place in feedforward hierarchies of visual areas; areas specialized to perform a variety of higher-order tasks. Currently, however, there is growing recognition that V1 does more. V1 does not represent stimulus qualities statically. Via dense

and intricate horizontal and feedback pathways, V1 dynamically interacts with higher visual and non-visual areas, as well as the thalamus, and alters its activity and message depending on attention, memory, context, and reward. Therefore, for efficiency, V1 cells bias their messages to emphasize moment to moment relevance. In this chapter we initially provide the reader with a road map to the organization of V1, we show how the anatomical architecture of the V1 sets limits on how visual signals can be processed, and we emphasize the laminar architecture, connections, and cell types. Next we review the traditional view of how receptive field properties are put together in V1 and review the hypothesis that the parallel inputs from the LGN relate in functionally specific ways to output channels of V1 (see also Chapter 31). The second to last section then briefly reviews more controversial ideas concerning the functions of V1, including whether V1 is conscious and participates in memory or is modified by reward and attention. The final section of this chapter summarizes key points.

Overview of cortical organization: a general road map

Human V1 ranges in size from 1400 to 3400 mm², is about 2 mm thick, and is located within the occipital lobe extending from the posterior pole along the medial wall of the hemisphere¹ (Fig. 30.1). Like the rest of the cerebral cortex, V1 contains 6 principal layers. V1 is often called striate cortex in recognition of its original identification by an Italian medical student (Francesco Gennari) more than 200 years ago. Gennari observed that if he sliced into the posterior pole of an unfixed human brain and observed the cortical layers of the slice a striking white stripe was visible, known today as the *stria of Gennari*. The stria of Gennari actually marks one heavily myelinated layer in the middle of the gray matter of V1. V1 also is referred to by several other names including, most commonly, area 17 of Brodmann² or primary visual cortex. For convenience we will use the term V1 in this chapter.

Damage to V1 results in a hole (scotoma) or blind spot in one visual hemifield. The location of damage to V1 can be predicted based upon the topographic map of the

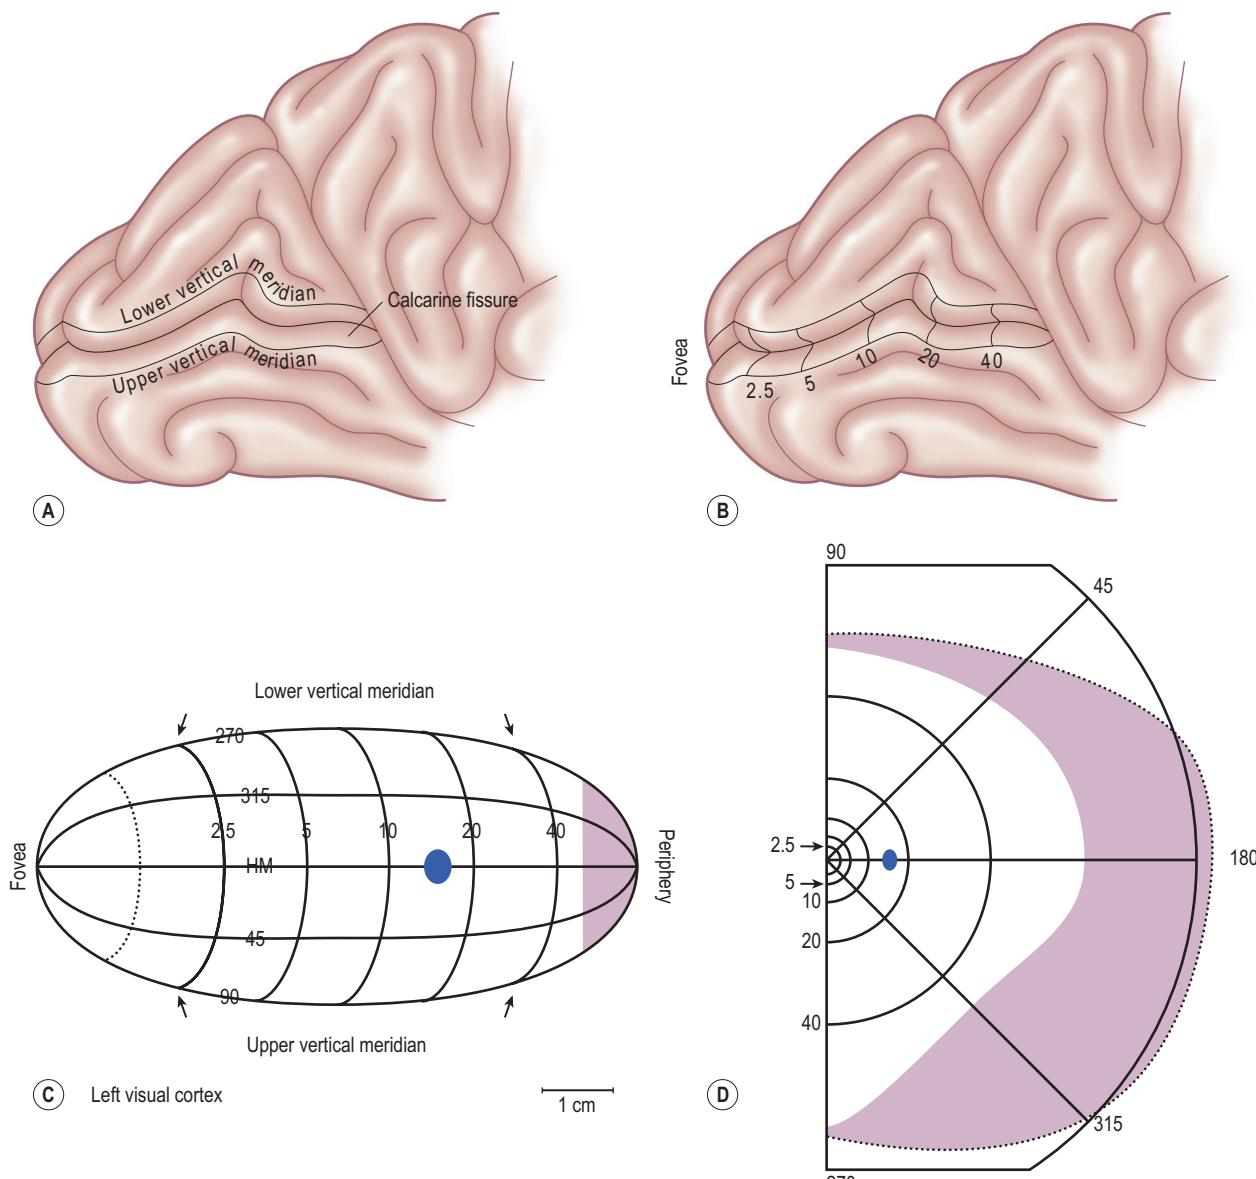

Figure 30.1 (A) Left occipital lobe showing the location of V1 within the calcarine fissure. (B) View of calcarine fissure of V1. The lines indicate the coordinates of the visual field map. The representation of the horizontal meridian runs approximately along the base of the calcarine fissure. The vertical lines mark the iso-eccentricity contours from 2.5° to 40°. V1 wraps around the occipital pole to extend about 1 cm onto the lateral convexity where the fovea is represented. (C) Schematic map showing the projection of the right visual hemifield upon the left visual cortex by transposing the map illustrated in (B) onto a flat surface. The row of dots indicates approximately where V1 folds around the occipital tip. The blue oval marks the region of V1 corresponding to the contralateral eye's blind spot. It is important to note that considerable variation occurs among individuals in the exact dimensions and location of V1. HM = horizontal meridian. (D) Right visual hemifield plotted with a Goldmann perimeter. The purple region corresponds to the monocular temporal crescent which is mapped within the most anterior 8 to 10 percent of V1. (Reproduced from Horton & Hoyt⁶ with permission of the publisher.)

opposite visual hemifield that is known to exist in this region in all mammalian species. In humans, detailed knowledge about the manner in which the visual field is mapped onto V1 has been obtained from a variety of sources including clinical assessments of damage, results of electrical stimulation, and transcranial magnetic stimulation (TMS). The latter is a non-invasive method used to excite neurons by using rapidly changing magnetic fields to produce weak electrical currents.³ Both direct invasive electrical stimulation and non-invasive TMS can give rise to the experience of

localized phosphene (flashes of light) experienced by the subject. Other methods of developing functional maps of V1 have used positron emission tomography (PET) and, most commonly, functional magnetic resonance imaging (fMRI).⁴⁻⁶ In the latter case the subject is presented with topographically restricted stimuli in different locations in space and the relative activation of V1 measured as a change in blood flow. Knowledge about the retinotopic organization of V1 in humans is relevant not only to the clinical evaluation of damage, but also to research efforts designed

Box 30.1 Developing Prosthetic Devices

Given the success of cochlear implants for the deaf, expectations have been high that a prosthetic “eye” could be developed soon. Although great strides have been made, the results so far are not yet optimal. Here we outline progress using V1 as the site for visual prosthetic development. Scientists have known for several decades that electrical stimulation of the visual cortex will cause blind patients to see phosphenes or small spots of light. These spots can appear bright or dim or colored or flickering depending on the level of electrical stimulation. There are a number of problems that need to be overcome to make electrical stimulation of V1 useful as a visual prosthetic device. These include, but are not limited to, the density and location of electrodes implanted in V1, tissue reaction to the electrodes and input devices to translate the visual scene into appropriate patterns of electrical stimulation. The ideal system would have a high density of electrodes activated wirelessly via a light-weight, high-performance camera/computer system appropriate for ambulatory patients.

Thus far, some successes have been achieved using this method by several groups. The most notable successes have been reported by the late Dr. William Dobelle and the Dobelle Institute (Portugal) where a number of patients have been implanted with arrays of electrodes in V1. Although these patients do not experience vision in the normal sense they are able to use the phosphene patterns generated in V1 to identify the outlines of objects and even, in one case (Jens), slowly drive a car around a parking lot.

to develop visual prosthetic devices involving visual cortical electrical stimulation for individuals with incurable retinal diseases or loss of eyes (Box 30.1). All of the methods used to understand the map of the visual field in V1 are in general agreement showing, as illustrated in Figure 30.1, that the fovea is represented in the occipital pole and the far periphery is represented in the anterior margin of the calcarine fissure with the upper and lower visual fields being mapped onto its lower (lingual gyrus) and upper (cuneus gyrus) banks, respectively.⁶ As in the LGN, the visual field map in human cortex is distorted such that the representation of central vision occupies much more tissue than does peripheral vision. Whether the foveal representation in V1 is expanded over what would be predicted simply by assigning each retinal ganglion cell or LGN cell the same amount of cortical tissue has been the subject of considerable debate. One explanation for this controversy is that the proportion of cortex devoted to central vision has been shown to be highly individually variable, at least in macaque monkeys.⁷ The latter finding indicates that the relative amount of tissue devoted to the fovea could be magnified at the cortical level relative to the retina in some individuals but not others.

Layers, connections, and cells of V1: The inputs, outputs, and general wiring

As in other cortical areas, V1 has six main layers that can be identified in a cell stain as shown in Figure 30.2. These layers

contain two main types of cells, pyramidal and stellate, in an 80/20 proportion. The layers and sublayers of V1 have been named in different ways depending on investigator interpretation. The most common laminar scheme is the one adopted by Brodmann.² Although Brodmann likely made a major mistake in his interpretation of V1 layers in all primates⁸ his scheme is the most accepted so we use it here (Fig. 30.2). As in other areas of neocortex, input from the thalamus ends primarily in the middle layers (IVC of V1), with the superficial layers (above IVC) sending information to other cortical areas and the layers below IVC sending signals to subcortical targets (Fig. 30.2).

LGN inputs

Studies done in anesthetized monkeys have demonstrated that activation of V1 neurons depends completely on input from the LGN, because when the LGN is inactivated, visually evoked potentials in V1 are blocked.⁹ LGN axons carrying signals from the left and right eyes and from K, M, and P layers remain segregated at the first synapse in V1 in non-human primates and presumably also humans (Fig. 30.3). The left and right eye segregation of axons from the M and P LGN layers ending in layer IVC of V1 is referred to as *ocular dominance columns*. These “columns” have been directly demonstrated to exist in humans as shown in the complete reconstruction of the pattern of left and right eye input to V1 in Figure 30.4.¹⁰ These zebra-stripe-like patterns of monocular segregation from LGN can be revealed in tangential sections of layer IVC of V1 in humans postmortem following long-standing loss of one eye. As shown in Figure 30.4, the patterns are revealed by a histochemical stain for the mitochondrial enzyme, cytochrome oxidase (CO) which becomes down-regulated in the zones of layer IVC innervated by LGN axons from the missing eye. As mentioned and shown schematically in Figure 30.3, K, M, and P LGN axons in macaque monkeys also terminate in separate V1 layers or sublayers. M and P axons synapse in sublayers of IVC, and K LGN axons synapse in layers IVA, III, and I. Also, K LGN axons are likely made up of several classes since those that end in different V1 layers appear to come from different populations of LGN cells in macaques.¹¹ It is noteworthy, however, that the LGN does not project to layer IVA in apes and humans,¹² reminding us that care must be taken in translating data directly from other primates to humans.

The fact that input from the left and right eyes remains segregated at the first synapse in V1 raises an interesting question concerning the retinotopic map. Recall that in the LGN each layer contains a continuous map of the opposite visual hemifield. This means that in cortex there must be two topographic maps, one for each eye, within the *same* layer, at least at the first synapse from the LGN. This is exactly what was found in layer IV of the macaque monkey using detailed electrophysiological recordings.¹³ Tangential recordings made within layer IVC revealed that the segments of the visual field mapped in one ocular dominance column for one eye were also represented in the adjacent column that received input from the other eye. As we will see below, information from the two eyes and from K, M, and P cells is combined in different ways within other layers of V1, hence, most cells in V1 receive a combination of many extrinsic and intrinsic inputs.

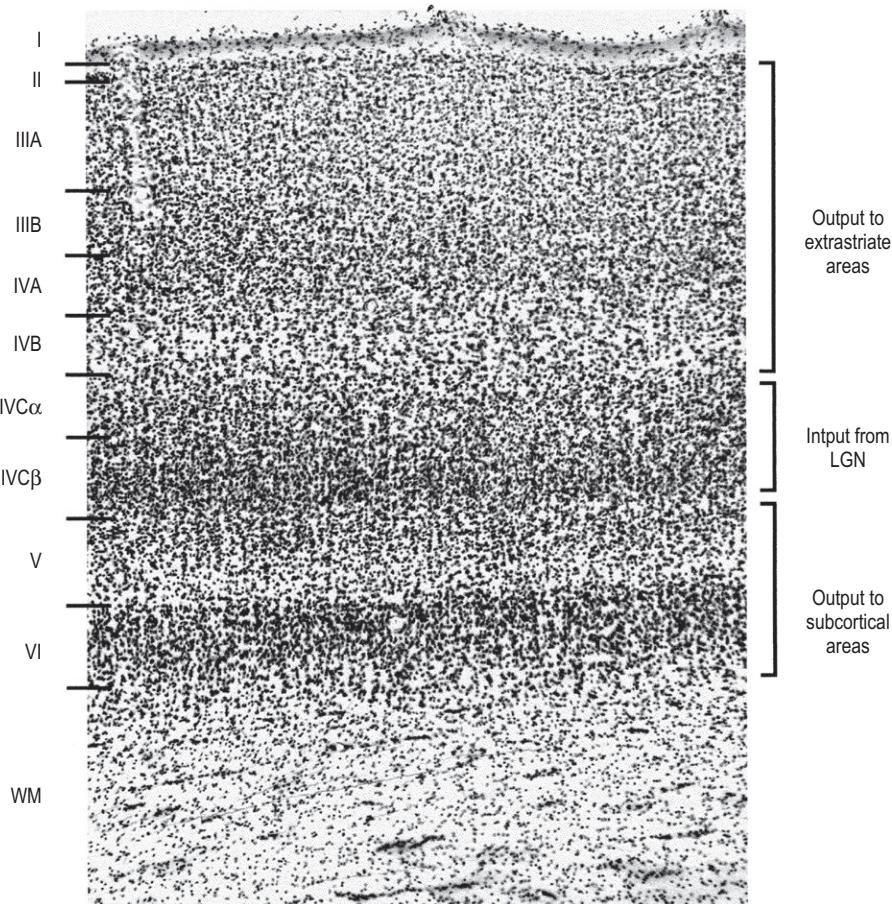

Figure 30.2 Nissl-stained section through macaque monkey V1. As indicated by the brackets, layer IVC receives its main input from the lateral geniculate nucleus. The layers above IVC send projections to other cortical areas, and the layers below IVC send projections to subcortical areas (see text for details). Roman numerals and letters refer to the layers of cortex. WM = white matter.

Other inputs to V1

Besides the LGN, V1 receives a variety of other modulatory inputs both from subcortical and cortical areas. These inputs include serotonergic, noradrenergic, and cholinergic inputs from the brainstem and basal forebrain nuclei, respectively.¹⁴ The latter inputs show differences in density in the V1 layers, but show a much less specific pattern of innervation than do LGN inputs. Other input sources include the intralaminar nuclei of the thalamus and the pulvinar, both of which send broad projections most heavily to layers I and II of V1. Additionally, there are retinotopically more specific sources of input to V1, including from the claustrum and visual (V) areas 2, 3, 4, & 5 (V4 and V5 are also referred to as the dorsal lateral (DL) and middle temporal (MT) visual areas, respectively).^{8,15} As a general rule any area to which V1 projects also sends feedback to V1. However, some higher-order visual areas in the temporal and parietal lobes that do not receive direct projections from V1 send axons to V1.¹⁶ With the exception of the claustrum, whose axons overlap with M and P axons in layer IVC, all of the other extrastriate visual inputs to V1 terminate outside of layer IVC.

So why are there so many other inputs to V1 if the main drive comes from the LGN? As with the LGN described earlier, the numerous non-geniculate inputs to V1 regulate which visual signals will be transmitted to higher-order visual areas. An example of the impact that these non-LGN connections to V1 can have has been demonstrated using fMRI neural imaging methods. Using fMRI in humans, it has

been shown that topographic regions of V1 can be activated simply by asking normal subjects to imagine (with eyes closed) visual objects within particular areas of the visual field (i.e. in the *absence* of any direct stimulus to the retina).¹⁷ Additionally, evidence indicates that, in congenitally blind subjects, major rearrangements of connections can take place such that somatosensory inputs can now activate V1,¹⁸ or changes in receptor distribution at the retina can cause rewiring of V1¹⁸ (Box 30.2). These findings argue that non-LGN inputs can have a strong impact on activity in V1 and that V1 is highly plastic during development.

Cell classes and connections within V1

In V1, cells containing glutamate account for the vast majority (~80 percent) with the remaining cells containing GABA.¹⁹ These two main cell classes are morphologically distinct. There are two types of glutamate-containing cells: the spiny stellate cells that occur mainly in layer IV, and the pyramidal cells that occur in all of the layers. Both of these glutamate-containing neurons have a high density of dendritic spines. In contrast to the pyramidal cells, the inhibitory GABAergic cells have few to no spines on their dendrites. The latter are multipolar neurons whose dendritic arbors come in a variety of shapes. Many subclasses of GABAergic interneurons have been identified based also on physiology and the presence of different types of proteins such as different calcium-binding proteins, or various peptides. Although many models have been proposed to explain the role(s) of

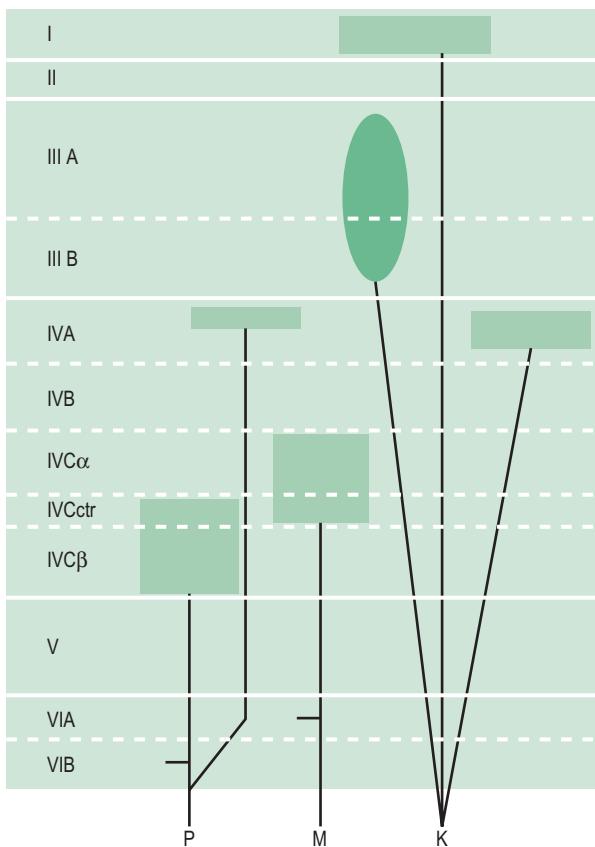

Figure 30.3 A schematic of the main LGN projection patterns to visual cortex in macaque monkeys. M and P LGN cells project, respectively, to layer IVC α and IVC β while K LGN cells project to IVA, the CO blobs in layer III and to layer I. Note, no LGN pathway to IVA exists in apes and humans. Roman numerals refer to V1 layers; P, parvocellular; M, magnocellular; K, koniocellular. (Reproduced from Casagrande & Kass⁸ by kind permission of Springer Science + Business Media.)

different types of inhibitory interneurons in V1 there is no general agreement on function for any class.

Connections between layers can be made by both excitatory and inhibitory neurons (see reviews^{20,21}). Efforts to trace the overall flow of information in V1 have been hampered by the multiplicity of connections and diversity of cell classes. Using pharmacological manipulations it was demonstrated that layer IVC becomes active first, then the upper layers, followed by the lower layers.²² Studies of cell responses in slices of visual cortex in monkeys (where photic uncaging of glutamate has been used to stimulate small groups of neurons) have shown that, although connections can be quite precise, there exists tremendous diversity of responses even among cells thought to have common inputs in the same layer.²³ If one attempts to trace anatomical pathways beyond the main input layer IVC, it also is difficult to decipher how separate output pathways are constructed in V1 due to the tremendous opportunity of intermixing; nevertheless, V1 does appear to give rise to distinct output pathways that emerge from somewhat different populations of input cells (Fig. 30.5).

Most of the connections between V1 cells are local, either within a layer, or within a vertically defined column of cortex approximately 350–500 μm wide. There are, however,

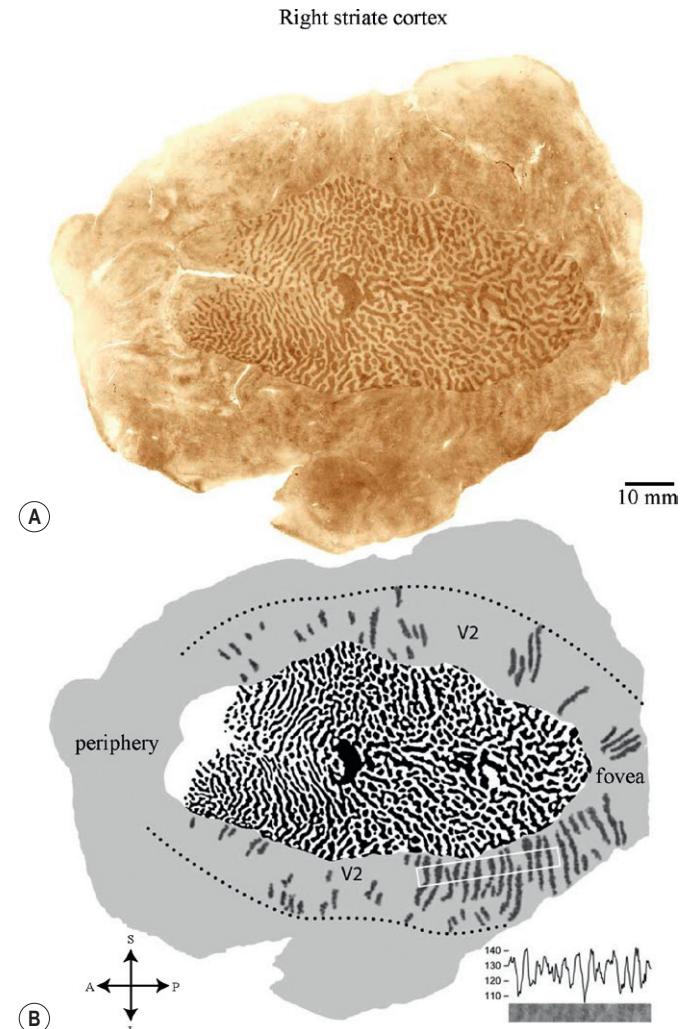

Figure 30.4 The complete pattern of ocular dominance columns in the human brain. (A) The surface area of the flat mount of the right hemisphere is 9413 mm^2 . The V2/V3 border can be identified, based on a subtle change in the pattern of CO activity. Alternating dark and light stripes are visible in some portions of V2. Their density (see inset in B) fluctuated with an average period of 2.3 mm. (B) Thresholded columns. Stripes were drawn where visible in V2; the white box shows where the CO density in (A) was sampled to measure V2 stripe periodicity by counting the number of peaks. Dotted line indicates V2/V3 border. S, Superior; A, anterior; I, inferior; P, posterior. Striate cortex = V1. (Reproduced from Adams et al¹⁰ with permission of the publisher.)

connections of up to 3 mm in macaque monkeys that occur typically between cells with similar properties (e.g. selectivity for the same orientation or ocular preference). These long tangential connections are generally found in layers I, III, and V.²⁴ These long horizontal connections have been implicated in the changes seen in V1 cell responses when areas outside their classical receptive fields are stimulated. We discuss this issue in more detail below (see also Box 30.3).

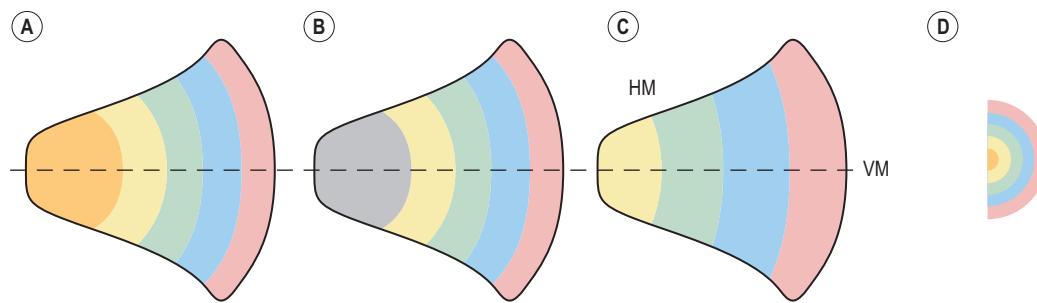

Output pathways from V1

Some cells in all V1 layers except IVC send axons to other brain areas (see reviews^{8,25}). The lower layers V and VI send axons to the thalamus and to the midbrain and pons. Layer VI is unique in that cells in this layer provide direct feedback

Box 30.2 Inherited retinal abnormalities can cause major reorganization of visual cortex

Cones are silent under dim light conditions. Since the normal human fovea is made up exclusively of cones, humans are blind in the area representing the fovea in dim light when only rods are operating. Using functional magnetic resonance imaging (fMRI) Baseler and colleagues (2002) were able to confirm that the area of V1 representing the fovea is inactive in normal humans under these dim light conditions. As the schematic below shows the fovea is represented over a substantial piece of tissue in cortex (several square centimeters). In other words, a large portion of V1 is presumably idle while you look for your seat in a dark theater or take a romantic moonlight walk.

Interestingly, these same investigators, using the fMRI were able to demonstrate a large-scale developmental reorganization in the human rod monochromats. Rod monochromats are congenitally color-blind individuals that almost completely lack retinal cones. In rod monochromats the foveal representation in V1 becomes reorganized so that it now responds strongly to visual stimuli presented under rod viewing conditions. These findings reinforce earlier work in both humans and animals suggesting that V1 is plastic and capable of large-scale reorganization when inputs are abnormal during development.

Schematic of the activation of V1 for normals (**A** and **B**) or for rod monochromats (**C**) under scotopic (**B** and **C**) and photopic (**A**) conditions. (**D**) represents the central 16 degrees of one visual hemi-field as described in the text. There is a mapping between visual space and cortical space, represented here by the correspondence between the colors in the schematic diagram of the right visual field (**D**) and the colors in the schematic diagrams of the left V1 unfolded and flattened (**A**, **B**, and **C**). Under normal

lighting conditions the entire visual cortex of normal viewers is activated (**A**). Under scotopic conditions in normals the foveal representation is inactive represented in gray (**B**). In rod monochromats no fovea exists and the cortex is reorganized to represent the rest of visual space (**C**). In (**A**), (**B**), and (**C**) the vertical meridian (VM) runs along the upper and lower edges of the figure while the horizontal meridian (HM) is represented by the dashed horizontal line.

to the LGN, and indirect inhibitory feedback to the LGN via axon collaterals to the thalamic reticular nucleus (see also Chapter 29). This feedback is precise such that M and P LGN cells receive axons from distinct cell groups in layer VI.²⁶ Cells in layer V provide the major driving input to many cells in the pulvinar nucleus of the thalamus in monkeys; the pulvinar, in turn, provides input to a number of extrastriate areas that also feedback signals to V1. In addition, cells in layer V send a major projection to the superficial layers of the superior colliculus and other midbrain areas such as the pretectum, as well as nuclei in the pons that are concerned with eye movements. Thus, V1 is in a position to inform these structures of its activities.

The superficial cortical layers of V1 provide output connections to a number of extrastriate cortical areas. These connections emerge from different layers or modules within layers suggesting that they carry different messages. Currently there is ongoing debate about how many pathways actually leave V1 and how separate they are in terms of their physiological signatures (Fig. 30.6). Regardless, most

investigators agree that in macaque monkeys the largest output connection is to visual area 2 (V2). Connections to V2 emerge from three or four populations of cells. Cells within the CO-rich blobs of layers IIIA and IIIB send a major output to thin CO-rich bands in V2 (see Chapter 31 for details). Cells located in the CO pale interblobs and cells in layer IVB send output to different locations within the pale and CO thick bands of V2. In addition to these connections there are direct connections from V1 layer IIIB and IVB to visual areas V3, V3A, V4, and V5.^{8,25} As the technology improves, the story of how many V1 to V2 channels exist will continue to be revised.^{25,27,28}

Receptive field properties: How is V1 different from the LGN?

Examination of the receptive field properties of V1 neurons suggests that visual signals are transformed from those seen

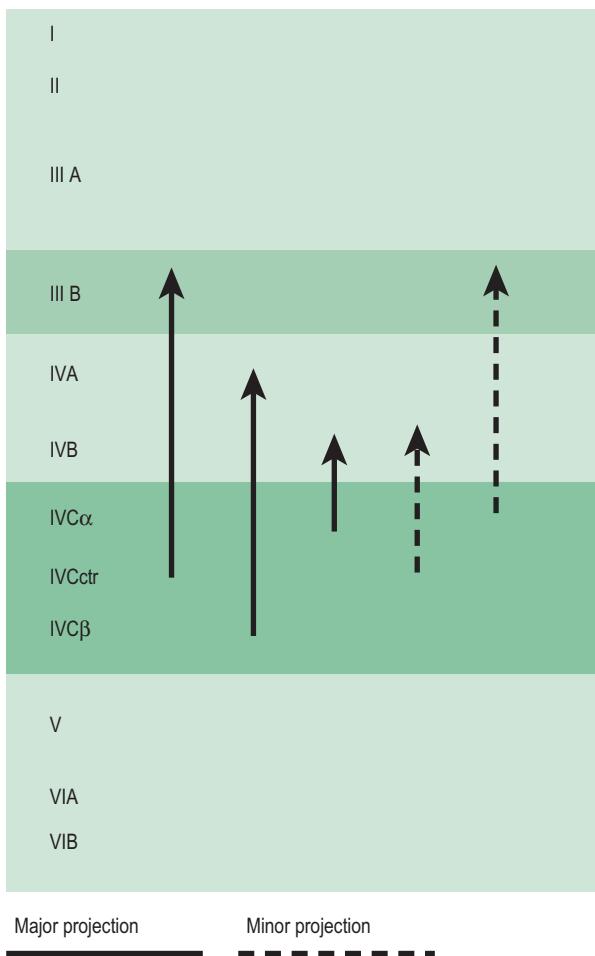

Figure 30.5 Schematic diagram showing the main projections from layer 4 to layer 3 in the owl monkey. IVC α projects primarily to IVB. IVC β projects primarily to IVA. IVC ctr , which receives overlapping input from the M and LGN axons, projects to IIIB where K axons from LGN also terminate. IIIA, the major output layer to visual area V2, receives signals from layer IVB only indirectly via other subdivisions of cortical layers III and layer V. (Modified from Boyd et al⁵⁰ with permission of the publisher.)

in the retina and LGN. In other words, new properties emerge in V1 such as binocularity and sensitivity to stimulus orientation and movement direction. At the same time, V1 cells retain the retinotopic selectivity of their LGN cell inputs, although receptive fields are a bit larger.

In the 1950s and 1960s Hubel & Wiesel^{29,30} began to characterize the properties of V1 receptive fields in cats and monkeys using a variety of patterns including line segments and spots of light displayed on a screen. In these seminal studies they showed that V1 cells could be subdivided based on their responses to such patterns. Hubel & Wiesel³¹ proposed that the cell types in V1 were arranged in serial order of complexity beginning with those that receive input directly from the LGN which they termed **simple cells**. They originally proposed that simple cell responses could best be explained by assuming that the receptive fields of a number of LGN cells were aligned as shown in Figure 30.7.³² Simple cells differ from LGN and retinal ganglion cells, most of which have more or less circular receptive fields. Simple cells have elongated receptive fields with adjacent excitatory and

Please refer to the printed publication.

Figure 30.6 Recent data suggest that there may be four output pathways from V1 to V2 based on anatomy. Each pathway is represented by arrows. One pathway (red) projects from the CO blobs in layer III (indicated by a circle) to the CO thin dark stripes in V2, indicated in blue. A smaller number of cells (orange) from layer IVB in V1 also project to the CO thin stripes in V2. A second pathway (dark green) emanates from cells in the interblobs of layer III and projects to the CO pale medial stripes in V2. The third pathway (light green) projects to the pale lateral stripes of V1 that also receive input from the interblobs in layer III but additionally receive projections (yellow-green) from layer IVB. The fourth pathway (blue) originates from both cells at the edges of blobs in layer III as well as cells in layer IVB that align with the edge of blob cells in layer III. (This description of the pathways from V1 to V2 is taken from the work of Federer et al²⁷ and Angellucci (personal communication 2009) with permission of the authors.)

inhibitory regions. Hubel & Wiesel called these cells simple because it appeared that the responses of these cells to complex shapes could be predicted by linear summation of their responses to individual spots of light. As can be appreciated by examining Figure 30.7, simple cells can give different responses depending upon the spatial arrangement of their inhibitory and excitatory regions. For example, although all the cells shown in Figure 30.7 respond to the same orientation, cells with longer receptive fields such as shown in panel C will respond to a narrower range of orientations than those with shorter receptive fields as shown in panel A. As this figure also illustrates, the receptive fields of simple

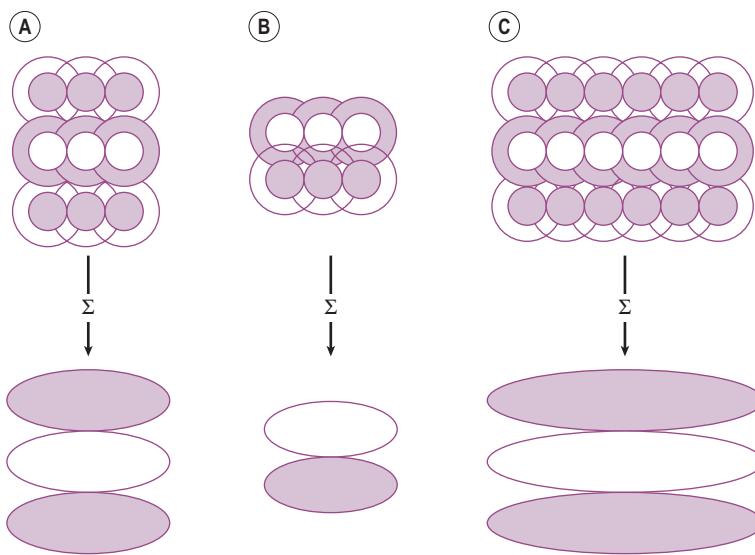

Figure 30.7 Orientation-selective receptive fields can be created by summing the responses of neurons with non-oriented, circularly symmetric receptive fields. The receptive fields of three hypothetical neurons are shown. Each hypothetical receptive field has adjacent excitatory and inhibitory regions. A comparison of (A) and (C) illustrates that the degree of orientation selectivity can vary depending on the number of neurons combined along the main axis. (Reproduced from Wandell³² with permission of the publisher.)

cells require that LGN ON and OFF center cells are aligned, since it is the center responses of these cells that dominate the subfield responses of simple cells within V1.

Hubel & Wiesel also identified other cell classes with more complex response properties. These cells, generally called **complex cells**, are different from simple cells in that their responses to stimuli cannot be predicted based upon linear addition of the cell's response to spots of light presented in different parts of the receptive field; complex cells do not have discrete regions of excitation and inhibition. Instead, complex cells respond to preferred orientations like simple cells but complex cells respond equally well to a preferred stimulus anywhere in their receptive field. A special type of V1 cell referred to as an **end-stopped cell** responds only if the correctly oriented stimulus is of appropriate length. Extending the length of a bar beyond the field into an inhibitory zone of an end-stopped cell diminishes the cell's responses suggesting that these cells may signal more complex shapes. Hubel & Wiesel originally proposed that the receptive fields of each cell class (namely, LGN, simple, complex, and end-stopped cells) built upon the properties of their predecessors in serial order. We know now that such a straightforward model can not account for all of the properties observed, that many complex cells can receive input directly from the LGN, and that end-stopped cells can either be simple or complex cells.

Other receptive field properties that emerge within area V1 are direction selectivity and binocularity. Although in some mammals such as rabbits, **direction selectivity** is a characteristic of many ganglion cells, in primates there are very few retinal ganglion and LGN cells that exhibit this property.³³ In V1 there are many cells that respond best to one direction of motion of a stimulus. Explanations for how direction selectivity emerges generally argue for a time delay in inputs either from different classes of LGN cells or between cortical cells with the same orientation selectivity such that one cell either enhances or suppresses the response of the other.

In addition to orientation and direction selectivity, many cortical neurons in cats and monkeys are **binocular** (i.e. receive signals from both eyes). V1 is the first place where

feedforward visual information from the two eyes is fused. In binocular V1 neurons, there exists a range of cells with many responding somewhat more to one eye than the other. The bias in ocular response is such that ocular preference within a column extending from layer I to layer VI tends to reflect the preference of cells in layer IV within that column. This is because cortical cells are connected preferentially in vertical columns. Binocular cells with slightly displaced monocular fields (i.e. cells with a disparity between the receptive fields of the left and right eye) have been proposed as the possible initial substrate for stereoscopic vision, although many researchers argue that the ability to see in 3D is actually the function of visual areas beyond V1.

Columns and modules: Outlining the functional architecture of V1

As we have seen, V1, like the LGN, is arranged in layers containing cells of different types. Unlike the LGN, new receptive field properties such as selectivity for stimulus orientation, movement direction, and binocularity are constructed in V1. Additionally, information about spatial frequency, temporal frequency, brightness, and color contrast, sent by cells of the LGN, must be either preserved or incorporated into the coding of V1 cells. Given the precision of the visuotopic map in V1, this means that critical stimulus attributes must be coded in an iterated manner to cover each location in visual space so that stimulus features that provide information relevant to form and movement can be appreciated equally well without holes or gaps at different locations in the visual field.

Hubel & Wiesel³¹ were cognizant of the problem that local stimulus features would need to be represented repeatedly at each locale in the V1 map. What they noticed early on in their studies was that orientation preference in cat and monkey V1 changed regularly as the electrode was moved tangentially within any layer (Fig. 30.8). An advance of 1–2 mm was usually found to be sufficient to rotate twice through 180 degrees of orientation preference. This distance also was found to be sufficient to include at least one left

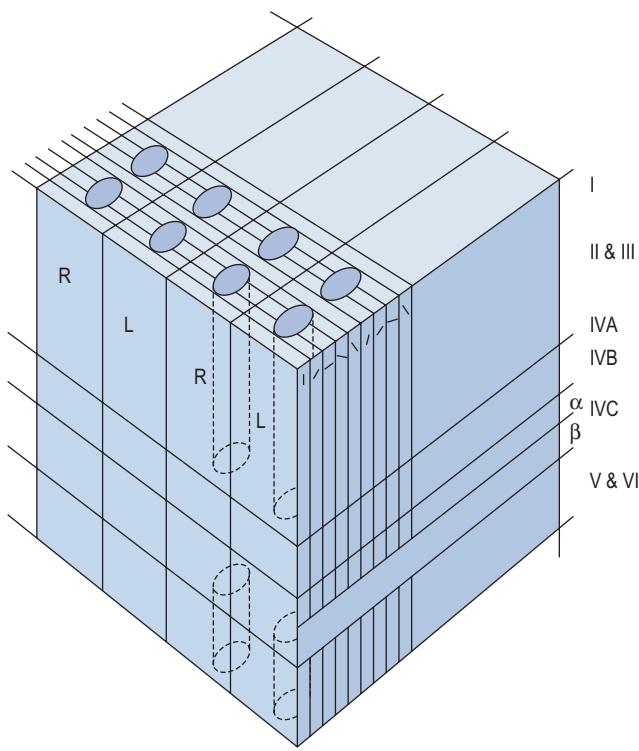

Figure 30.8 Schematic diagram of the modular organization of V1. Each module (or hypercolumn; see text for details) consists of two ocular dominance columns (representing right and left eyes), a series of orientation columns (representing 180 degrees of rotation) and cytochrome oxidase blobs (representing color information). (Reproduced from Livingstone & Hubel²⁸ with permission of the publisher.)

and one right eye ocular dominance column. From this information Hubel & Wiesel constructed a model in which they proposed that the cortex is organized as a series of repeating modules called **hypercolumns**. They argued that each hypercolumn should contain all of the machinery necessary to analyze one portion of visual space. Subsequently, Livingstone & Hubel²⁸ argued that CO blobs should be added to this modular organization as zones uniquely equipped to transmit color signals to the next cortical level. Although there is debate as to whether CO blobs are actually uniquely designed for color processing,⁸ the fact that these modules are the targets of LGN input from a separate class of cells, the K cells, suggests that CO blobs do process some important attributes, perhaps color contrast and brightness contrast. Moreover, there appear to be enough CO blobs so that whatever is processed within these modules can be represented across the V1 topographic map without gaps. Since CO blobs are positioned in the centers of ocular dominance columns in macaque monkeys, they were added as another dimension to be included within a V1 hypercolumn (Fig. 30.8).

The geometric problem is not so difficult for the cortex to solve when only three stimulus properties (i.e. orientation, ocular dominance, and color) must be represented, but when more properties such as spatial frequency, temporal frequency, direction selectivity, texture and binocular disparity (among others) are added, the task becomes more challenging. Currently, a number of investigators are engaged in

modeling how different feature maps may be represented in V1.^{34,35}

Optical imaging of signals in V1 has been used to further elucidate the relationship between maps of different stimulus properties in single animals. The technique of optical imaging of intrinsic signals makes use of tiny differences in the reflected light from cortex based upon dynamic differences in oxygenated and deoxygenated blood that occur as a result of changes in the activity of cells. Using this invasive technique in non-human primates, it has been found that changes in orientation selectivity are represented mainly in pinwheel formation, with some regions also showing more gradual linear or abrupt fractures in the orientation map. The structure of orientation maps in different primates and in other species shows a great deal of similarity suggesting that orientation selective cells are organized the same way in humans. Maps of different stimulus qualities also suggest that, although not organized exactly as originally envisioned in the hypercolumn model of Hubel & Wiesel, maps of stimulus attributes are nevertheless iterated in such a manner that there are no “holes” in the map across space. Figure 30.9 shows an optically imaged map of orientation preference in owl monkey V1, V2, and V3.³⁶ The functional compartments in V2 are also apparent in this surface image.

How do parallel inputs relate to parallel outputs?

It has been popular to suggest that there is a direct link between the input and output pathways of V1. There is considerable support for the idea that two hierarchies of extrastriate visual areas exist: one devoted to object vision, or *what* something is, and one to support spatial vision and complex tasks related to *where* items are in space relative to ourselves.^{28,37} The “what” and “where” pathways, also called the ventral and dorsal streams, consist of two hierarchies of visual areas that receive input from separate cell groups in V1 as described earlier. The ventral stream consists of a pathway from V2 through V4 to the temporal cortex and the dorsal stream consists of a pathway from V2 through MT to the parietal cortex²⁵ (see review³⁸). It is less clear whether the dorsal and ventral extrastriate pathways are directly linked to the K, M, and P LGN input pathways to V1. The best evidence for such a direct link comes from studies in which input from the M and P pathways and associated K cells were blocked in the LGN of macaque monkeys with micro injections of GABA.³⁹ This study demonstrated that the majority of input to visual area MT comes from M LGN cells or M and neighboring K cells since the two could not be inactivated separately in these studies. In spite of this finding, some MT cells could still be driven by the remaining P and/or K LGN cells.

As described in Chapter 29, we now know that some K cells send axons directly to area MT so this is not surprising. A fairly direct pathway for signals from M LGN cells to area MT has also been demonstrated anatomically, given that cells in layer IVCo, the target layer for LGN M cells, send axons directly to cells in layer IVB which, in turn, can send signals to area MT. Nevertheless, cells in layer IVB that project to MT do not reflect the receptive field properties of M cells; instead most are complex direction-selective cells

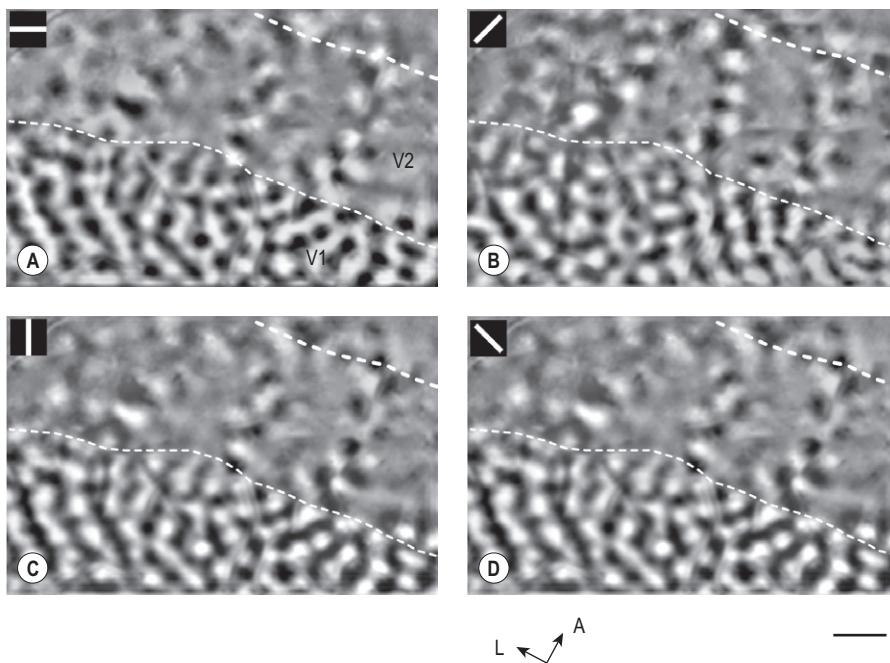

Figure 30.9 Orientation difference maps of V1 and V2 in the owl monkey obtained from optical imaging of the cortical surface. Four orientation difference maps are presented as follows: (A) 0/90°; (B) 45/135°; (C) 90/0°; (D) 135/45°. The data were obtained by presenting the monkey with full field rectangular gratings (duty cycle, 0.2; spatial frequency, 0.5 cycles/degree; temporal frequency, 2 Hz). The thin and thick dashed lines delineate the V1/V2 and V2/V3 borders, respectively. Note that orientation preference is represented continuously throughout V1 but in a series of alternating bands of high and low selectivity within V2 and V3. High selectivity for the stimulus is indicated by black or white while low selectivity is indicated by gray. A, Anterior; L, lateral. Scale bar, 1 mm. (Reproduced from Xu et al³⁶ with permission of the publishers.)

whose receptive fields are presumably constructed through complex cortical circuits.⁴⁰ Even more opportunity for integration between pathways seems to exist before signals enter the ventral stream ("what" pathway). Blockade of the P layers and surrounding K layers does not silence cells within output layers IIIA and IIIB, both of which respond well with either M or P layers blocked.⁴¹ Moreover, anatomically, much of the output to the ventral stream leaves from layer IIIA which gets no direct input from layer IVC, but receives signals only after they have passed to other layers. Thus, both the wiring and physiology suggest that considerable integration of signals takes place in V1 before they are transmitted into the ventral stream for further analysis of object identity. Finally, as discussed in Chapter 29, the fact that lesions of either M or P layers in the LGN (together with associated K layers) do not completely eliminate either form or motion vision reinforces the view that it is inappropriate to equate complex visual behavior with the threshold properties of retinal and LGN cells.

Does V1 Do More?

In the classical view of V1, the visual field is analyzed by small receptive fields within separate modules and V1 layers. These receptive fields are depicted as static, isolated, and stable with respect to attributes being tested including orientation, direction, spatial frequency, etc. The emphasis in this classical model is one of serial processing where information constructed within these small localized receptive fields in V1 is sent, via feedforward connections, to higher visual areas where it is combined in different ways until complex objects or motions are acted upon by the brain areas concerned with executive function. In this model, V1 becomes a staging area to prepare signals for more complex perceptually relevant tasks performed only at the highest cortical levels. This classical view, however, does not take

into account that the responses in V1 cells can be affected by time, the visual context of a stimuli and previous experience. Yet the anatomy described above alerts us to the fact that more information may be returning from higher visual areas back to V1 than is traveling the other way, and that local V1 areas are heavily interconnected both vertically across layers and tangentially via horizontal axon pathways, and that many other input pathways to V1 from the brainstem and thalamus exist. Returning to our introductory remarks, we remind the reader that the visual system is not designed to represent all physical constants, but to represent what is important for survival. In this section we give examples to show that V1 may do much more than classical models would predict.

The importance of time

What is difficult to appreciate from descriptions of wiring alone is that the visual system is highly dynamic. The problem is that the visual system must maintain stability while we move and objects move relative to us. Therefore, the receptive fields of V1 neurons can only provide useful snapshots within short windows of time. When researchers measure receptive field properties, they generally average the firing response of cells over long periods of time (a half second to several seconds). We can discriminate objects in as little as 250 ms; so the question is, does a cell prefer the same orientation or spatial frequency if you sampled at different windows of time? The answer is no. Using peak firing rate as a measure of preference, investigators have shown that cells shift their orientation and spatial frequency preferences over time significantly. Ringach and colleagues^{42,43} have demonstrated that many V1 cells shift both their orientation tuning and spatial frequency tuning quite dramatically over time with some cells actually changing from being excited by to being inhibited by the same stimulus attribute in as little as 20 ms. As techniques for sampling from many

neurons over time in awake monkeys become more sophisticated, it is clear from these examples that our concept of how V1 cells contribute to vision will have to move from static depictions of single simple cell receptive fields to plots that also represent changes in response over time across a network of cells.

The importance of context

As described earlier, the connections of V1 are complex and include horizontal connections that integrate information across separate parts of the visual field, as well as massive, fast-conducting feedback connections.^{44,45} Although these feedback connections are retinotopically precise,⁴⁴ they arise from higher visual area neurons that have very large, complex receptive fields. Therefore, this heavy feedback connects individual higher-order visual cells with large numbers of V1 cells. When the visual field is analyzed using the small receptive fields of V1 cells, one forgets that these limited views of visual space will need to be combined with the rest of the field, both in space and in time. Clearly, both horizontal and feedback connections could provide the substrate for such information. The difficulty, however, of determining the role of connections that do not provide the main drive to a cell is that their impact can only be measured against the baseline or driven activity that the V1 cell exhibits.

Within the past few years a number of investigators have successfully demonstrated that the activity of a V1 cell can be modulated by the activity of its neighbors even when these neighbors lie well outside of the classically defined receptive field of a V1 cell. One method used to demonstrate the impact of stimulating neighboring cells is illustrated in Figure 30.10, which shows an example of a V1 cell that prefers (based on stimulation of its classical receptive field) a vertical bar of light as shown in (A). When, however, bars of similar orientation are presented in the receptive fields of neighboring cells simultaneously, the response of the V1 cell is significantly reduced. Note that stimulating the neighbors without simultaneously stimulating the receptive field of the V1 cell under study has *no effect*. Interestingly, as shown in (C) the V1 cell's response is actually enhanced if the neighbors are stimulated with a different orientation. Finally in (D) if the neighbors are stimulated with orientations that include a mix of matched and unmatched orientations, the V1 cell response is unaffected. In other words context matters. These effects at the single V1 cell level are surprisingly similar to the effects one sees perceptually. It is known that the context of a line segment changes its perceptual salience. A line segment by itself is quite salient but when it is embedded among like neighbors it becomes much less obvious. When the neighbors are different the salience is again high as the "different" orientation of the target "pops out" from the background. If the background and target are similar the target is less visible. There are many more examples.⁴⁶

Other forms of context also appear to matter for V1 cells. Although there currently exists debate as to the timing of effects in V1, a number of laboratories have shown that visual spatial attention to a target can modulate the activity of V1 such that areas representing the focus of attention show enhanced activity at the expense of areas of V1 that are not the focus of attention.⁴⁷ As discussed in Chapter 29, such

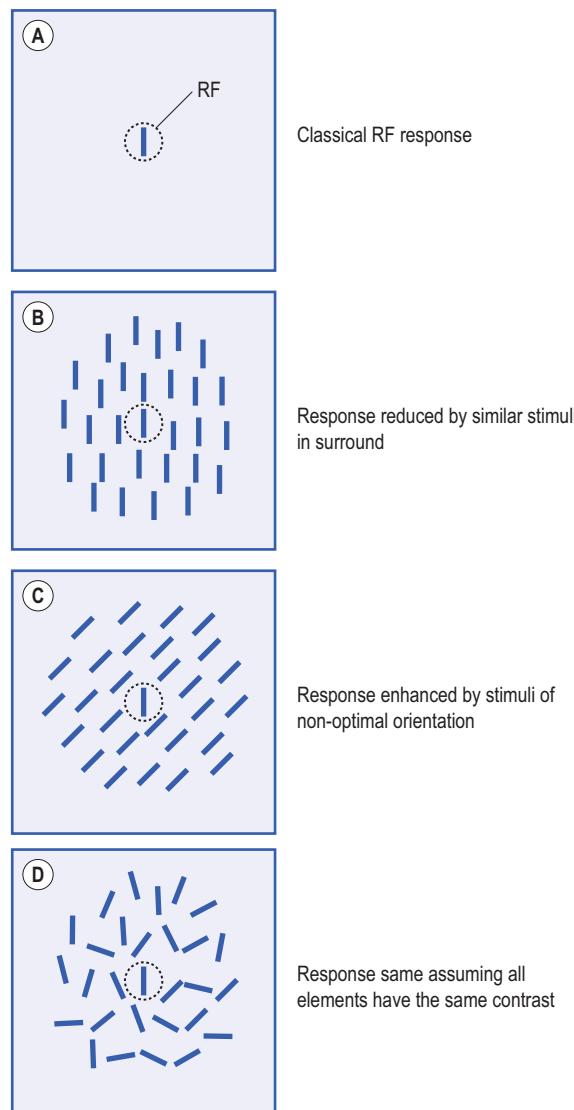

Figure 30.10 The context of a line segment changes both the local firing rate of cells and its perceptual salience. (A) A lone line segment is perceptually most salient and cells with a preference for this orientation will produce a high firing rate. (B) The same line segment, now embedded in similar ones, is much less conspicuous and the cells representing that line will show significantly lower firing rate to the same stimulus as in "A". (C) The line segment may pop out when its orientation differs from that of the surrounding line segments, restoring its perceptual salience to some extent and the cells representing that line segment will again show a high firing rate. (D) Global stimulus aspects are taken into consideration, since a similar local orientation difference does not produce popout when surrounding elements all have different orientations. Thus, when a V1 neuron is stimulated by presenting these displays, so that its RF only covers the same center line segment in all cases, contextual modulation signals the perceptual salience of the center line segment. (Modified from Lamme⁴⁶ with permission of the publisher.)

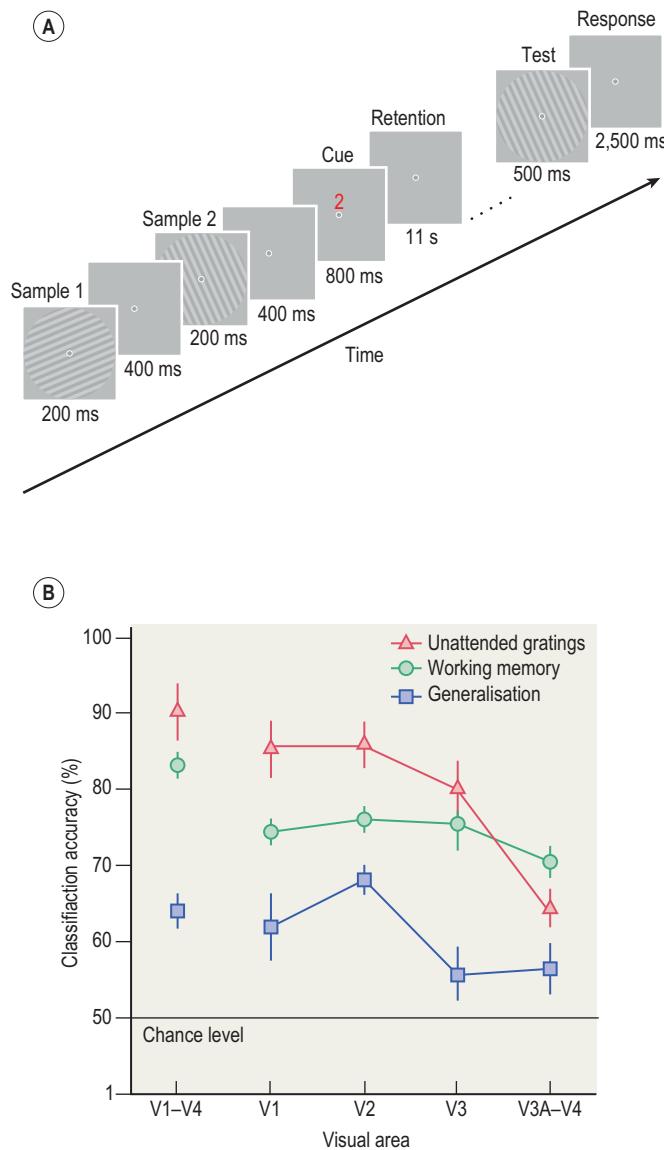

attention effects even have been reported at the single cell level in the LGN.

Even more surprising are results that show that reward and memory can impact the responses of V1 cells. Recently Shuler & Bear⁴⁸ reported that when adult rats experience an association between visual stimuli and subsequent rewards, the responses of a substantial fraction of cells in V1

Box 30.3 Does V1 remember?

How do we remember details of our visual world when higher-order visual areas do not appear to have the selectivity of early sensory areas such as V1? This problem was recently addressed using fMRI of human subjects in an elegant set of experiments designed to test if V1 showed sustained activity during a working memory task when no visual stimulus was present.⁴⁹ As illustrated in (A) subjects were presented with two different orientations (1 and 2) and then shown a number indicating which orientation they should remember during the blank working memory period. At the end of this working memory period they were shown a test pattern and asked to judge if the test pattern was rotated clockwise or counterclockwise relative to the remembered pattern. Although the task was difficult the subjects were able to perform the task with ~75 percent accuracy. Imaging results clearly showed that orientations held in working memory could be decoded by the relative change in activity patterns in V1. This surprising result does indeed support the conclusion that cells in V1 are capable of remembering visual patterns in the absence of stimulation at least for several seconds.

Orientation decoding results for areas V1–V4 (B). The accuracy of orientation decoding for remembered gratings in the working memory experiment (green circles), unattended presentations of low-contrast gratings (red triangles), and generalization performance across the two experiments (blue squares). Error bars indicate s.e.m. Decoding was applied to the 120 most visually responsive voxels in each of V1, V2, V3, and V3A–V4 (480 voxels for V1–V4 pooled), as determined by their responses to a localizer stimulus (1–4° eccentricity). Individual areas V3A and V4 showed similar decoding performance but had fewer available voxels, so these regions were combined. (Figure reprinted from Harrison & Tong⁴⁹ with permission from the publisher.)

gradually begin to predict the timing of reward. In addition to revealing a remarkable type of response plasticity in V1, these findings demonstrate that reward-timing activity, which is considered a higher brain function, can actually occur very early in the sensory pathway. These results, and others showing how memory can affect V1 activity in humans⁴⁹ (Box 30.3), challenge our traditional interpretation of the role played by V1 neurons in conscious visual perception.

Conclusion

V1 is perhaps the most thoroughly researched area in the primate brain. Motivated by the fact that V1 is necessary for conscious visual perception in primates, researchers have produced volumes of work on the firing patterns, projections, and internal anatomy of this area. Some of the most

enduring themes of these writings are that V1 cell firing encodes for local features (especially orientation) and that these cells are organized modularly in retinotopic maps. However remarkable our knowledge of V1 is, it is more remarkable that this tremendous amount of knowledge has only begun to explain the function of V1. We are only now beginning to understand V1 as part of a dynamic network that transmits signals to higher visual areas while simultaneously being transformed by feedback signals from these areas. This work argues V1 is not a mere conduit from the retina to higher-order brain areas but alters its message dynamically based on context so that only the essentials are transmitted for efficient processing.

Extrastriate Visual Cortex

Jamie D. Boyd & Joanne A. Matsubara

What is extrastriate visual cortex?

The term “extrastriate” refers to all visually responsive cortex other than primary visual (striate) cortex, and does not receive strong direct projections from the lateral geniculate nucleus (LGN) (see Chapter 30). A central hypothesis in studying extrastriate cortex is that it is composed of discrete cortical areas which can be identified by histology, retinotopic mapping, patterns of connections with other areas, and the unique contribution each area makes to visual processing. Extrastriate areas that receive strong inputs directly from primary visual cortex can be thought of as a lower tier within a processing hierarchy, compared to a higher tier of areas that receive their main visual inputs from relays through other extrastriate areas.⁵⁴ The more relays between an extrastriate area and primary visual cortex, the higher its position in the processing hierarchy and, generally speaking, the more complex is its visual processing. Superimposed on this hierarchy is the concept of parallel streams of visual areas that are more strongly interconnected with each other than with areas of different streams, and that are all concerned with some common aspect of visual processing, such as object recognition (ventral stream) or object location (dorsal stream).⁴⁵ At least 25 cortical areas predominately or exclusively engaged in vision have been described in monkeys,⁵⁴ the number of visual areas identified in humans is rapidly approaching, and will probably surpass, that total (Fig. 31.1, Box 31.1 and see also Box 31.6).^{133,160}

Methods used to identify extrastriate areas in monkeys and humans

Identifying cortical areas and their borders is neither straightforward nor completely resolved, and different schemata for parceling extrastriate cortex into areas exist, depending upon how the criteria of histology, retinotopy, connectivity, and physiology are weighted. There is most consensus regarding areas lower in the hierarchy, nearer to V1, and most divergence of opinion for higher-level areas in the temporal and parietal lobes.^{71,118,133,160,177}

Histology

Cortical areas can be expected to have a uniform and distinct histology, such that anatomical borders can be recognized by changes in the laminar organization, density, or size of neurons, myelinated fibers, enzyme activity, neurotransmitter levels and their receptors, and so forth. However, not all borders can be recognized with all stains. Early parcellation schemes based on classical histological techniques are still in wide use,¹⁶² although containing many known inaccuracies. Based on Nissl staining of neuronal cell bodies (cytoarchitectonics), Brodmann²³ divided most of extrastriate occipital cortex, in both human and monkeys, into only two areas, 18 and 19, each of which includes multiple areas defined by other criteria such as retinotopy and connectivity. Other histologic stains not available to Brodmann, such as cytochrome oxidase (CO; a metabolic enzyme that serves as a marker for long-term activity levels of neurons) histochemistry, reveal the borders of the many visual areas within the cortical territory occupied by Brodmann's areas 18 and 19.^{76,91,159,161} Even with improved staining techniques, however, it is likely that some areal boundaries may escape detection by any histologic methods.

Retinotopic mapping

Each visual area comprises a single map of receptive field locations, with V1 demonstrating the most complete map of visual space (see Chapter 30). These maps can be studied with electrophysiologic recordings in monkeys and with functional magnetic resonance imaging (fMRI) or positron emission tomography (PET) in humans. However, none of the extrastriate maps are as regular as in striate cortex (V1). Extrastriate areas have larger receptive fields and more scatter in the position of each receptive field, resulting in “cruder” maps. Between extrastriate areas, there is generally a smooth transition of receptive field locations. Contiguous visual areas can have “mirror-image” representations, where the topography of the visual field map is reversed at the border of the two contiguous areas. When a mirror-image area like V1 borders a non-mirror-image representation like V2, the vertical meridian representation forms the border of the two

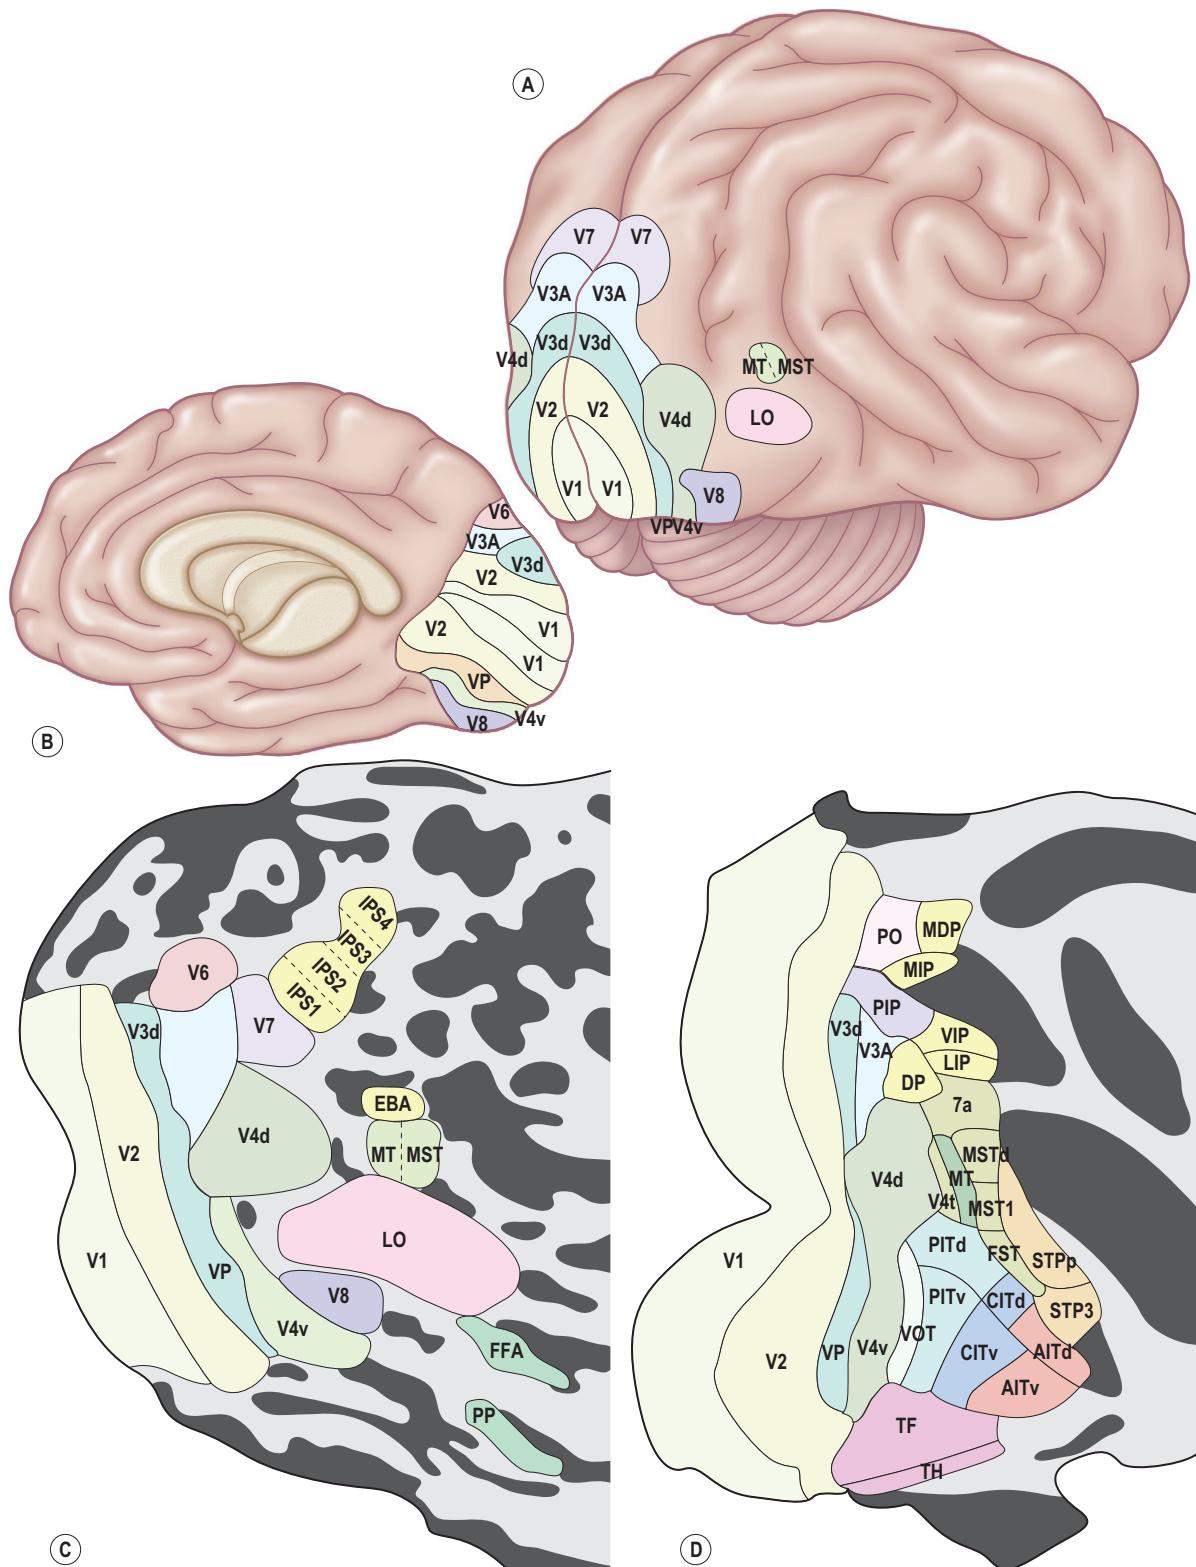

Figure 31.1 Human (**A, B, C**) and monkey (**D**) visual cortical areas. Visual cortical areas are shown on a schematic diagram of the human brain from the posterior aspect (A) and mid-sagittal plane (B). Many of the areas cannot be appreciated on the surface view of the brain, and a flat map of the human (C) visual cortical areas is also shown. Areas involved in vision are colored and labeled. The depths of the sulci are shown in black and gyri in white to give a perspective to location relative to the sulcal patterns. For comparison, a flat map of visual areas in the macaque monkey is shown in (D). Homologous areas, insofar as they can be identified, are given the same color and nomenclature, but many more areas have been studied in monkey brain than in human. In the occipital cortex of humans, there are: the second visual area (V2); the third visual area, broken into a dorsal (V3d) and a posterior half (VP); V3 anterior (V3A); the ventral (V4v) and dorsal (V4d) subdivisions of V4; and the sixth, seventh and eighth visual areas (V6, V7 and V8). Visual responsive areas in the parietal lobes include: the middle temporal area (MT); the medial superior temporal area (MST); the lateral occipital area (LO); and the extrastriate body area (EBA). Several visual areas in the intraparietal sulcus have been recently studied and named (IPS1, IPS2, IPS3, IPS4). In the occipitotemporal cortex are found the fusiform face area (FFA) and the parahippocampal place area (PPA). Monkey extrastriate areas shown in (D) include, in the temporal lobe: the posterior inferotemporal area, with dorsal (PITd) and ventral (PITv) subdivisions; the central inferotemporal area, with dorsal (CITd) and ventral (CITv) subdivisions; the anterior inferotemporal area, with dorsal (AITd) and ventral (AITv) subdivisions; the superior temporal polysensory area, with anterior (STPa) and posterior (STPp) subdivisions; the floor of the superior temporal sulcus (FST); and temporal areas F (TF) and H (TH). In the parietal lobe are found: the medial and superior temporal area, with dorsal (MSTd) and lateral (MSTl) subdivisions; the parieto-occipital area (PO); the posterior intraparietal area (PIP); the lateral intraparietal area (LIP); the ventral intraparietal area (VIP); the medial intraparietal area (MIP); the medial dorsal parietal area (MDP); the dorsal prelunate area (DP); and Brodmann's area 7a (7a). (Adapted from Swisher et al 2007,¹⁴⁹ Larsson & Heeger 2006,⁸⁸ Sereno & Tootell 2005¹³³ and Tootell et al 2003.¹⁶⁰ (Extrastriate areas have been variously named by the order in which they were studied, by their position relative to sulci and gyri, and by the classical histological areas to which they most closely correspond. A single area can be named by all three methods, as for the Middle Temporal area (MT), known also as V5 and as Brodmann's area 37, and similar sounding names can refer to unrelated areas, as for V7, named in order of its discovery, and 7a, a completely unrelated visual area located in Brodmann's cytoarchitectonic area 7.)

Box 31.1 Organization of extrastriate visual areas

"Lower tier" extrastriate visual areas receive predominantly from primary visual cortex.

"Higher tier" extrastriate areas receive less from primary visual cortex, and more from both lower and higher tier areas and generally have more complex visual processing.

areas and allows continuity of receptive field locations across the border. Visual field sign (mirror image or non-mirror image) can be computed from the local gradient of receptive field position, and can be used to infer borders of extrastriate areas.¹³² Extrastriate maps also tend to show breaks in the retinotopy (split representations) along the horizontal meridian representation (Fig. 31.2). These breaks often form the borders of visual areas, allowing smooth transitions of receptive field locations from one area to the next, at the expense, in this case, of splitting the receptive field map within a single area. The splitting of maps within a single area and the continuity of receptive field positions at the borders of different areas make it difficult to identify areal boundaries on the basis of receptive field maps alone.

Connection patterns

Each visual area is interconnected with a subset of the other visual areas and subcortical visual structures, giving it a unique connectional signature. Neuroanatomic tracing methods in monkeys involve injecting tracers into one area either to label cells projecting to the injected area or to label axons projecting from the injected area to other areas. Tracing connectivity in human visual cortex was classically limited to postmortem staining for degenerating axons after cortical lesions.³⁰ Two new techniques suitable for studying connectivity in human extrastriate areas have recently been developed. Connections can be traced between cortical areas with an MRI technique that analyses the anisotropy of diffusion of water within oriented bundles of axons (diffusion tensor analysis; DTI).^{58,104} Currently, DTI is not, and may never be, sensitive enough to demonstrate all connections among visual areas,^{47,83} but it has proved useful in demonstrating pathological changes.^{135,155} Connectivity can also be inferred by imaging a rise in activity of target areas following noninvasive activation of a projecting cortical area with transcranial magnetic stimulation (TCMS).^{14,56,122} TCMS induces a brief electrical current inside cortical neurons by external application of a large, rapidly fluctuating magnetic field, and, with proper stimulation paradigms, can either activate or inactivate cortical areas.^{35,102,154} It is important to note that connections are between retinotopically corresponding points in the visual field representation of the interconnected areas. Thus connectivity information has been used to infer receptive field maps. This is especially true for interhemispheric connections, which, especially for areas in the lower tier of the processing hierarchy, are concentrated in representations of the vertical meridian.

Functional specificity

The functional properties of neurons are often characteristic of each extrastriate area. A range of visual stimuli, selected to emphasize, for example, motion versus form and color information, can be used to selectively activate specific areas. These studies, like those detailed above on retinotopy, can be performed in humans using functional imaging techniques (fMRI, PET) or in monkeys using imaging or

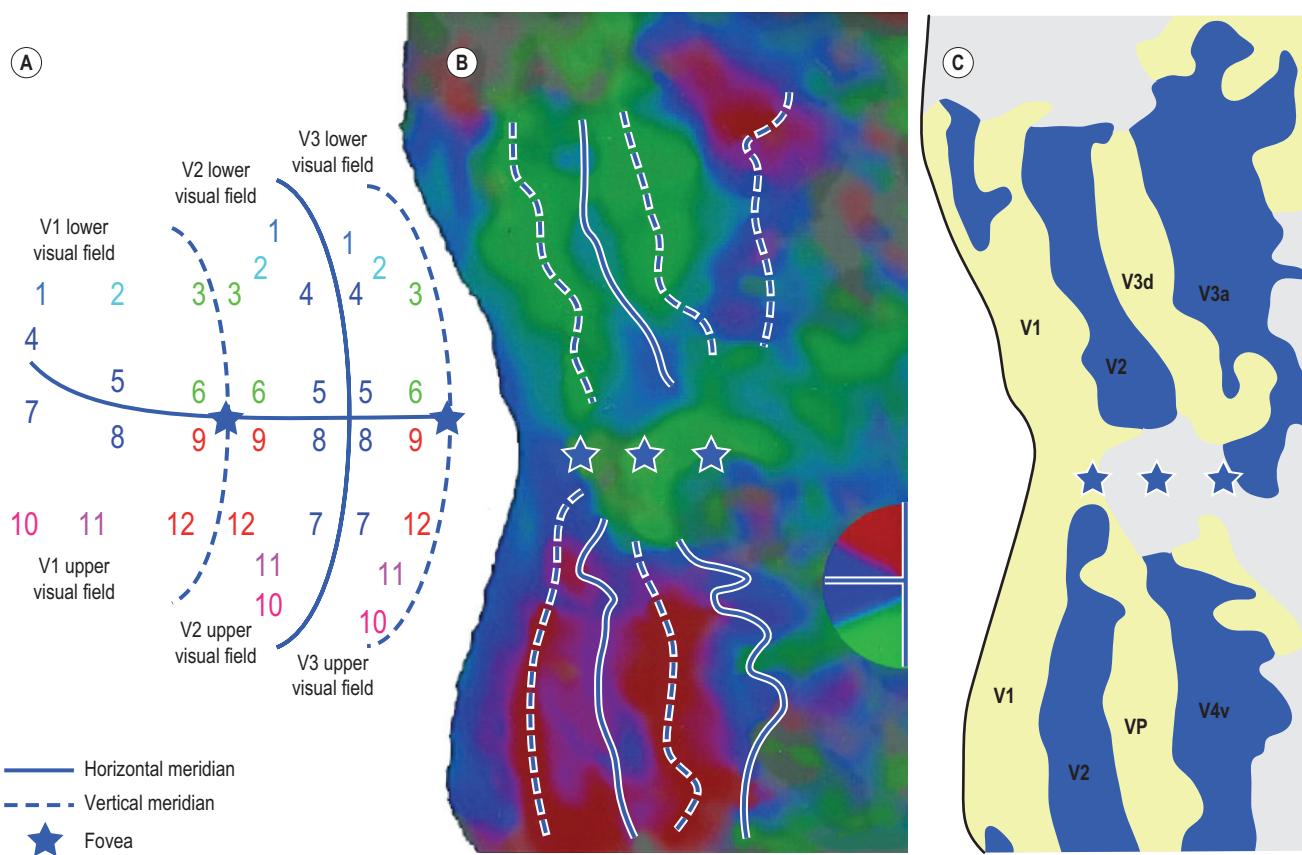

Figure 31.2 Maps of human visual areas, generated by functional imaging using visual stimuli that vary in retinotopic locations. **(A)** Schematic view of the retinotopy in V1, V2, and V3 (including upper and lower visual fields). The vertical (dashed line) and horizontal (solid line) meridians and foveal representations (stars) are shown. The numbers represent corresponding retinotopic locations in visual space in the three areas. The maps in **(B)** and **(C)** are flattened views of a right hemisphere, as if the cortex had been removed from the brainstem and flattened. Dorsal is to the top of each map and ventral is towards the bottom. In making the reconstruction, a cut (visible to the left in **B** and **C**) was introduced along the horizontal meridian representation of V1 to relieve the curvature of the cortical mantle and reduce distortion. **(B)** A map of cortical response plotted as a function of the polar angle of an annular stimulus (see text). The dashed and solid lines show the representations of the vertical and horizontal meridians, which form the boundaries of several cortical areas. The asterisks mark the location of the foveal representation. **(C)** A map of the local visual field sign, where yellow is a mirror image representation, like V1, and blue is a non-mirror image representation like V2. The locations and extent of V1, V2, V3d/VP, V3A, and V4v can be identified in this fashion. (From Tootell et al 1997.¹⁵⁶)

electrophysiological techniques. *In vivo* imaging in humans can reveal functional deficits due to cortical lesions caused by stroke, and localize the site of the damage to particular cortical areas. Repetitive TMS can be used to reversibly inactivate extrastriate cortical areas in humans, allowing deficits in function to be associated with the inactivated area.^{6,35}

Comparing visual areas in monkeys and humans

Related to the problem of identifying different areas in a single species is that of identifying homologous visual areas in different species. The functional organization of cortical areas has been studied extensively in monkeys, but it has been only with the recent advent of new non-invasive methods, that comparable studies have been done in humans. Most non-human data are from a genus of Old World monkeys (*Macaca* sp.). Although these species are more closely related to apes (including humans) than other primate groups (e.g. New World monkeys and prosimians), at least 25 million years of evolutionary history separate humans and macaque monkeys, with many new cortical

areas being added in humans.⁸¹ Lower-level areas (V1, V2, V3d/VP, and MT) appear to be present in all primates, including humans, but there are important species differences in cortical organization for higher-level visual areas.^{118,133,160} In addition to similarities in histology, retinotopy, connectivity, and physiology, relative position on the cortical surface and with respect to common sulcal and gyral landmarks is used to compare human visual areas with those of monkeys. This is not straightforward, however, as borders of cortical areas relative to sulcal landmarks vary among individuals, even more so in humans than in monkeys.⁷⁹ Moreover, there is no clear human analog of the macaque monkey's lunate sulcus, in which lie visual areas V2, V3, and V4.⁵ Comparisons between human and monkey extrastriate cortex are also made more difficult by the fact that human V1 does not extend onto the external aspect of the hemisphere as much as in monkeys; accordingly, all of the human extrastriate areas appear displaced posteriorly relative to their positions in monkeys. The best positional clues to correspondence between monkey and human extrastriate areas are from each area's location relative to other cortical areas,¹¹⁸ which does seem to be relatively well conserved.

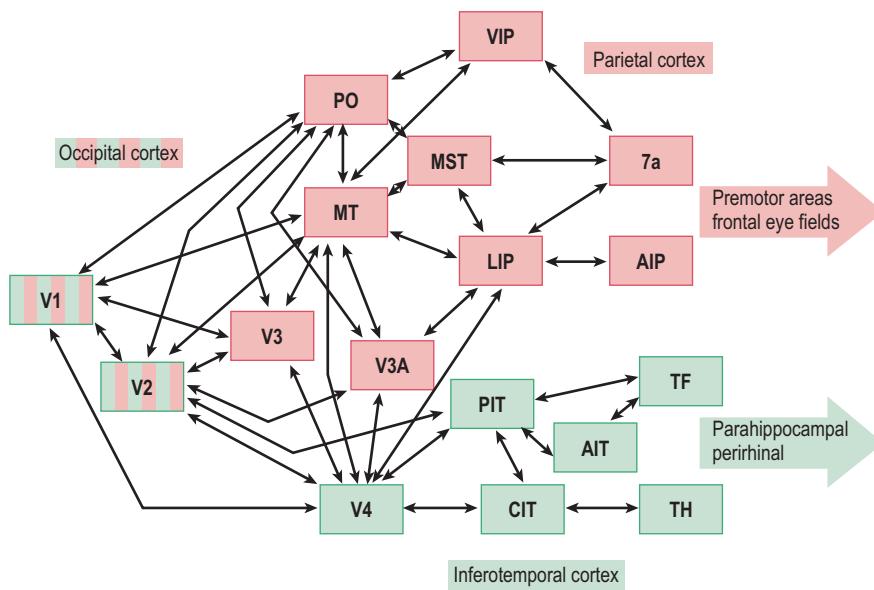

Figure 31.3 Summary diagram depicting the hierarchy of visual areas associated with the ventral and dorsal processing streams in monkey and the major interconnections between them. All connections are shown with bidirectional arrows to emphasize that each projection to a higher level visual area is matched by a feedback projection. Areas V1 and V2 are colored both red and green to depict their contributions to processing both “what” and “where” information for further, more segregated processing in extrastriate cortex. The dorsal stream areas, colored in red, process information about object location (where stream) and project to parietal cortical zones, eventually ending in premotor and frontal eye fields. The ventral stream areas, colored in green, process details of the form, color, shape of objects (what stream) and project to inferotemporal cortical zones and parahippocampal and perirhinal areas.

Processing streams in extrastriate cortex

As nearly all of the projections from the LGN terminate solely in striate cortex, the extrastriate areas receive their visual inputs through area 17, either directly or indirectly. (Some extrastriate areas do receive minor thalamic inputs from the lateral geniculate body^{144,182} and the pulvinar, which may contribute to blindsight.³⁷) The main extrastriate projections of V1 are to V2, V3, V4, and MT. As mentioned earlier (see Chapter 30), these projections arise from different subsets of neurons in V1 with different laminar and columnar distributions and likely different functional properties. Zeki¹⁸⁶ first pointed out that striate cortex thus acts to initially segregate and then recombine the visual inputs of the three retinogeniculocortical pathways, magnocellular, parvocellular, and koniocellular, such that different visual information is parceled out to different extrastriate cortical areas for further analysis. As described in Chapter 30 and shown in Figure 31.3, projections from V1 give rise to two main streams of extrastriate cortical processing, a dorsal stream devoted to spatial vision (“where” stream) and a ventral stream devoted to object vision (“what” stream).⁴⁵ As in V1, there is often a tangential organization of the inputs and outputs from different streams, forming a mosaic pattern when viewed from the cortical surface. This columnar and tangential organization of connectivity is often marked by differences in histochemical, particularly CO, staining.

V2

In nearly all mammals, the second visual area, V2, borders V1 laterally and dorsally, extending around V1 nearly completely in the case of primates.¹²⁷ V2 has a mirror-image visual field map, with the representation of the vertical meridian forming the boundary with V1 and a split representation of the horizontal meridian forming the boundary

Box 31.2 Area V2

- Part of both the “what” and “where” streams
- Composed of thick, thin, and pale CO stripe compartments
- Thin stripes receive from CO blobs of V1 and project to V4; unoriented and color-selective receptive fields predominate
- Thick stripes receive from the interblobs of V1 and project to MT; orientation and retinal disparity-sensitive receptive fields predominate
- Pale stripes receive from the interblob regions of V1 and project to V4; orientation-selective receptive fields predominate
- Local connections in V2 interconnect all CO stripe compartments
- In humans, V2 is split into four quadrants, with an upper and lower visual field representation in each of the two hemispheres
- Lesions in V2 give rise to selective visual loss depending on the CO stripe compartment affected

with V3d dorsally and VP ventrally.¹³⁶ V2 functions closely with V1 to organize information for output to higher visual areas such as V4 and MT (Box 31.2).¹⁴³

The segregation of inputs, outputs, and physiological properties within area V2 is as dramatic as within V1 and, as in V1, is associated with a special pattern of CO staining. CO staining in sections of monkey V2 shows a series of parallel stripes of alternating dark and light staining that are oriented perpendicularly to the V1/V2 border.^{77,158} The V2 stripes, which are larger than the blobs in V1, extend across the whole width of the area, allowing its borders to be demarcated histologically using the CO stain.¹¹⁵ The darkly staining stripes differ in thickness, with thin and thick stripes alternating, thus defining three compartments (thick, thin, and the pale interstripes) within V2. Sections through human V2 also reveal a striped organization when stained for cytochrome oxidase and other histological stains.^{25,31,78,179} The

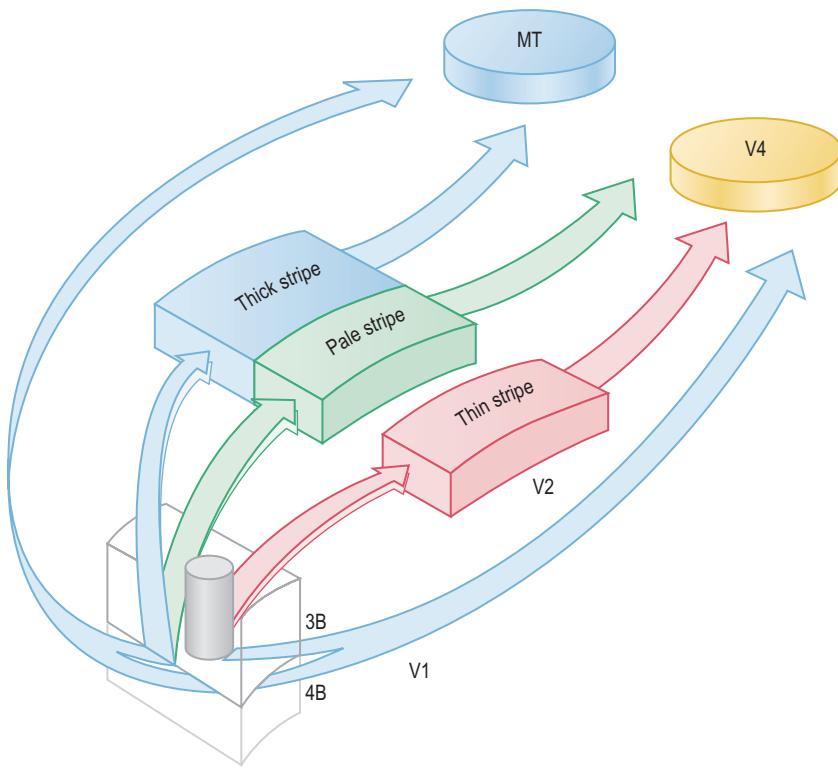

Figure 31.4 Schematic diagram depicting the parcellation of information from V1 into CO stripe compartments of V2 and onwards to MT and V4. MT, a dorsal stream area associated with motion processing, receives a direct projection from layer 4B of V1, from both blob and interblob columns. Interblob areas in layers 3A, 3B, and 4B of V1 project to the thick stripes of V2, and thence into MT. Interblob areas in layers 3A, 3B, and 4B of V1 also project to the pale stripes of V2, which then project into V4, a ventral stream area associated with color and form processing. V4 also receives from the blob compartments of V1 via the thin stripes of V2 as well as a direct projection from the blobs and interblobs of V1. Although not shown in the diagram, blob and interblob streams through V2 terminate in different columns within V4. (Adapted from Sincich & Horton, 2005.¹⁴³)

stripes are not as regular as in monkeys, and differentiation into thick and thin stripes is not clear based on CO staining. However, histologic stains known to differentiate thick and thin stripes in monkeys demonstrate a clearer stripe organization^{76,159} with a periodicity of about 0.7–1 cm for a complete set of stripes, several times larger than in monkeys. As in monkeys, the extent of the stripes shows the extent of V2.^{2,159} The presence of stripes in human V2 suggests that it may have the same intricate functional and connectional organization as shown in other primates (see below).

Each of the CO stripes has a different set of connections (Fig. 31.4). The thin stripes receive input from CO blob columns within V1, whereas the thick stripes and the pale-staining interstripes receive input from inter-blob columns.¹⁴¹ In each case, the projection originates from magnocellular-dominated layer 4B (layer 3C of Hassler; see Chapter 30 for the equation of Hassler's and Brodmann's layering schemata), layer 3B, which combines inputs from magno- and parvocellular channels (plus koniocellular input in CO blob columns), and layer 3A, which has little or no direct input from LGN recipient layers. The corticocortically and subcortically projecting cells of V2 are also segregated into CO compartments. The thin stripes and interstripes project to V4,^{44,137,187} a ventral stream area involved in form processing, whereas the thick stripes project to MT^{44,138} a dorsal stream area associated with motion processing. Cells projecting subcortically to the superior colliculus are also preferentially clustered in the thick stripes.¹ However, not all connections are segregated by stripe type. Feedback connections from higher-order visual areas tend not to be stripe specific and the local pathways within V2 interconnect stripes of all types.^{89,98} Thus there is a substrate for binding different attributes of a visual stimulus into a coherent perceptual whole, even at relatively early levels of visual processing.

There are differences in the receptive field properties of cells in V2 that correlate with CO stripe type,^{44,94,123,139} although the absolute degree of segregation of receptive field types within and between CO compartments is debated.^{66,144} Studies reporting segregation of single cell receptive field properties generally agree that thin stripes contain proportionately more cells with receptive fields that are unoriented and color opponent, whereas the interstripes contain more oriented cells and fewer color-coded units. Clustered in the thick stripes are cells that are oriented and sensitive for retinal disparity, which is important for generating depth perception. The clustering of properties within stripe types is thus consistent with the physiology of the areas to which they project.

The segregation of selectivity for orientation, color, and disparity within compartments of monkey V2 is supported by imaging experiments.^{28,82,95,126,164,178} There is one report of imaging experiments in human using high-resolution techniques to show that, within V2, stripes activated more strongly by slowly changing chromatic stimuli interleave with those activated by rapidly changing luminance stimuli, with a periodicity roughly equal to that of human V2 stripes.⁹² Within an individual CO compartment, there is a columnar organization according to preferred orientation^{95,163} (thick and pale stripes), disparity²⁸ (thick stripes), luminance¹⁷⁸ (thin stripes), or color^{95,180} (thin stripes), similar to maps of orientation preference in V1 (see Chapter 30).

The visual topography of V2 is interesting in that the CO stripes are oriented perpendicular to lines of isopolarity in V2, but parallel to the isoeccentricity lines. If V2 had a fine-grained continuous map of the visual field, sub-modalities of visual function associated with each stripe type would be restricted to parts of the visual field mapped onto that stripe. In fact, the visual map in V2 consists of three distinct,

interleaved maps.^{125,140} Each region of visual space is represented three times, once for each stripe type. The regular progression of receptive field positions seen when traversing across a single stripe are interrupted by jumps in receptive field location at stripe borders. This ensures that visual space is represented completely in all of the stripe types of V2.

Areas of the dorsal stream

The dorsal stream of visual processing deals with the general problem of where objects are in visual space and how to manipulate them. The dorsal stream solves two main problems, processing motion, and decoding position and 3-D features from 2-D retinal images. Dorsal stream-bound outputs from V1 and V2 funnel through MT and V3 to reach areas of the parietal cortex.

MT/V5 and related areas

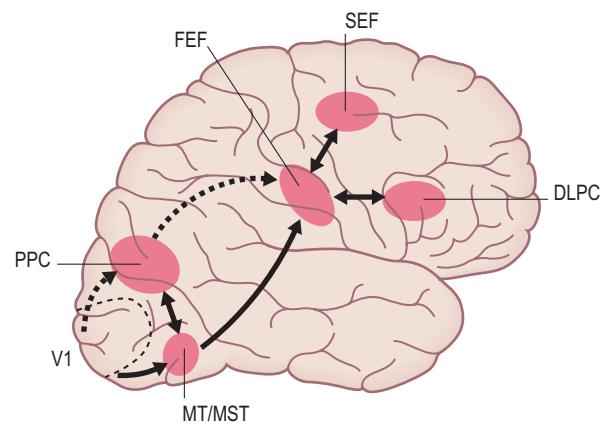

A group of visual areas exists in the superior temporal sulcus (STS) of the macaque monkey, with likely homologs in other primate species, including humans. These areas are recognized by their interconnections and by the fact that many of their neurons are sensitive to the direction of motion of moving stimuli.¹¹⁸ The largest of these areas, V5, also known as MT (for Middle Temporal area), is probably the most easily identified visual area outside of V1. In addition to direction selectivity, MT is marked by heavy myelination and dark, patchy CO staining, a complete representation of the contralateral visual field, and strong direct input from V1 (Box 31.3). In humans, MT corresponds to an area near the occipitotemporal junction, in the dorsal part of the inferior temporal sulcus, showing the dense myelination and dark, patchy CO staining seen in other primates.^{31,159} Motion selectivity in human MT/V5 has been shown with imaging and evoked potential studies comparing activation with moving versus stationary stimuli; such studies also show human MT to have higher contrast sensitivity than surrounding cortex and to respond poorly to contours demarcated solely by wavelength.^{8,93,159,188}

MT receives projections from direction-selective cells in layers 4B (Hassler's 3C) and 6 of both blob and interblob columns in V1^{103,142} and from the thick stripes of area V2.^{53,138} As discussed previously (Chapter 30), layer 4B is associated with the magnocellular pathway, while V2 thick stripes receive a mixture of both magnocellular and parvocellular inputs. Nevertheless, blocking the magnocellular layers of

the LGN greatly affects the responses in MT, whereas blocking the parvocellular layers has much smaller effects on responses in MT, suggesting a dominance of the magnocellular pathway to MT.¹⁰⁰ MT thus serves as a gateway for magnocellular information into other areas important for motion processing in the STS, the parietal lobe, and the frontal eye fields. Not surprisingly, lesions of MT in monkeys lead to deficits in motion processing, assessed behaviorally. Monkeys with lesions in MT have elevated detection thresholds of a motion signal in the midst of masking motion noise.¹¹² The detection threshold for contrast of a visual stimulus was not affected by the MT lesion, showing that the MT lesion effect was selective for motion perception. Deficits for eye movements made to moving targets are also impaired by MT lesions (Box 31.4), whereas eye movements made to stationary targets are unaffected by the MT lesions,

Box 31.4 Cortical control of smooth pursuit and saccadic eye movements

- Smooth pursuit involves motion processing in dorsal stream areas, MT, and MST
- Other cortical areas such as the frontal eye fields (FEF) and supplementary eye fields (SEF) contribute to the control of smooth pursuit
- Asymmetric smooth pursuit function indicates focal lesions in the lateral occipitotemporal (MT/MST) or dorsomedial frontal (FEF and SEF) regions (lesions limited to V1 do not impair smooth pursuit)

- Saccadic eye movements involve posterior parietal areas (PPC), the frontal eye fields (FEF), and the dorsolateral prefrontal cortex (DLPFC)
- Parallel descending pathway from the FEF and SEF to the caudate nucleus, midbrain, and brainstem structures are also involved with saccadic eye movements
- Unilateral, focal cerebral lesions throughout frontal and parietal lobes may cause abnormalities of the in latency and accuracy of saccades
- Bilateral frontal or frontoparietal lesions may abolish saccades, sparing the quick phase of the vestibular ocular reflex (VOR), leading to acquired ocular motor apraxia
- Complete loss of all saccades, including reflexive saccades, quick phases, and smooth pursuit is called acquired supranuclear ocular motor apraxia and has been reported after small bilateral infarcts of both the posterior parietal cortex and FEF¹¹⁰

Box 31.3 Area V5/MT

- Extrastriate area of the dorsal (where) stream
- Displays motion, direction, and disparity sensitivity
- Strong direct inputs from layers 4B and 6 of V1
- Patchy CO staining and heavy myelination pattern
- Located in the occipitotemporal junction near the inferior temporal sulcus in humans
- Clinical condition of akinetopsia (loss of motion perception) develops after bilateral lesions to the lateral occipitotemporal cortex; unilateral lesions lead to a contralateral deficit that may go unnoticed by patients

suggesting that monkeys with MT lesions have more difficulty responding to moving than to stationary stimuli.¹¹³ Human patients with lesions that include MT have difficulty with motion perception, a condition known as akinetopsia.¹⁸⁵ One such patient complained that she could not cross the street because of her inability to judge the speed of a car, although she could identify the car itself without difficulty, showing the specificity of the deficit.^{147,193} Temporary inactivation of MT with TCMS causes a similar akinetopsia.¹³

Several forms of columnar organization are found within MT. These include organizations for direction tuning, disparity tuning, and selectivity for wide-field versus local motion contrast.^{4,15,40} The tangential organization of direction selectivity in MT resembles the organization of orientation selectivity in V1 (see Chapter 30); regions of gradual change in preference are interrupted by sudden shifts of approximately 180 degrees. Approximately 180 degrees of axis of motion are represented in 400 to 500 μm of cortex, similar to the size of orientation columns in V1. This organization of direction-selective neurons made possible an elegant experiment using cortical microstimulation in awake behaving monkeys, showing how the stimulus selectivity of neurons in visual cortex underlies the perception of visual stimuli.¹²⁹ A microelectrode in MT in the middle of a cluster of neurons that shared a common preferred direction of motion was used to stimulate those neurons while the monkey performed a motion-discrimination task. Monkeys were required to discriminate between motion shown either in the direction preferred by the neurons or in the opposite direction, and noise was added to make the difficulty of discrimination near the monkeys' threshold for being able to perform the task. When electrical micro-stimulation was applied, the monkeys indicated that the motion was in the stimulated neurons' preferred direction more frequently than without stimulation. Thus a functional link was established between the activity of direction-selective neurons and perceptual judgments of motion direction.³²

In addition to motion selectivity, MT is also important for stereoscopic depth perception. Within MT, patches of disparity-selective neurons alternate with neurons not selective for disparity. Within a disparity-selective patch, there is a smooth progression of preferred disparity across the cortical surface and neurons in the same column have similar disparity tuning.⁴⁰ The presence of disparity-tuned neurons in MT is not surprising, given the disparity tuning found in the thick stripes of V2 and the connections between the thick stripes and MT. Microstimulation experiments on disparity-tuned columns in MT similar to the previously described experiment for the direction columns show that electrical stimulation of clusters of disparity-selective MT neurons bias perceptual judgments of depth in a way that is predictable from the disparity preference of neurons at the stimulation site.³⁹ Selectivity for stereoscopic depth has also been shown in human MT using fMRI.²¹ Thus MT is also important in the perception of depth, as well as motion. Moreover, the two certainly interact, as image movement is an important cue for depth perception.¹⁰⁵

V5 is strongly interconnected with three nearby motion-selective areas in the superior temporal sulcus, the lateral and dorsal divisions of the medial superior temporal areas (MSTl and MSTd), and area FST in the Fundus of the Superior Temporal sulcus.^{17,43,99} FST has a lower proportion of

direction-selective cells than MT or MST, while MST has cells with larger receptive fields than in MT. MST can be divided into a lateral division preferring smaller stimuli and a dorsal division with cells responding to "optic flow" stimuli, i.e. rotation and expansion of objects, as would occur during movement through the environment. In humans, only a single visual area has been identified in this region, and it has been tentatively identified as MST, based on its large receptive fields and responses to optic flow stimuli.^{12,50,176} An area dorsal to MT in humans has been identified as being specialized for processing images of the human body,⁴⁹ perhaps being involved in the analysis of biological motion.⁹

V3

V3 consists of a narrow belt of cortex immediately adjacent to V2, with the representation of the horizontal meridian forming its border with V2, and the vertical meridian representation forming its outer border.¹⁸⁹ The dorsal flank of V3 contains the lower visual field representation, and the ventral flank contains the upper field representation. Because the two parts of V3 appeared discontinuous across the representation of the horizontal meridian, being interrupted by V4, and because some studies also suggested functional and connectional differences between the two parts, the ventral flank was originally referred to as the ventral posterior area (VP) as distinguished from dorsal V3 (V3d), or V3 proper.^{26,52}

V3 has neurons selective for the basic stimulus parameters including orientation, color, direction, and binocular disparity. In both dorsal and ventral halves, cells preferring similar orientations are grouped into columns.^{3,175} As in MT, cells with similar preferred disparity are also arranged in columns.³ About half the cells are strongly selective for direction of motion, more than any cortical area other than MT.^{3,67} VP (ventral V3) has been reported to have more cells selective for color and fewer cells selective for direction.⁵²

V3 receives projections from V1 and V2 and is strongly interconnected with dorsal stream areas MT (and surrounding areas), and areas in the parietal lobe (PIP and VIP), although it also is connected with V4.⁵² Although it was originally thought that only dorsal V3 received projections from V1,⁵² connections between V1 and VP have been demonstrated.⁹⁶ The V1 projections originate mostly from magnocellular-dominated layer 4B; the connections from V2 are discontinuous, suggesting they arise from a subset of V2 CO compartments, but it is not yet known which subset.⁵² V3 itself does not show a modular organization with CO staining, and it is not known how or if different classes of inputs from V1 and V2 are segregated within it.

V3 has been identified in human functional imaging studies, by its position relative to V2 and its similar visual field organization,^{136,156} though it is not as narrow relative to V2 as it is in monkeys.⁴⁸ Functional imaging studies show similar properties compared to monkey V3. Human V3 is sensitive to direction of motion and stereoscopic depth, but not as strongly as V3a, MT, and parietal areas.^{21,145,146,168} With regards to differences between the dorsal and ventral halves, these studies show little difference between V3d and VP in humans. Interestingly, VP did show, compared to dorsal V3, more activation during a color discrimination task relative to activation during a brightness discrimination task,²⁹ consistent with earlier results in monkey V3. However, the same

study showed a similar, though not as extensive, difference in relative activation of upper and lower visual field representations of V2 and V1. The consensus is thus emerging that V3d and VP are two parts of a single area, and that the differences between V3d and VP in monkeys are either not large enough to warrant division into two areas, or are due to mistakenly including adjoining areas in the analysis of VP due to its extreme narrowness in macaque monkeys.^{96,118,160}

V3A

V3A corresponds to a complete representation of the visual field located anterior to dorsal V3.^{19,59} Although originally thought to function as an “accessory” to V3,¹⁹² this area is not especially tied to V3 functionally. In monkeys, the neurons of V3A differ from those of neighboring dorsal V3 in being less selective to the speed and direction of stimulus motion.^{64,174} In humans, however, V3A is more motion sensitive than V3.¹⁵⁶ Repetitive TCMS to V3A disrupts judgment of stimulus velocity as much as TCMS to MT.¹⁰¹ In both humans and monkeys, V3A is activated by disparity stimuli¹⁶⁸ and responds better to achromatic stimuli than to color-defined stimuli,^{34,93} placing it in the dorsal stream of visual processing. V3A receives ascending projections from V1, V2, and V3 and projects most strongly to other dorsal stream areas, including MT and MST¹⁷ and to parietal area LIP, an important area for coordinating stereoscopic vision with prehensile hand movements.¹⁰⁸ Projections to temporal lobe areas exist, but are relatively minor.⁴⁶

PO/V6

PO and V6 were defined independently in macaque monkeys, but were later concluded to correspond, at least in part, to the same area in the parietal-occipital sulcus.⁶² V6 contains a complete representation of the visual field, with the representation of the horizontal meridian forming the posterior border, and the vertical meridian forming the anterior border.⁶¹ Peripheral visual field representation is enhanced in V6, relative to other areas. V6 receives an extensive, topographically organized, projection from V1,⁶³ arising mostly from layer 4B, but with a component from layer 3B as well. As a dorsally located projection zone of V1, V6 resembles the medial area (M) and/or dorsal medial area (DM) described previously in New World monkeys⁸¹ (see Chapter 30). V6 is connected with other dorsal stream areas, and provides input to parietal cortex, especially cortex immediately anterior to it, known variously as V6A or MIP.⁶³ An area claimed to correspond to V6 in humans was discovered in the posterior and superior part of the parieto-occipital sulcus, at the medial border of V3 and V3A.¹²⁴ Large field stimuli were needed to generate responses in this area, as, similar to V6 in macaque monkeys, the map emphasizes the periphery of the visual field.

Parietal lobe areas

The dorsal stream of visual processing continues in a constellation of areas in the parietal lobe, particularly in the intraparietal sulcus, which form the interface between perceiving visual stimuli and planning motor actions for controlling arm and eye movements in space.⁶⁸ In the macaque monkey, the most important of these are the lateral intraparietal area

(LIP) and surrounding areas and area 7a. LIP receives input from MT and MST and, in turn, projects to area 7a.⁹⁰ Area 7a sends ascending projections to frontal cortex, including the frontal eye fields, which are important in programming eye movements (Box 31.4), as well as cingulate and parahippocampal cortices.²⁷ Area 7a is also interconnected with subcortical structures related to ocular and vestibulo-ocular function.⁵¹

Receptive fields of intraparietal areas are large, as much as 60 degrees across, and often extend across the midline. Different classes of intraparietal neurons have been identified with sensitivities for: depth relative to the fixation plane, linear movement in depth, rotation in depth, 3D orientation for object manipulation, and 3D axis or surface orientation.¹²⁸ Neurons in area 7a also receive extra-retinal oculomotor inputs, and their firing may be modulated by the horizontal and vertical position of the eyes in the orbits.⁷ The combined eye position and visual signal in area 7a is sufficient to determine the spatial location of an object. Accordingly, lesions in this area lead to deficits in reaching for an object in three dimensions using visual guidance.⁸⁷

As in monkeys, the intraparietal sulcus in humans is important for visuomotor tasks comprising target selections for arm and eye movements, object manipulation, and visuospatial attention. At least four intraparietal visual areas have been identified in humans,^{134,149} although the homology of each of these areas with individual areas in macaque monkeys is unresolved, probably reflecting true species differences.^{68,117} Lesions of parietal visual areas in humans lead to apraxia, neglect, and Balint’s syndrome. Similarly, TCMS of human posterior parietal cortex degrades accuracy of saccades to remembered locations,^{119, 18} disrupts visually guided reaching behavior,¹⁷¹ and reduces detection and exploration of contralateral stimuli.^{106,114,170}

Areas of the ventral stream

The ventral stream of visual processing deals with the general problem of object recognition. Ventral stream-bound outputs from V1 and V2 funnel through V4 to reach areas of the temporal lobe.

V4

V4 was first described in the macaque monkey as a target field of projections from V2 and V3 in the lunate sulcus (Box 31.5).¹⁹¹ V4 is sandwiched between ventral V3 and MT, with the lower visual quadrant represented dorsally and the upper visual quadrant represented ventrally.⁶⁵ The upper visual quadrant apparently extends into the temporal lobe, although the border of V4 here is unclear. Retinotopic mapping with functional imaging suggests that the temporal extension, V4v, is actually a separate area distinct from V4d.⁵⁹ The borders of V4, especially with regard to the issue of extension into the temporal lobe, are not architectonically distinct.⁹¹ A transitional area, V4t is more closely related to MT than V4, and separates V4 proper from MT.⁴³ In humans, as in monkeys, the boundaries of V4 have been difficult to resolve. It has been proposed that a dorsal V4d and a ventral V4v exist as in monkeys.⁷⁵ It has also been proposed that, instead of a single V4d, two complete maps of the visual

Box 31.5 Area V4

- Extrastriate area of the ventral (what) stream
- Displays orientation and color sensitivity as well as binocular disparity
- Strong inputs from blob and interblobs of V1 and thin stripes of V2 as well as V3
- Projects to PIT and CIT in the inferotemporal areas
- Located in the lingual and fusiform gyri in humans
- Bilateral lesions may cause complete cerebral achromatopsia (loss of color perception) in which patients perceive the world in different shades of gray; unilateral lesions may go unnoticed by patients

field, given the names LO1 and LO2, occupy the space between V3 and MT, and that V4v is a completely separate area.^{88,149} Monkey V4d has also been proposed to be composed of rostral and caudal subdivisions,¹⁴⁸ although they may not correspond to the proposed human subdivisions.¹⁶⁹

V4 receives ascending projections from V1, V2, and V3.¹⁶⁹ The neurons of origin of the V1 projection are concentrated in the foveal part of V1 and arise from neurons in layers 3A and 3B, from both CO blobs and interblobs.^{109,183} Inactivation studies show that V4 depends on both the parvocellular and magnocellular LGN channels.⁵⁷ From V2, projections arise from cells in thin stripes and interstripes, so neurons projecting from V2 to V4 interdigitate with those projecting to MT.^{137,187} Although no mosaic organization is present in CO staining in V4, the projections from thin stripes and interstripes appear to be segregated within V4, suggesting that the separation of blob/interblob-related information may continue in V4, although not yet seen in the histology.^{55,181} The size and arrangement of these columns are not well characterized, although they are larger than the modules in V2.

The main outputs of V4 are to areas PIT and CIT in the temporal lobe, involved in detailed form analysis for object vision. These temporal lobe projections also demonstrate segregation related to the CO-defined streams, as injection sites in V4 labeling thin stripes tended to receive more restricted feedback from temporal cortex than injection sites labeling interstripes.¹⁸¹ Peripheral, but not central, field representations of V4 are connected with parietal areas (LIP, PIP, VIP) which could involve V4 in circuits serving spatial vision and spatial attention.¹⁶⁹

V4 contributes to many aspects of visual processing, including form, color, visual attention, and stereopsis.¹²⁰ Cells in V4 show selectivity for stimulus hue, orientation, size, and binocular disparity.^{41,42,131,190} Only a small proportion of cells in V4 show direction selectivity. Cells selective for color are concentrated in ventral V4,¹⁹⁰ and this area may best be considered an area separate from V4d. Cells in ventral V4, but not in V1 or V2, display shifts in preferred hue with changes in illumination. This is necessary for color constancy, the ability to perceive an object as being the same color when illuminated with light of different spectral composition.⁸⁶ Computation of color constancy, which entails taking the spectral information from an object and subtracting the spectral information from a large area surrounding it, is thought to be accomplished in V4 neurons by their large, spectrally sensitive, suppressive surrounds.¹³¹

Many V4 neurons show strong systematic tuning for the orientation and acuteness of angles and curves.¹²¹ Unlike the responses of neurons in V2 to complex shapes,⁸⁰ the tuning in V4 can not be accounted for by selectivity for the orientation of a single edge of the angle, but is determined by the curvature at a specific boundary location within the shape. The computation of curvature selectivity in V4 from more basic orientation and spatial frequency-selective inputs from V1 and V2 is an intermediate step towards the complex shape selectivity found in inferotemporal cortex.¹¹⁶

Inferotemporal cortex

The areas of the inferotemporal cortex form the final stage of the ventral visual pathway for the recognition of visual objects.⁶⁰ The inferotemporal cortex receives projections from V2 and V4, and is interconnected with many multimodal brain sites including the hippocampal formation, prefrontal cortex, amygdala, and the striatum. Although inferotemporal cortex definitely contains several different visual areas, the borders of these areas are unclear, and several different naming schemes are used.¹⁷² Nevertheless, it is generally agreed that IT cortex can be divided into more posterior areas that receive dense inputs from V4 and V2 (subdivisions of PIT; roughly corresponding to the classical cytoarchitectonic temporal occipital area, TEO), and more anterior and ventral areas (CIT and AIT; within cytoarchitectonic temporal area TE) that are interconnected strongly with PIT/TEO but only weakly with V4 and not at all with V2.^{17,46,107,169}

PIT/TEO

Within PIT, retinotopic mapping shows a complete hemifield representation ventrally (PITv) and some evidence for a dorsal (PITd) subdivision.^{16,20,59,173} Receptive fields are larger and shape selectivity is more complex for neurons in PIT/TEO than in V4, requiring particular arrangements of multiple contour fragments,²² but PIT neurons are not selective for complex objects as are neurons in TE.

PIT receives most of its input from V4, with some inputs from V2; the V2 inputs arise from thin and interstripes, the same compartments that project to V4.¹⁰⁷ Individual columns in PIT receive projections from multiple, separate patches in V4. Adjacent columns in PIT receiving inputs from separate, interleaved sets of V4 patches, showing that the segregation of connectivity (and likely function) that is found in V2 continues through V4 and into PIT.⁵⁵ PIT projects to visual areas in TE.

Not surprisingly, given its inputs from areas known to contain color-responsive cells, PIT contains a class of cells that respond selectively to colors.^{34,85,150} Color-selective cells in PIT resemble those in V1 and V4 in their tuning properties, responding selectively to a similarly narrow range of hues and saturation, but with larger receptive field sizes.⁷⁴ Divergent feedback projections from these cells to V4 is thought to create the large, color-selective surrounds of V4 neurons. Color-selective cells are found in separated patches several millimeters wide throughout a large extent of occipitotemporal cortex including ventral V4, PIT/TEO, and posterior portions of CIT/TE, suggesting that this region could best be described as comprising a single cortical area with a large-scale modular organization.^{33,157} Monkeys

with lesions of medial occipitotemporal cortex that include PIT and surrounding cortex show deficits in color discrimination.^{24,36}

In humans, a color-selective area (known variously as V8, V0, and hV4) has been reported adjoining ventral V4, in the region of the lingual and fusiform gyri.^{10,19,73} Although its receptive field organization and homology with visual areas in monkeys is still unclear,^{133,177} it appears to correspond to the area damaged in clinical cases of cerebral achromatopsia.^{153,184}

TE

With further progression along the ventral pathway into cytoarchitectonic area TE, retinotopic organization of visual areas is no longer apparent. Neurons have large receptive fields that nearly always include the fovea but also include most of the contralateral visual field, and many receptive fields extend bilaterally.⁷² Neurons in TE show stimulus selectivity for images of complex objects or shapes such as hands and faces, and show translation invariance, i.e. a neuron responds similarly to its preferred stimuli no matter where they are placed in the receptive field. TE neurons may also show invariance for stimulus size and rotation.¹⁵¹

The images of complex objects that stimulate TE neurons can be systematically simplified to find the minimal critical features for activation.¹⁵¹ A cell that responded to a picture of a water bottle, for example, also responded to a simpler stimulus composed of a vertical ellipse with a downward projection, but it did not respond to the ellipse alone. There is a columnar organization to the selectivity for these critical features in inferotemporal cortex, such that cells within the same cortical column respond to similar, although not identical, features. Furthermore, adjacent columns have partially overlapping feature selectivity, as, for example, profile and frontal views of faces.¹⁵² Feature selectivity in inferotemporal cortex partly depends on experience, such that training monkeys to discriminate a specific set of shapes increases the proportion of TE cells responding to the shapes of the training set.⁸⁴

In humans, as in monkeys, non-retinotopic, object-selective visual areas ventral and anterior to V4 can be recognized.^{69,71} Due to the expansion of the human brain, however, these areas are in lateral occipital (LO) cortex rather than extending into the temporal lobe. Not containing an orderly map of the visual field, they are defined functionally as areas that show a greater fMRI response to images of objects compared to non-object control images.⁶⁹ Adaptation, the lessening of fMRI responses to repeated presentation of similar visual stimuli, was used to show that neurons in LO generalize responses for the same objects across differences in size, shape, and viewpoint,^{70,130} i.e. LO shows constancy similarly to monkey inferotemporal cortex.

Face-selective responses were first shown for single neurons in monkey inferotemporal cortex.⁷² Several concentrated patches of face-selective cells in this region have been identified by fMRI and verified by single unit recording within the identified patches.^{165–167} Within a patch, 97% of the cells were face selective, showing, on average, an almost 20-fold larger response to faces than to non-face stimuli. In humans, there are at least two extrastriate areas that respond more to pictures of faces than objects, one in the middle fusiform gyrus (FFA), and one more posteriorly, in the

Box 31.6 Summary of major points

- Extrastriate visual cortex contains a constellation of richly interconnected areas comprising large portions of the occipital, parietal, and temporal lobes and contributes to a diverse array of visual information-processing tasks
- Extrastriate visual areas are identified by a combination of features including receptive field mapping, histology, patterns of connections with other brain regions, and functional specificity
- In both monkeys and humans a dorsal visual pathway dealing with object location extends through V2, V3, MT, PO/V6, and into parietal cortex
- In both monkeys and humans a ventral pathway dealing with object recognition extends through V2, V4, and into temporal cortex

inferior occipital cortex OFA, although it should be stressed that these areas are not homologous with face-preferring regions in monkeys.⁷¹ Patients with lesions of these areas display difficulty in face processing, including prosopagnosia, a specific inability to recognize individual faces.^{11,38,111}

Visual cortical areas in TE project to more ventral and rostral parts of the temporal lobe which integrate polymodal sensory inputs and are critically involved in the formation of memory, including visual memory.⁶⁰ Functional imaging in humans suggests an area on the parahippocampal gyrus (parahippocampal place areas; PPA) which is preferentially activated by images of places, i.e. buildings and landscapes, and appears to be involved in the encoding of places in memory (Box 31.6).⁹⁷

Early Processing of Spatial Form

Robert F. Hess

Introduction

Vision is our most developed sense and unsurprisingly a substantial amount of brain processing is devoted to it, with over half the primate brain involved in vision-related processing.¹ A first step in understanding the nature of this processing involves an appreciation of the capabilities and specialization that define human vision. Such an understanding of our overall visual strengths and weaknesses provides a framework within which the emerging neurophysiology and neuroanatomy of different parts of the pathway can be best understood.

Early visual processing of spatial form has to contend with the fact that information that first impinges on receptors in the eye must be transmitted to the main processing sites in the brain. There are transmission bandwidth considerations to ensure the optic nerve/optic track remains of manageable size. What this means is that of all the information contained in a retinal image, only a fraction of it can be efficiently transmitted and processed; hard choices have to be made. This leads us into the concept of sensory filtering and information compression. The fact that individual cells have limited dynamic ranges also leads to a consideration of distributed parallel processing. These notions, namely filtering, compression, and parallel processing, are important principles in sensory analysis in general and visual analysis in particular.

Foveal window of visibility

It has only been relatively recently that quantitative methods have been developed to help quantify human vision. These developed from the realization of the importance of contrast and object size (or spatial frequency). That contrast is fundamental to the visibility of objects had been known for a long time. Bouguer² developed the first quantitative measurements of contrast sensitivity, using the visibility of the shadow of a rod produced by a candle at a specified distance away. That the size of objects (more correctly their retinal image size) also determines their visibility has also been appreciated for a long time, being the basis of acuity testing in the last century. The realization that the relationship

between these two variables could provide a more complete description of human vision was a logical consequence of the emerging work on optical transfer functions and was accelerated by the need for calibrated photographic surveillance methods during World War II.³ Amid great controversy, particularly from certain optical physicists of the time, Campbell and co-workers^{4,5} used this approach to great effect to provide a quantitative description of the capability of the human visual system, which in turn provided a starting point for considerations of optical quality of the human eye and its neural limitations. This function, often referred to as the spatial contrast sensitivity function, provided the first quantitative description of our “window of visibility” and makes explicit the information that our visual system processes best.

Figure 32.1 displays a sinusoidal grating stimulus that was first developed by Fergus Campbell and John Robson at Cambridge in which the spatial frequency (number of cycles subtended in one degree at the eye) is modulated along the abscissa (low spatial frequencies on the left, high spatial frequencies on the right) and contrast is modulated along the ordinate (low contrasts at the top, high contrasts at the bottom). The reader can observe an inverted U-shaped region in which the stripes are visible – this is a demonstration of our window of visibility.

In Figure 32.2 laboratory measurement of the contrast sensitivity function is displayed for a normal observer; its overall shape mirrors that seen in Figure 32.1. Here, contrast sensitivity, the reciprocal of the contrast needed for threshold detection, is plotted against the spatial frequency of a luminance-defined sinusoidal grating (filled circles), in cycles per degree of angle subtended at the eye. Our window of visibility is defined by an inverted U-shaped function that shows we are best at detecting objects subtending about a half to a third of a degree (approximately half the width of one’s finger nail at arms length). Our sensitivity for detecting smaller objects (i.e. of higher spatial frequency) progressively declines, as it also does for detecting objects larger (i.e. of lower spatial frequency) than one degree. Information in the very low contrast range, particularly if it is of very low or very high spatial frequency, is not processed at all by our visual system; human vision is specialized in the intermediate spatial frequency range and within this limited range our contrast sensitivity is good to one part in 500 (i.e. 0.2

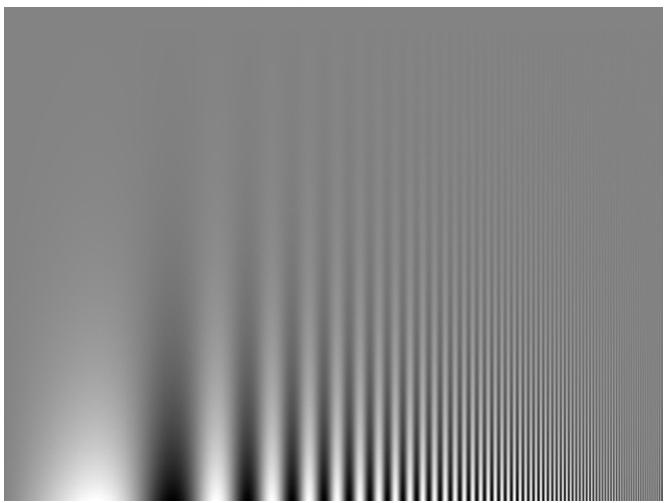

Figure 32.1 A demonstration of the window of visibility. A sinusoidal grating is increased in spatial frequency, going from left to right along the abscissa and its contrast is reduced, going from bottom to top along the ordinate. The inverted U-shaped region over which the stripes are seen is a facet of our visual systems (developed by Campbell & Robson).

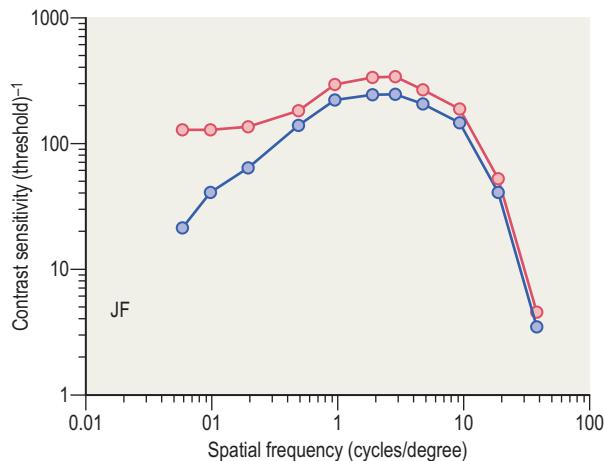

Figure 32.2 The contrast sensitivity function for sinusoidal (blue circles) and squarewave (red circles) gratings. Contrast sensitivity (reciprocal of the contrast threshold) is plotted against the spatial frequency for vertically oriented gratings. At each spatial frequency, five cycles of the grating were present and the length of the bars was greater than the critical length.⁶⁶ The exceptions were the data at 30 and 40 c/d where 120 cycles were used. When measured under comparable conditions of areal summation (length and height), the contrast sensitivity function has a broader peak centered at around 3 c/d and a low spatial frequency decline beginning at around 0.5 c/d (data from Hess & Howell¹⁰).

percent) under monocular conditions. Other animals have visual capabilities adapted to match their particular needs; the cat is better than the human at detecting low spatial frequencies and the falcon is better than the human at detecting high spatial frequencies. These benefits, however, come with associated costs. The cat is much worse than us at detecting high spatial frequencies and the falcon much worse than us at detecting low spatial frequencies. In other words the size of the window of visibility is approximately the same for different animals but shifts along the abscissa (i.e. the spatial frequency axis) to best suit the needs of the

animal. For the cat, this means things within pouncing distance (resulting in a shift of the function to lower spatial frequencies) and for the falcon, for detecting ground prey when hovering high in the sky (resulting in a shift of the function to higher spatial frequencies).

What limits our contrast sensitivity?

Why are we poor at detecting objects of very high and very low spatial frequency? In terms of the former, an obvious possibility is that the retinal image may not contain this information in the first place due to optical (i.e. cornea, lens) losses. Campbell & Green,⁴ using a laser interferometric technique to bypass the optics, showed that the fall-off of contrast sensitivity at high spatial frequencies only had a small (about one-third) optical component. They argued that two-thirds of the sensitivity loss at high spatial frequencies was neural in nature, due to limitations at the retina/brain (Box 32.1). More recently it has been suggested that the quantal fluctuations in light itself may account for the loss at high spatial frequency.⁶ Although not yet resolved, in light of the discussion below in the section on luminance effects, the original suggestion that this fall-off is neural in nature seems more likely. The sensitivity loss at low spatial frequencies only occurs for sinusoidal stimuli (i.e. as opposed to squared-edged stimuli, as shown in Figure 32.1) and many different explanations have been put forward including, relative image stabilization,⁷ a consequence of reduced cycles⁸ or lateral inhibition.⁹ None of these hold up to scrutiny; providing a comparable temporal stimulation and having the same number of spatial cycles does not eliminate the low spatial frequency decline in sensitivity.¹⁰ The lateral inhibition explanation can also be rejected for reasons that are outlined in the section below on the relation to single cells. Its explanation has proved elusive.

What is the relationship between the contrast sensitivity function and the response of single cortical cells?

Neurons at various levels of the visual pathway exhibit spatially overlapping excitatory and inhibitory receptive field properties¹¹ that endow them with size or spatial frequency dependence,¹² as illustrated in Figure 32.5. This size selectivity becomes greater as one progresses from retina to cortex owing to the increased strength of the antagonistic surround. These neurons also exhibit contrast thresholds, quasi-linear contrast response regions and contrast saturation responses.¹³ Indeed, efforts to outline the optimum spatial frequency response of a sample of contrast-sensitive neurons in the monkey have provided a distribution similar to that of the human behavioral contrast sensitivity function.¹⁴ This can be seen in Figure 32.3 from the histogram of the distribution of cellular contrast sensitivities in monkey V1 relative to human behavioral sensitivities. The contrast sensitivity function represents the envelope of all the contrast-responding cells with the most sensitive ones defining the threshold limit.

Visual cortical neurons have sufficiently strong surrounds to their classical receptive fields to make them selective over a limited part of the spatial frequency range;^{15–17} an example is shown in Figure 32.4. Thus different populations

Rights were not granted to include this figure in electronic media.

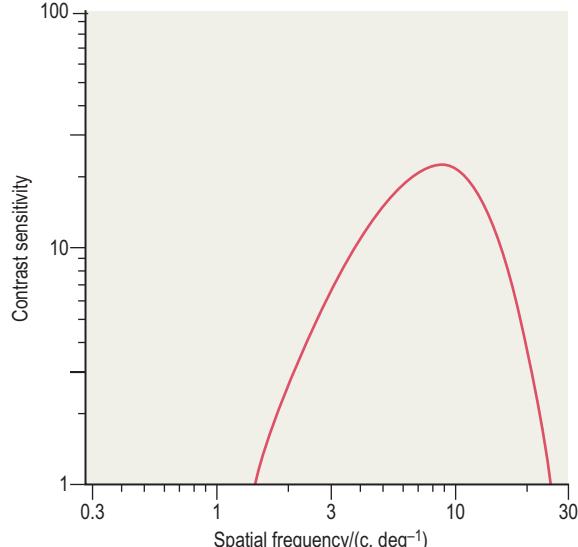

Figure 32.4 Typical spatial tuning function of a cortical cell in area V1. Cellular response in spikes/sec is plotted against the spatial frequency of an optimally oriented grating stimulus (data from Hawken & Parker¹⁴).

of cortical cells underlie the contrast sensitivity curve at different locations along the spatial frequency axis; the overall contrast sensitivity curve being the envelope of the sensitivity of the most sensitive cortical cells. This is diagrammatically illustrated in [Figure 32.5](#).

Psychophysical supporting evidence comes from the finding that adaptation or prolonged viewing of stimuli of one particular spatial frequency desensitizes responses for only stimuli of a similar spatial frequency, also suggesting that the overall curve is composed of a number of more discrete "channels".^{8,18} At one time it was thought that the low spatial frequency fall-off in sensitivity was a reflection of the surround inhibition of the largest (or lowest spatial frequency-tuned) mechanism whose peak was located around 1 c/deg.⁹ There is now ample evidence to doubt this;

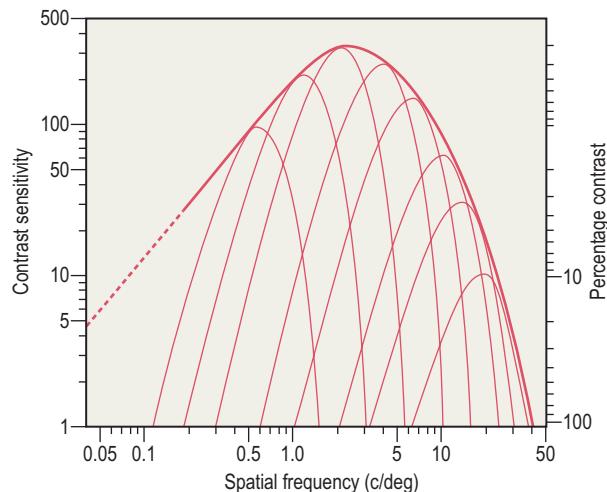

Figure 32.5 Illustration of the relationship of the spatial frequency selectivity of single cortical cells, measured neurophysiologically, to that of the overall contrast sensitivity function of the visual system, measured psychophysically.

individual spatial frequency selective mechanisms have been reported down to as low as 0.2 c/deg.^{10,19,20} Thus individual cortical mechanisms extend across the full extent of the visible spatial frequency range. The reason why the lower spatial frequency mechanisms are less sensitive is unknown but one possibility is that it may be due to a purely retinal cause; larger receptive fields must inevitably contain more inactive rods (contributing no signal but possibly contributing noise) under photopic conditions.

The contribution of M & P pathways to contrast sensitivity

In the retina there are morphologically and functionally different populations of ganglion cells²¹ two of which, the parasol (magno; 10%) and midget (parvo; 80%) retinal ganglion cells send their afferents along the retino-geniculate pathway. These projections are kept separate in the geniculate terminating in the magno- and parvo-cellular layers respectively (so called M-cells and P-cells). The afferents of these two geniculate cell types are sent to different layers of 4C of the visual cortex (i.e. 4C alpha and 4C beta) and ultimately make a dominant (though not exclusive) contribution to the dorsal and ventral extrastriate streams respectively.

Do these two parallel systems carry the same or different contrast sensitivity information?

The combination of single cell recording²² and lesion studies^{23–25} has revealed that these two systems carry different though overlapping visual information to the cortex. The M-cell information is biased to lower spatial and mid-temporal frequencies. P-cell information is biased to mid-higher spatial and lower temporal frequencies. A particular subdivision of the M-cell system, the Y-like M cell, exhibits properties that suggest it may have a special role²⁶ in perception. The results shown in [Figure 32.6](#) are from the lesion studies of Merigan and colleagues^{23–25} and represent how the spatial and temporal contrast sensitivity function is affected

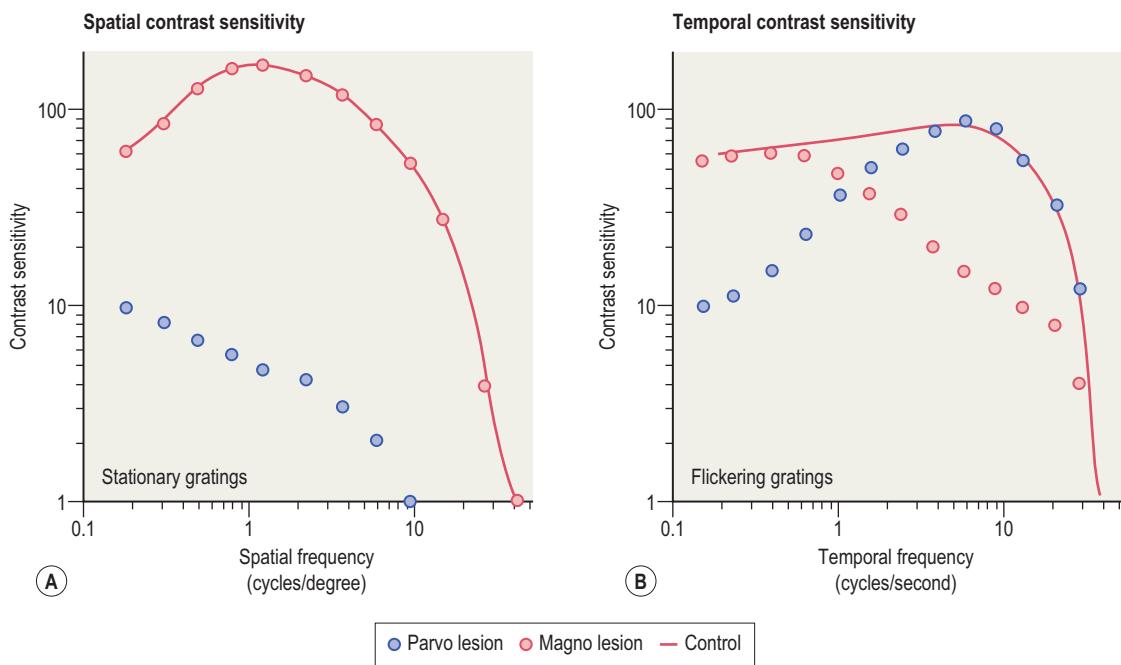

Figure 32.6 The relative contribution of M- and P- systems to spatial and temporal contrast sensitivity from the LGN lesion work of Merigan and colleagues.^{23–25}

by lesions to parvo- and magno-cellular regions of the LGN of the monkey. Parvo-cellular lesions have a large effect on spatial contrast sensitivity at all spatial frequencies for static stimuli. Magno-cellular lesions reduce temporal contrast sensitivity in the mid range for spatial stimuli of low spatial frequency. Parvo-cellular lesions also produce a loss of color vision since red/green chromatic information is conveyed by this system.

The contribution of different cortical areas to contrast sensitivity

A number of different regions of the visual cortex contain a retinotopic map and are therefore given the status of being "distinct" visual areas.²⁷ V1 receives the majority of the input from the geniculate although there is evidence that V2²⁸ and MT²⁹ also receive a direct input in primates, although its role may be more modulatory in nature.³⁰ Although V1 contains cells with both small and large receptive field sizes at each eccentricity (approximately a factor of 4 in receptive field size at any one eccentricity from the data of Hubel & Wiesel³¹), cells with smaller receptive fields progressively drop out as eccentricity increases, resulting in a shift of the mean receptive field size with eccentricity to larger values.³¹ Other visual areas have cells with larger receptive field size and consequently diminished retinotopy. Area V2 has cells that are tuned to lower spatial frequencies than those found in V1,³² however there is no compelling evidence from lesion studies that cells other than in V1 make a major contribution to spatial contrast sensitivity.³³

The effect of disease on contrast sensitivity

Having a more quantitative approach for specifying the quality of normal vision also provides a more sensitive

Box 32.1

A contrast sensitivity loss at high spatial frequencies may be optical or neural in nature.

method for documenting visual loss. Given that contrast sensitivity is not a unitary function but one representing the envelope of a large number of more narrowly tuned functions (i.e. the individual sensitivity of different populations of cortical neurons tuned to different ranges of spatial frequency), there was hope that a knowledge of the relative susceptibility of these neural populations might lead to a better understanding of a number of retinal and cortical diseases affecting the visual system. This expectation has been only partially realized because although the specification of the contrast sensitivity function provided more information than before it also has inherent limitations. Without an understanding of these limitations any simple interpretation of contrast sensitivity in disease becomes hazardous. The strengths and weaknesses of the approach can be best appreciated by one or two examples, one involving a developmental condition called amblyopia, the other, an acquired condition called optic neuritis. The reader can imagine how comparable issues could concern the interpretation of anomalous contrast sensitivity in related conditions, for example glaucoma and age-related maculopathy.

One of the first conditions to be studied with the contrast sensitivity approach was amblyopia, a common developmental disorder in which the vision in one eye is compromised in early life. It was shown (Fig. 32.7) that high spatial frequencies were selectively affected.³⁴ Although in some strabismic amblyopes it was subsequently shown³⁵ that additional and unrelated losses can occur at low spatial frequencies, the picture today is not substantially different

from that originally outlined by Gstalder & Green³⁴ over 30 years ago. Indeed its application to the study of amblyopia has highlighted some potential pitfalls of using this approach. The first concerns the fact that it is limited to threshold. Amblyopes need much more contrast in order to

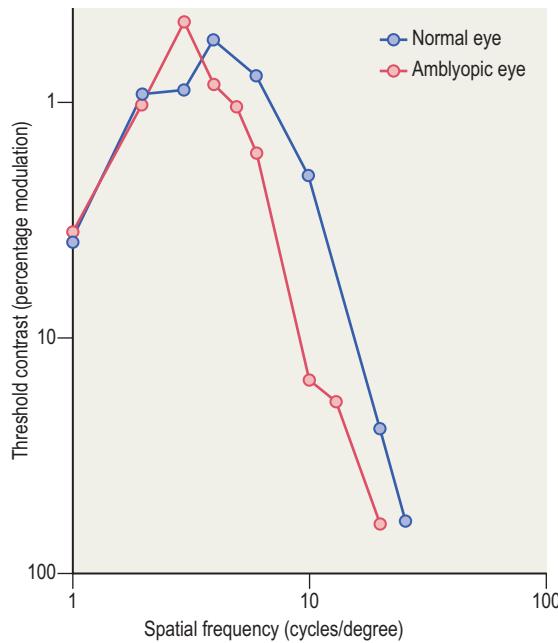

Figure 32.7 The first contrast sensitivity function measured in amblyopia. The reciprocal of the contrast threshold is plotted against the stimulus spatial frequency. The higher the spatial frequency, the greater the loss of sensitivity of the amblyopic (red symbols) compared with the fellow fixing eye (blue symbols) (data from Gstalder & Green³⁴).

detect higher spatial frequencies; however at and above their raised thresholds they perceive contrast normally with their amblyopic eye.³⁶ This is illustrated in Figure 32.8 in which results are shown for contrast matches made between the eyes of the two most common types of amblyopia, strabismic (A) (i.e. turned eye) and (B) non-strabismic (i.e. anisometropia without a turned eye). Thresholds are raised (unfilled symbols) but as the contrast is raised to suprathreshold levels, it is perceived normally (solid diagonal line indicates matches that are veridical). The difference between the raised thresholds and normal perception of suprathreshold contrast is abrupt in the case of strabismic amblyopes (Fig. 32.8A) but more gradual in the case of non-strabismic, anisometropic amblyopes (Fig. 32.8B). In other words, thresholds are not representative of contrast vision above threshold; the contrast sensitivity function is highly nonlinear when it comes to contrast.

In optic neuritis, which commonly occurs as part of multiple sclerosis, similar high spatial frequency loss is observed in the contrast sensitivity function but it is not just limited to threshold. Sufferers of optic neuritis who need, for example, a factor of 10 more contrast to detect a given spatial frequency will perceive that spatial frequency to be a factor of 10 reduced in contrast, no matter what its absolute contrast is.³⁷ With respect to the results of Figure 32.8 for strabismic and non-strabismic amblyopia, the equivalent contrast-matching function for a person with optic neuritis would run parallel but below the normal matching line (solid diagonal). Amblyopia and optic neuritis can exhibit similar threshold losses but their suprathreshold contrast losses are very different.

Another limitation is that contrast sensitivity may be normal and yet spatial vision may be severely degraded.

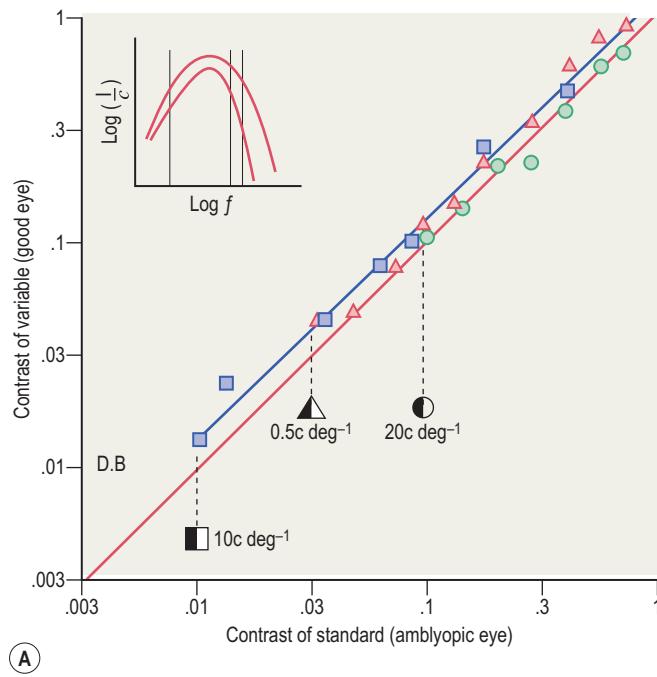

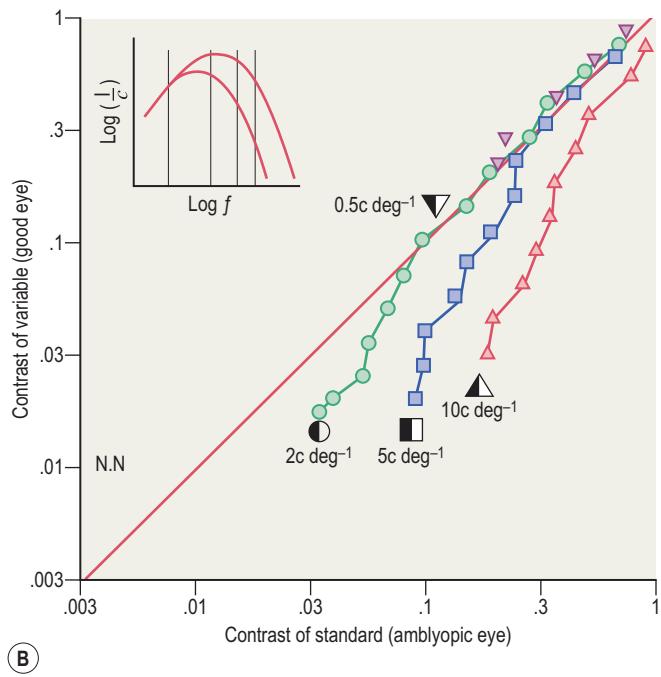

Figure 32.8 Contrast matching results showing how contrast is perceived by the amblyopic eye. The results plotted in (A) are for a strabismic amblyope while those in (B) are for a non-strabismic anisometrope. The amblyopic eye sees a number of fixed contrasts and a variable contrast stimulus seen by the fellow normal eye is used to match it. The half-filled black/white symbols are thresholds, the solid diagonal line represents the prediction for a normal observer who sees the contrasts comparably in the two eyes (from Hess & Bradley³⁶).

Box 32.2

Measurement of constant sensitivity has minimal value for differential diagnosis as similar losses occur in different diseases but is of value in monitoring sensitivity changes.

Box 32.3

Contrast sensitivity supplies information about threshold detection not suprathreshold perceptions.

Box 32.4

To delineate the regional distribution of the contrast loss, sensitivity has to be measured for localized stimuli at multiple field positions.

Some amblyopes perceive severe spatial distortions that would render a 1-D sinusoidal grating unrecognizable (i.e. spatially scrambled), yet the contrast thresholds for detecting such a scrambled stimulus may be normal.³⁸ Finally the fact that the assessment involves large repetitive patterns means that it supplies no information about how the dysfunction is distributed across the visual field corresponding to the test stimulus. For example, the contrast sensitivity loss of strabismic and anisometropic amblyopes when measured with a relatively large (i.e. 10 degree) centrally fixed stimulus is very similar, yet the visual field is affected very differently in these two conditions; the central field is selectively affected in strabismics and the whole field is evenly affected in anisometropes.^{39,40}

In optic neuritis, initial reports suggested that the loss of contrast sensitivity could be restricted to just a small subset of spatial channels producing a very localized loss of contrast sensitivity within the contrast sensitivity function.⁴¹ Later studies showed that contrast sensitivity could be reduced in a variety of different ways; high-frequency loss alone, low-frequency loss alone, similar loss at all spatial frequencies, or a regional frequency loss (the latter was quite rare). More importantly, all of these different signatures of the contrast sensitivity loss in optic neuritis could be simulated by different types of visual field loss, suggesting that the exact nature of the loss across the visual field could be the primary determinant of the contrast sensitivity loss.⁴² To decipher the regional nature of any visual loss necessitates the use of much more localized stimuli (i.e. a Gabor patch) and measurements made at multiple field positions.

Peripheral window of visibility

One of the more important ways the bandwidth of the visual system has been kept within limits is due to the fact that our ability to process information depends upon where it is imaged on our retinae. The density of retinal ganglion cells is greatest in the fovea¹¹ and much more of the cortical area is devoted to the processing of foveal information than to comparable regions of the periphery.⁴³ As a consequence of

this, our best spatial vision is obtained when fixating with the fovea. Visual acuity is best at the fovea and is progressively reduced away from the fovea which is one of the reasons why we can't read print when we look away from the text. The way in which our visual spatial capacity varies with eccentricity has been the subject of many investigations, but the work of Robson & Graham⁴⁴ has been particularly insightful. They measured the rate at which contrast sensitivity falls off with eccentricity and showed that the higher the spatial frequency the faster the decline in sensitivity with eccentricity and that, when considered in terms of a relative eccentricity metric (i.e. eccentricity not in absolute degrees but in number of cycles at a particular spatial frequency), all spatial frequencies higher than the peak (i.e. $> 1 \text{ c/d}$) followed the same rule; sensitivity was lost at the rate of 60 periods/decade. A later study by Pointer & Hess⁴⁵ extended this to lower spatial frequencies (i.e. $0.8\text{--}0.2 \text{ c/d}$) and showed that a different rule was in operation for these frequencies, namely sensitivity when considered in units of relative eccentricity (i.e. number of equivalent spatial cycles) fell off at a much more gradual rate (i.e. 30 periods/decade). We still don't know why there are two different rules, one for mid-high spatial frequencies and another for low spatial frequencies, though one possibility is that spatial frequencies in these two ranges are processed in different cortical areas, each with their characteristic eccentricity dependence. For example V1 is likely to process the mid-high spatial frequency information, while other higher areas, say V2, process lower spatial frequency information.³²

Whatever the reason, the consequence when we consider eccentricity in terms of degrees is that our window of visibility narrows in a very characteristic way for progressively more eccentric locations. Our visual system selectively loses sensitivity at high spatial frequencies; at low spatial frequencies our sensitivity is relatively constant (Fig. 32.9). It's not that the fovea is best at high spatial frequencies and the periphery is best at low spatial frequencies, as is sometimes thought, humans are just as good at detecting low spatial frequencies across the visual field but simply better at detecting high spatial frequencies with the fovea. The fovea is specialized for the detection of high spatial frequencies.

It is worth stressing that contrast sensitivity measurements are limited by their very nature to threshold and may not give the complete picture. For example, a peripherally imaged high spatial frequency target that can be detected may require say 10 times more contrast than the same target viewed with the fovea, as Figure 32.9 suggests. However, when the peripheral high spatial frequency target is detectable, it does not appear to be reduced in contrast compared with its foveal counterpart. In fact, if the contrast of a peripherally viewed target is slowly increased from below the detection threshold, at some point it is first detected but at this point its perceived contrast will be high, in fact as high as it would be if it were viewed with the fovea. This is illustrated by matching the perceived contrast of a foveal and peripheral spatial target as shown in Figure 32.10. A range of different fixed contrasts for a peripherally viewed target is matched with the same target of variable contrast viewed by the fovea. If foveal and peripheral targets are perceived to be of the same contrast, the results would fall along the solid diagonal line. In fact they do, apart from the fact that a higher contrast is needed to first detect the peripheral target

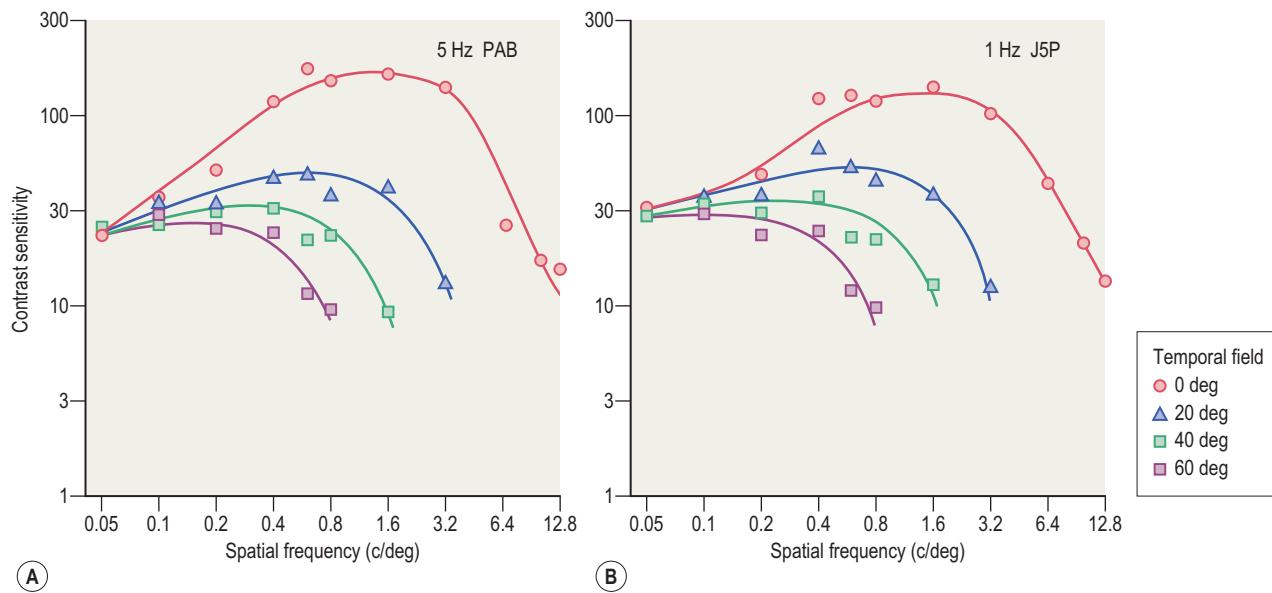

Figure 32.9 The characteristic loss of high spatial frequency sensitivity with eccentric viewing (data from Pointer & Hess⁴⁵). Note that low spatial frequency sensitivity shows little or no decline with eccentricity.

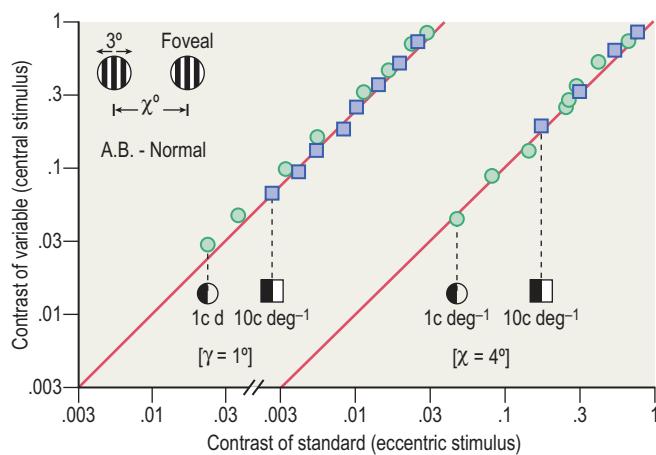

Figure 32.10 Contrast matches made between a peripheral and foveal target. The fixed contrasts were presented peripherally and a foveally viewed stimulus of variable contrast was used to obtain a perceptual match. The half-filled symbols refer to the contrast thresholds and the solid diagonal line represents the prediction that contrast is seen veridically in the periphery (data from Hess & Bradley³⁶).

compared with that of its fovea counterpart (half-filled symbols). It is as if there is a switch that simply truncates the contrast range of the mechanism processing the peripheral stimulus.

Is the periphery specialized for detecting anything?

The fact that we can detect a rapidly flickering (> 60 Hz) pattern-less field in the periphery and not in the fovea⁴⁶ does suggest that for some forms of purely temporal stimulation, the periphery does show a specialization. This is shown in Figure 32.11 where the temporal contrast sensitivity of the fovea and periphery (60 degrees) are compared for a stimulus of low spatial frequency (0.25 c/d). Notice that the

Box 32.5

Reduced temporal acuity for a large pattern-less field suggests a peripheral loss of function.

periphery exhibits slightly better temporal contrast sensitivity (and a higher temporal acuity) in the high temporal frequency range. However this does not apply to the temporal sensitivity of patterned stimuli (i.e. > 1 c/d) whose sensitivity in the periphery is marginally lower than their foveal counterparts.⁴⁵

Why does contrast sensitivity for high spatial frequencies decline with eccentricity?

First, as previously explained, the visual system allocates fewer neural resources to peripheral vision; peripherally, there is a reduced density of retinal ganglion cells and proportionally less allocated cortical area. Also the size of retinal receptive fields increases with eccentricity⁴⁷ and there is a progressive loss of smaller receptive fields with eccentricity in the cortex.³¹ This inevitably means that the spatial range over which we can see restricts with eccentricity. This translates to a foveal specialization. Foveal analysis can be undertaken at a large number of different spatial scales and this provides optimum performance on a number of tasks that rely on combining information across different scales. These include the so-called "spatial hyperacuities",⁴⁸ which have erroneously been considered "acuity" measures but are more readily understood in terms of sensitivity,⁴⁹ often involving multi-scale analyses.⁵⁰

Luminance

One of the truly impressive things about visual processing is the fact that it can operate with such high sensitivity over

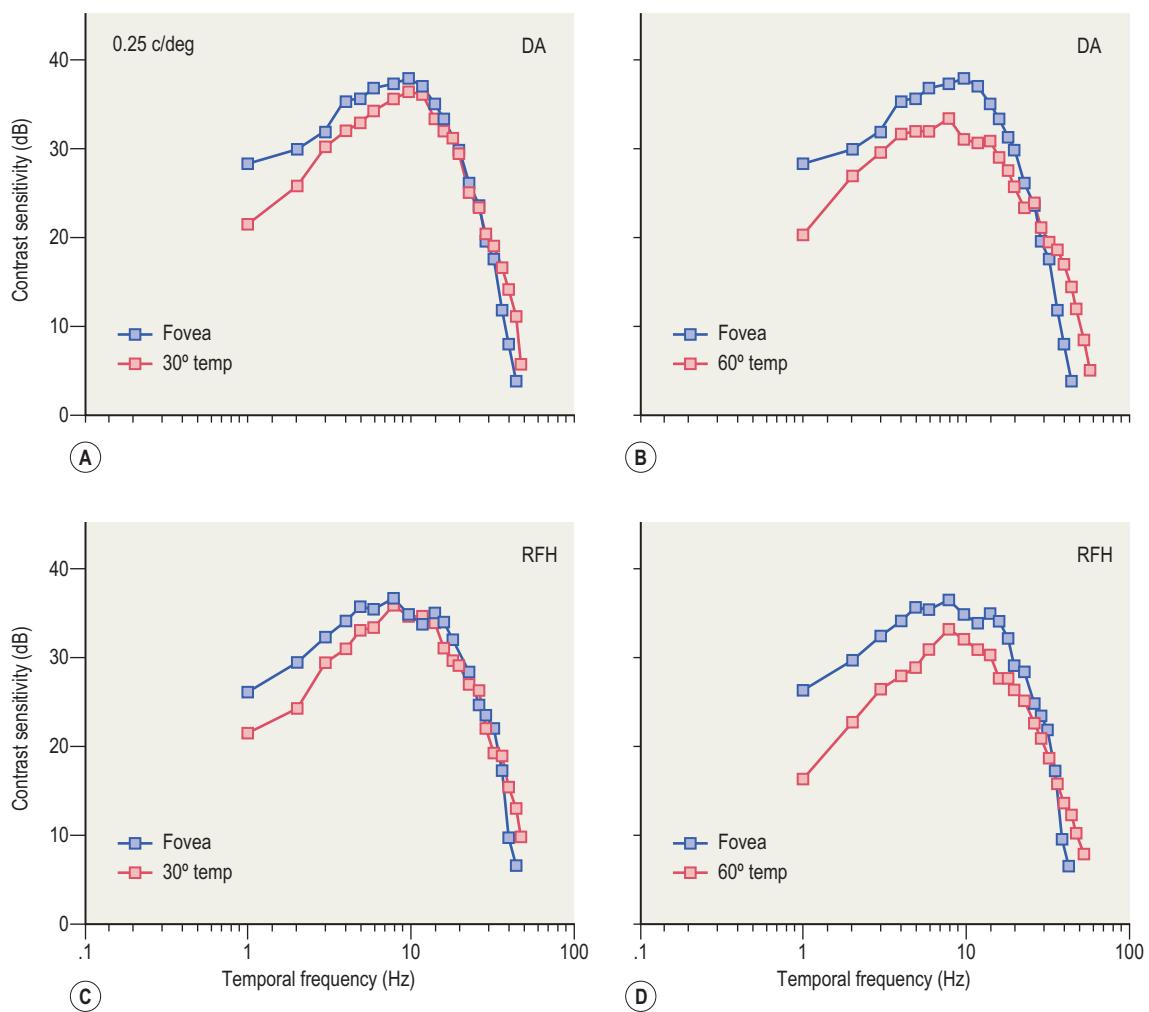

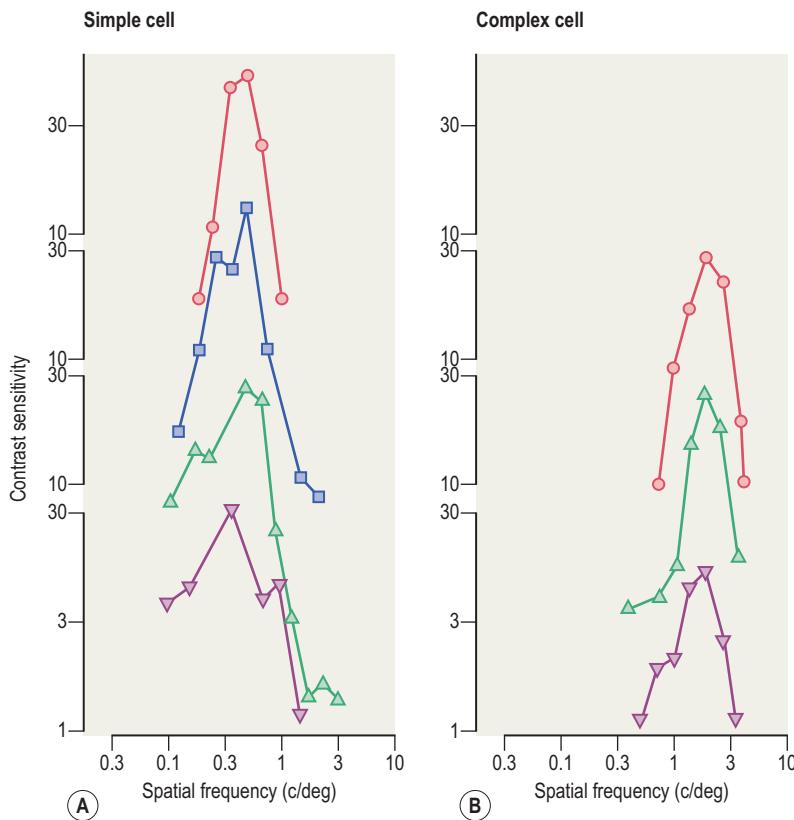

Figure 32.11 Superior temporal sensitivity of the peripheral visual field for a uniform field stimulus (data from Allen & Hess⁴⁶).

such a large luminance operating range. Our luminance operating range is over a million, million to one (i.e. 15 log units) – from a moonlit night to direct sunlight. The fact that we have two receptor systems, one designed to operate optimally during the day, the cones, and another designed to operate optimally during the night, the rods, certainly helps. However it still means that each receptor system has a 7 log unit operating range over which to maintain optimal sensitivity. To achieve this feat, cells in the retina undergo light adaptation. They change their response gain depending on the prevailing luminance. This allows individual cells to be just as sensitive, that is able to respond to just as small luminance increments at very different mean luminances, often many log units apart. The combined effects of the receptoral duality and postreceptoral luminance-dependent response gain changes, allowing our visual processing to operate largely independent of the prevailing luminance conditions. Light adaptation is accomplished in the retina,⁵¹ however the cortex also makes an important contribution to our visual stability when the ambient light level is reduced. In the primary visual cortex the information contained in the retinal image has been decomposed into its spatial components, and cells with different-sized receptive fields that carry

pieces of this spatial puzzle vary in a differential way with luminance. The spatial tuning of these cells remains constant with reducing luminance (unlike their retinal counterparts¹²), only their sensitivity changes and it does so in a way that is dependent on the spatial tuning of the cell.⁵² This is illustrated in Figure 32.12 where the spatial tuning of a cortical simple (A) and complex (B) cell from the cat is shown at a number of different mean luminance conditions.

The cell's response, in terms of contrast sensitivity using an auditory criterion, is plotted against the stimulus spatial frequency. Notice the peak response of the cell remains constant as the ambient light level is reduced by 4 log units (300 cd/m^2 to 0.03 cd/m^2). The same is true for the temporal tuning properties as luminance is reduced.⁵² The lower the peak spatial tuning, the more resistant it is to reductions in the ambient luminance. This means that as luminance is reduced, we lose the contribution of the cells tuned to higher spatial frequencies conveying fine scale information but we retain the information processed by cells tuned to lower spatial frequencies that convey coarse scale information. This results in a relatively stable vision as luminance is reduced but at the expense of spatial detail. The spatial scale dependency of the sensitivity change as luminance is reduced

is best seen in psychophysical measures of sensitivity. This was first shown by Van Nes & Bouman⁵³ and their results are reproduced in Figure 32.13.

Contrast sensitivity is plotted against the mean luminance for a range of different spatial frequencies. Notice that there is a similar form to the response (Fig. 32.13C) at each spatial scale; a sloping region (termed the Rose-de Vries region) where sensitivity depends on the reducing luminance (varies with the square root of the luminance) and a flat region (termed the Weber region) where sensitivity is invariant with mean luminance. The luminance that corresponds to the transition from one behavior to the other also depends on the spatial frequency of the stimuli; the lower the spatial frequency, the lower the luminance needs to be before it begins to affect sensitivity. This is also seen in the responses of individual cortical cells tuned to different spatial scales.⁵² A limit is reached for human vision¹⁰ at a spatial frequency of 0.2 c/d, thought to be the largest summation area available (corresponding to the lowest spatial frequency tuned cell).

Chromatic sensitivity

Primates are unique amongst mammals in having well-developed color vision. The beginnings of this are seen in the retina where information is distributed between different sub-populations of ganglion cells coexisting in the same retinal regions.⁴⁷ The majority of ganglion cells (80%) are of the midget variety (parvo) and these convey one type of chromatic information reflecting their long/medium

wavelength receptor input. Another retinal circuit comprising the short wavelength cones connected to small bi-stratified ganglion cells conveys another form of chromatic information reflecting the short/long+medium wavelength opponency of their receptor input.⁵⁴ The parasol retinal ganglion cells (magno) are not so numerous (10%) and carry the achromatic signals, reflecting a receptor input comprising the addition of all three photoreceptor signals. These three different signals are kept separate in the lateral geniculate nucleus in the parvo- (chromatic long/medium wavelength opponent system), konio- (short/long+medium wavelength opponent system) and the magno-cellular layers (the achromatic system).⁵⁵ The short/long+medium wavelength opponent system that underlies our perception of blue/yellow has a relatively sparse representation as only 7% of cones are short wavelength.⁵⁶ For this reason, the representation of the konio-cellular layers in the geniculate is weak, however there is evidence from both neuro-imaging in humans⁵⁷ and single cell physiology in animals⁵⁸ that this signal is amplified in the transmission from geniculate to cortex such that there is a comparable representation for the two types of chromatic systems in the cortex.⁵⁹

Our chromatic windows of visibility can be obtained by making similar measurements to those already described for luminance-defined sinusoidal gratings by using stimuli whose periodicity is defined solely by either a long/medium wavelength modulation (perceived as red/green bars) or short/long+medium wavelength modulation (perceived as blue/yellow bars). A demonstration is shown in Figure 32.14. The first detailed measurements⁶⁰ of our chromatic sensitivities are shown in Figure 32.15 where modulation

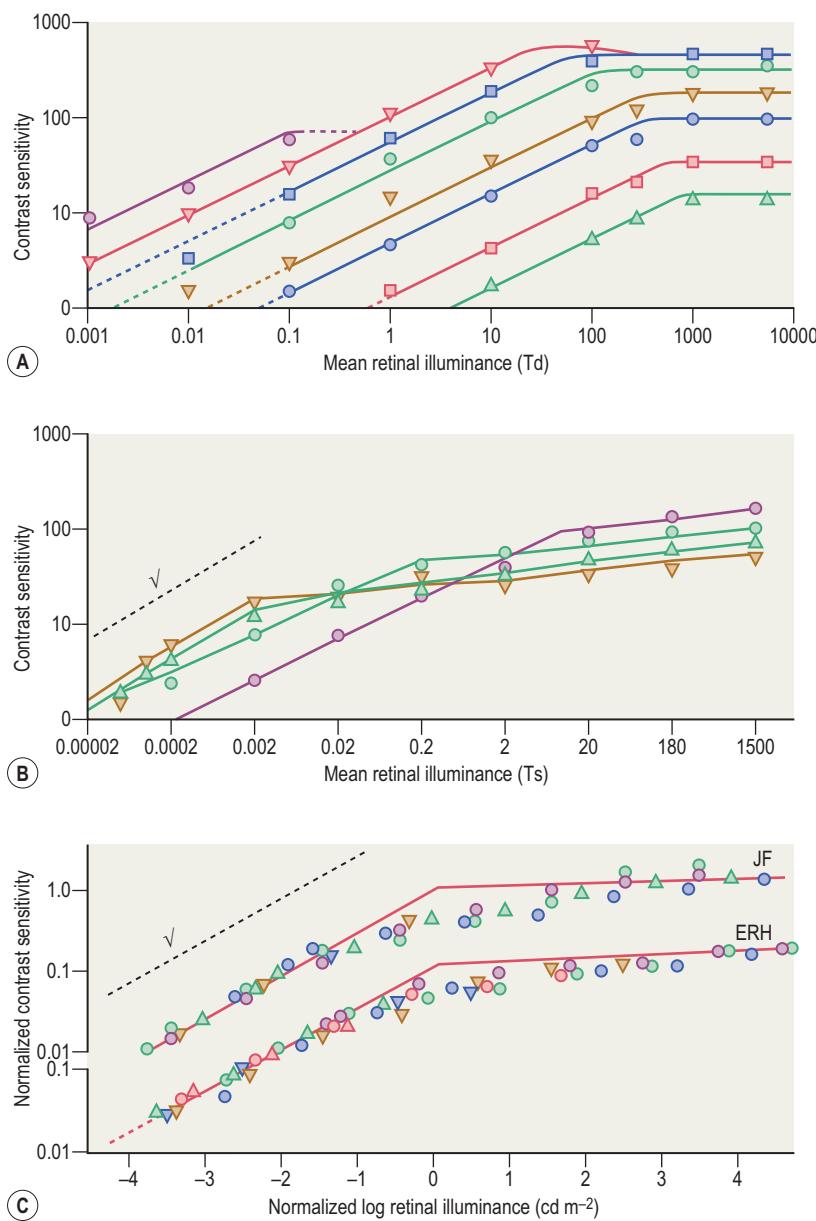

Figure 32.13 The effect of mean luminance on contrast sensitivity. In (A), the results of van Nes & Bouman⁵³ for spatial frequencies in the mid to high range. In (B), the results of Hess & Howell¹⁰ for low spatial frequencies. In (C), normalized sensitivity at different spatial frequencies showing the characteristic features of the dependence of sensitivity on mean luminance (data from Hess & Howell¹⁰).

sensitivity is plotted against the spatial frequency of the stimulus as described above (see Fig. 32.1) for luminance-defined stimuli. The difference now is that the stimuli are only visible by virtue of their chromatic content (red/green or blue/yellow symbols), being invisible to the achromatic system. Notice that the sensitivity characteristics of the two chromatic systems are quite similar. Two differences are immediately obvious between these chromatic contrast sensitivity functions (red/green or blue/yellow symbols) and their achromatic counterparts (black/green or black/yellow symbols), namely the chromatic function is lowpass in its overall shape (as opposed to the bandpass shape of the achromatic contrast sensitivity function) and secondly sensitivity is reduced at higher spatial frequencies. Our chromatic sensitivity is specialized for the low spatial frequency range where its sensitivity is superior to that of the achromatic system. Therefore, color vision does not provide fine detail information but does help to detect boundaries

between large regions that have subtly different chromatic content.

These overall contrast sensitivity functions represent the envelope of numerous much more selectively tuned mechanisms, just as has been shown for the achromatic contrast sensitivity function.^{61,62} Their bandpass shape suggests that they represent the responses of chromatically tuned cortical neurons that are optimally responsive to different spatial frequency ranges, similar to their achromatic counterparts. A comparison of how chromatic sensitivity varies across the visual field highlights changes that occur to the peripheral chromatic window of visibility.⁶³ “Blue/yellow” sensitivity shows a gradual decline with eccentricity, not unlike that found for achromatic stimuli. However, sensitivity for detecting “red/green” stimuli falls off much more sharply with eccentricity. Therefore, the fovea is specialized for red/green chromatic processing. This is illustrated in Figure 32.16 where, on the right, weighting functions are shown that

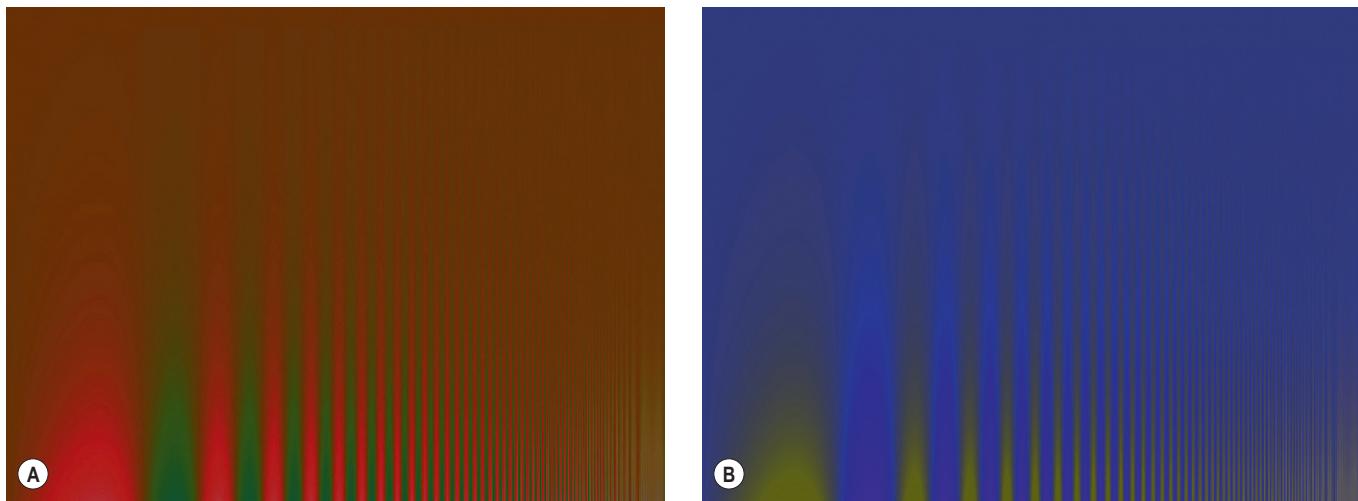

Figure 32.14 Demonstration of the chromatic window of visibility for the human visual system (from Mark E McCourt, NDSU). The sinusoidal bars are chromatically defined (by red/green chromatic contrast in the left frame (**A**) and by blue/yellow chromatic contrast in the right frame (**B**)) and vary in spatial frequency along the abscissa and chromatic contrast along the ordinate. Notice that the bars are now seen in an inverted-L shaped area (i.e. lowpass shaped function). Reproduced with the permission of Mark McCourt.

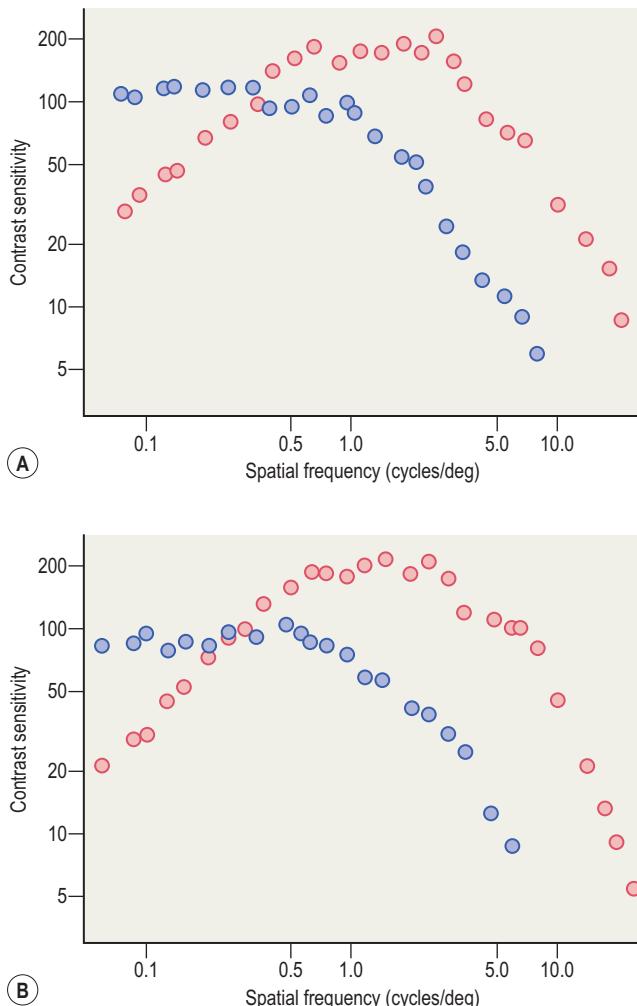

Figure 32.15 Comparison of the contrast sensitivity functions for achromatic and chromatic stimuli. In each case the chromatic (red/green on left and blue/yellow on right) and achromatic (black/green on left and yellow/black on right) contrast sensitivities are compared from the work of Mullen.⁶⁰

Box 32.6

A selective loss of red/green chromatic sensitivity may simply reflect a central field deficit not a selective chromatic deficit per se

approximate the sensitivity fall-off with eccentricity for red/green chromatic stimuli (top) and achromatic stimuli (bottom) from the work of Mullen et al.⁶³ On the left, the perceptual effects of these different eccentricity dependences are illustrated. Red/green chromatic stimuli are much more visible in the fovea compared with the periphery. Achromatic (and blue/yellow chromatic) stimuli are only slightly less visible in the periphery.

Suprathreshold sensitivity

The use of contrast sensitivity to define a window of visibility for the human visual system is an important step in appreciating the quality of our visual perception, but it by no means represents the complete picture. The visual system is highly non-linear, comprising cells with different thresholds and contrast gain control, specialized to encode contrast in a distributed fashion.²² One consequence of this is that threshold and suprathreshold sensitivity may be quite different. For example, Georgeson & Sullivan⁶⁴ showed that the typical inverted U-shaped contrast sensitivity function measured using thresholds as described above, is not present for stimuli above threshold. In other words, more contrast may be needed to detect a stimulus of higher spatial frequency at threshold without the stimulus looking different in their contrast above threshold. The suprathreshold contrast sensitivity function is relatively flat compared with its threshold counterpart. This is shown in Figure 32.17 where the matched contrast is plotted against the stimulus spatial frequency for a range of different suprathreshold contrasts. The same is true for the periphery;³⁶ more contrast may be needed for

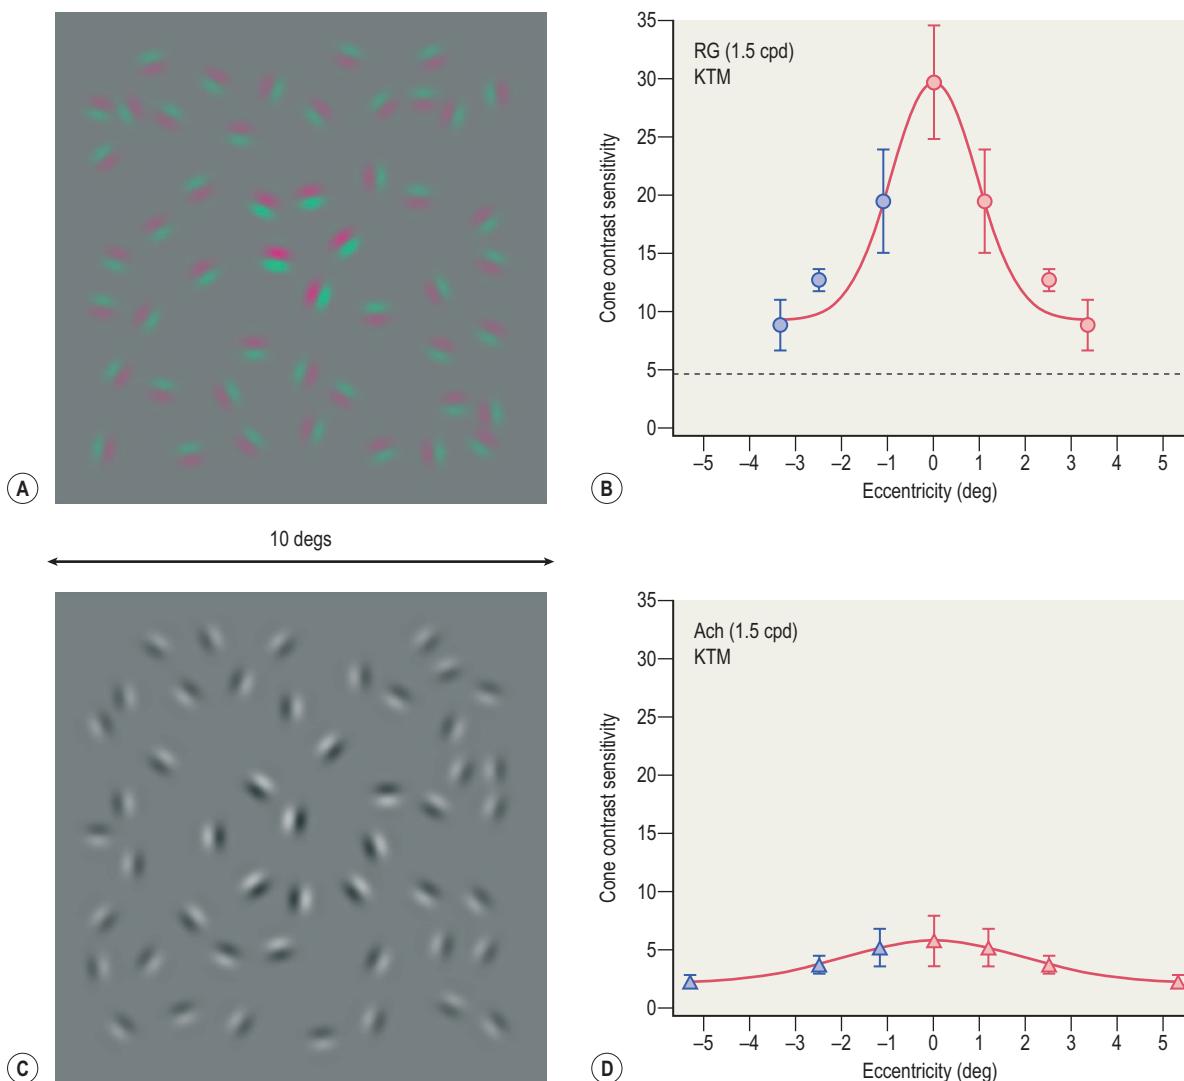

Figure 32.16 On the right, the fall-off in sensitivity for achromatic and red/green chromatic stimuli is depicted. The sensitivity fall-off for blue/yellow is similar to that for the achromatic stimulus. On the left, the simulated visibility effect this would have on the perception of an array of spatially narrowband stimuli. Notice the foveal specialization for red/green chromatic stimuli (data from Mullen et al^[63]).

peripheral stimuli to be detected without their perception at threshold being any different in terms of contrast (see Fig. 32.10).

There are a number of different ways of thinking about this. First, one could assume that the visual thresholds are noise-limited, where the signal is reduced to such levels that any intrinsic noise begins to play an important part. The shape of the contrast sensitivity function reflects the spatial frequency dependence of the noise whose influence is progressively diminished as the signal (i.e. contrast) is increased. Alternatively, the lack of spatial frequency dependency reflected in contrast constancy at suprathreshold contrast levels could be a side-effect of contrast gain control,^[65] a network of interactions that regulates the contrast responsiveness of individual cells. Finally one could argue that thresholds reflect the properties of cells with the best sensitivity whereas suprathreshold measures reflect the properties of different cells, those with optimal contrast coding properties in the higher contrast range; the spatial frequency

dependence of these two populations of cells being different. Although at present we do not know the exact explanation, from a practical viewpoint a comprehensive understanding of visual processing requires both threshold and suprathreshold information.

Conclusion

Not only does information have to be conveyed from retina to cortex via an optic nerve of limited size but also sensory cells have limited dynamic ranges. Only a fraction of the information that impinges on the retina can be transmitted to cortex; to maintain relatively high sensitivity, it needs to be parceled out among a population of cells such that all cells carry only a part of the information. Parallel processing is a fundamental part of visual processing. We have different windows of visibility for achromatic and chromatic processes, for photopic and scotopic processes, for central and

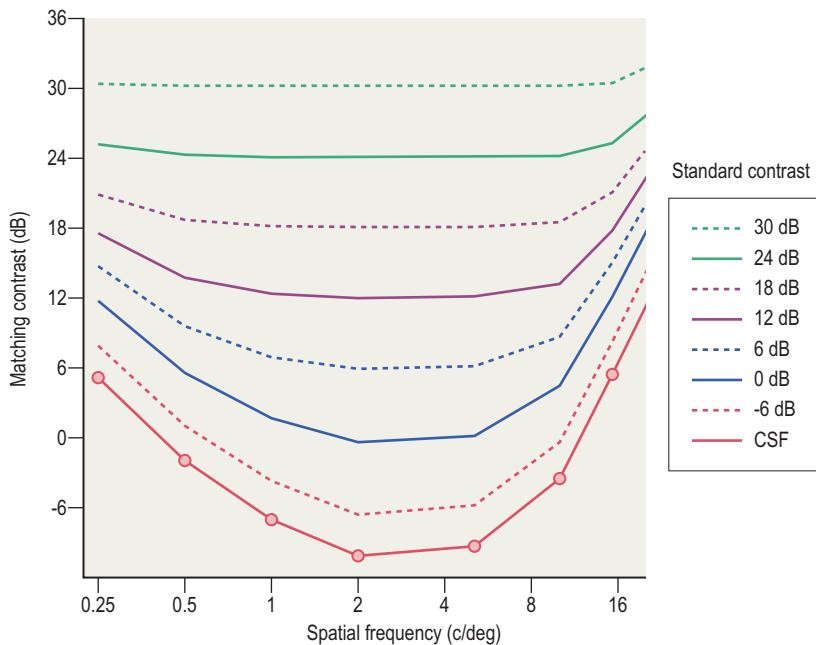

Figure 32.17 The shape of the contrast sensitivity function at threshold (lower red filled circles) compared with contrast matching functions above threshold (colored curves). The flattening of the function was first shown by Georgeson & Sullivan.⁶⁴ These results are simulations from a contrast gain control model (Hess et al⁶⁵).

peripheral processes and for threshold and suprathreshold processes. The fovea exhibits a specialization in terms of spatial scale and in terms of red/green chromatic processing. The periphery exhibits a specialization for detecting rapid temporal change for low spatial frequency stimuli. Without the need to maintain comparable spatial and temporal sensitivity throughout the visual field, substantial saving can be made in the processing bandwidth. A more complete understanding of the early visual processing of spatial form involves an appreciation of the neural substrate of each of these different aspects of the parallel processing of visual information.

Visual Acuity

Dennis M. Levi

Visual acuity is a measure of the keenness of sight. The Egyptians used the ability to distinguish double stars as a measure of visual acuity more than 5000 years ago.¹ Over the centuries visual acuity has been studied, measured and analyzed because it represents a fundamental limit in our ability to see. Consequently, visual acuity has been used as a criterion for military service and various other occupations, driving, and for receiving social security benefits.

Visual acuity is limited primarily by the optics of the eye and by the anatomy and physiology of the visual system. As such, visual acuity is perhaps the key clinical measure of the integrity of the optical and physiological state of the eye and visual pathways (Box 33.1).

Defining and specifying visual acuity

How do we define the keenness of sight? Visual acuity is used to specify a spatial limit, i.e. a threshold in the spatial dimension.² Over the centuries there have been a large number of different ideas about how to define, measure and specify visual acuity, and these can be distilled down to four widely accepted criteria:

- Minimum visible acuity – detection of a feature
- Minimum resolvable acuity – resolution of two features
- Minimum recognizable acuity – identification of a feature
- Minimum discriminable acuity – discrimination of a change in a feature (e.g. a change in size, position or orientation).

These different criteria actually represent different limits and may be determined by different aspects of the visual pathway (Table 33.1).

Minimum visible acuity

- Minimum visible acuity refers to the smallest object that one can detect.

As early as the 17th century, de Valdez measured the distance at which a row of mustard seeds could no longer be counted, and early astronomers like Robert Hooke were interested in the size of stars that could be detected and their relation to retinal anatomy.¹ In this context, the minimum visible acuity refers to the smallest target that can be detected.

Under ideal conditions, humans can detect a long, dark wire (like the cables of the Golden Gate bridge) against a very bright background (like the sky on a bright sunny day) when they subtend an angle of just 0.5 arc seconds (≈ 0.00014 degrees). It is widely accepted that the minimum visible acuity is so small because the optics of the eye (described below) spread the image of the thin line, so that on the retina it is much wider, and the fuzzy retinal image of the wire casts a shadow which reduces the light on a row of cones to a level which is just detectably less than the light on the row of cones on either side. In other words, although we specify the minimum visible acuity in terms of the angular size of the target at the retina, it is actually limited by our ability to discriminate the intensity of the target relative to its background.

Increasing the target size, up to a point, is equivalent to increasing its relative intensity. Hecht & Mintz³ measured the visual resolution of a black line against a background over a large range of background brightness. They found that the minimum visible acuity varied from about 10 minutes at the lowest background levels, to about 0.5 arc seconds at the highest. The limiting factor in the case of minimum visible acuity is the observers' sensitivity to small variations in the stimulus intensity ($\Delta I/I$), i.e. their contrast sensitivity (discussed below). Indeed, Hecht & Mintz³ state that the retinal image produced by the 0.5 arc second line represents a "fine fuzz of a shadow extending over several cones", and they calculated that at the highest intensity levels tested, the foveal cones occupying the center of the shadow suffers a drop in intensity (relative to the neighboring cones) of ≈ 1 percent – just at the limit of intensity discrimination.

Although the minimum visible acuity represents one limit to spatial vision, it is in fact a limit in the ability to discern small changes in contrast, rather than a spatial limit per se, and minimum visible acuity is not used clinically.

Minimum resolvable acuity

- Minimum resolvable acuity refers to the smallest angular separation between neighboring objects that one can resolve.

More than 5000 years ago the Egyptians assessed visual acuity by the ability of an observer to resolve double stars.¹ There is currently still debate about how best to define and measure resolution. However, today, the minimum

resolvable acuity is much more likely to be assessed by determining the finest black and white stripes that can be resolved. Under ideal conditions (e.g. high contrast and luminance), humans with very good vision can resolve black and white stripes when one cycle subtends an angle of approximately 1 minute of arc (0.017 degrees). This minimum resolvable acuity represents one of the fundamental limits of spatial vision: it is the finest high-contrast detail that can be resolved. In foveal vision the limit is determined primarily by the spacing of photoreceptors in the retina. The visual system "samples" the stripes discretely through the array of receptors at the back of the retina (Fig. 33.1). If the receptors are spaced such that the whitest and blackest parts of the grating fall on separate cones (Fig. 33.1B), we should be able to make out the grating. But if the entire cycle falls on a single cone (Fig. 33.1C), we will see nothing but a gray field (or

we may experience a phenomenon called **aliasing**, in which we misperceive the width or orientation of the stripes). Cones in the fovea have a center-to-center separation of about 0.5 minutes of arc (0.008 degrees), which fits nicely with the observed acuity limit of 1 minute of arc (0.017 degrees – since we need two cones per cycle to be able to perceive it accurately), and each foveal cone has a "private" line to a ganglion cell. Rods and cones in the retinal periphery are less tightly packed together, and many receptors converge on each ganglion cell. As a result, visual acuity is much poorer in the periphery than in the fovea (more about that later).

Box 33.1 Visual Acuity

Visual acuity is a measure of the keenness of sight. Visual acuity is limited primarily by the optics of the eye and by the anatomy and physiology of this visual system. As such, visual acuity is perhaps the key clinical measure of the integrity of the optical and physiological state of the eye and visual pathways.

Table 33.1 Summary of the different forms of acuity and their limits

Type of acuity	Measured	Acuity (degrees)
Minimum visible	Detection of a feature	0.00014
Minimum resolvable	Resolution of two features	0.017
Minimum recognizable	Identification of a feature	0.017
Minimum discriminable	Discrimination of a change in a feature	0.00024

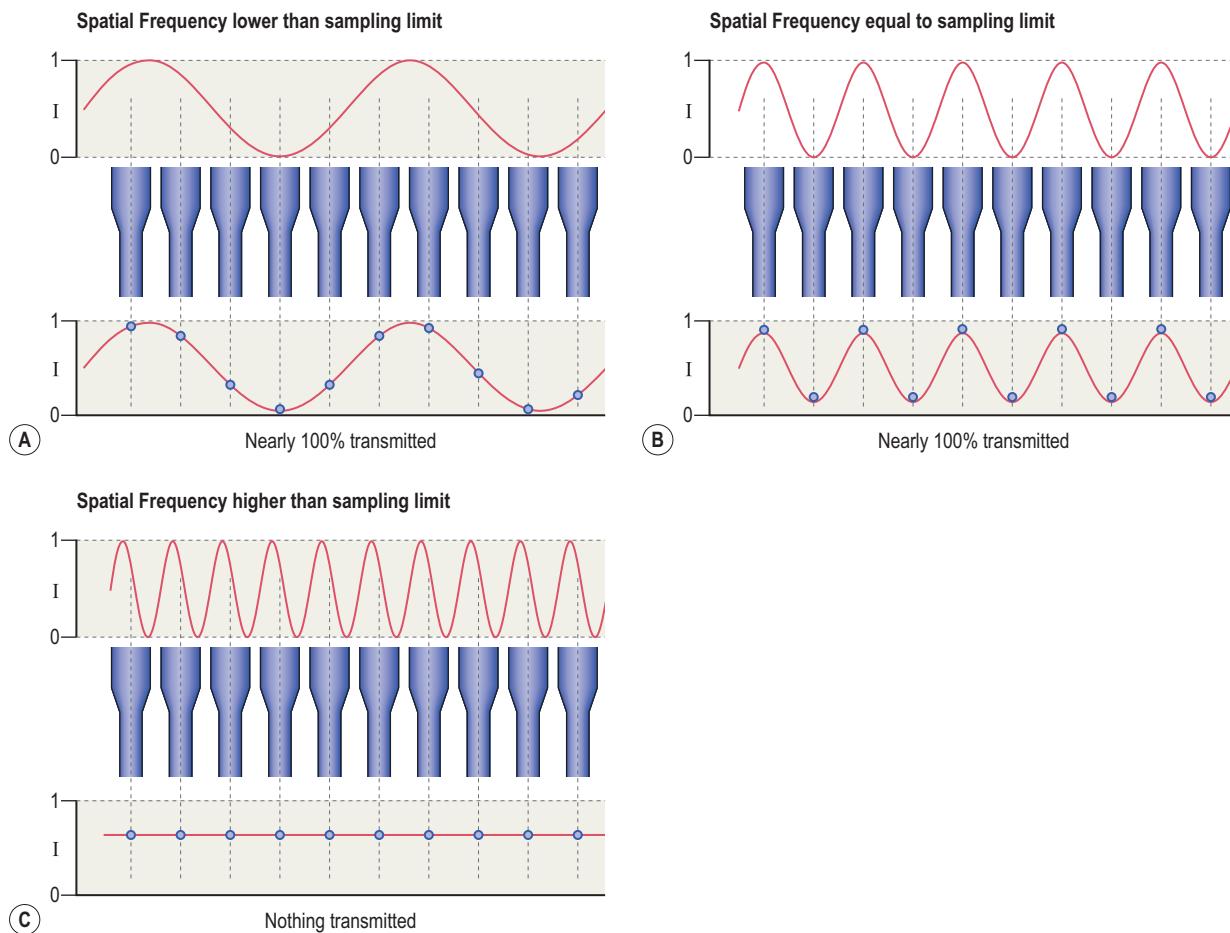

Figure 33.1 Spatial sampling of a sinusoid whose spatial frequency is (A) lower than the sampling limit set by the spacing of the cones, (B) equal to the sampling limit set by the spacing of the cones, (C) higher than the sampling limit set by the spacing of the cones.

Minimum recognizable acuity

- Minimum recognizable acuity refers to the angular size of the smallest feature that one can recognize or identify.

Although this method has been used since the 17th century, the approach still used by eye doctors today was introduced more than a century ago by Herman Snellen and his colleagues. Snellen constructed a set of block letters for which the letter as a whole was five times as large as the strokes that formed the letter (Fig. 33.2). The distance of the patient was varied until they could no longer accurately read the letters. In later adaptations of the Snellen test, the viewer was positioned at a constant distance (typically 20 feet [6 meters]), and the size of the letters, rather than the position of the viewer, was altered and visual acuity was defined as:

The distance at which the patient can just identify the letters / The distance at which a person with "normal" vision can just identify the letters

Thus, "normal" vision came to be defined as 20/20 (6/6 in metric units). To relate this back to visual angle, a 20/20 letter is designed to subtend an angle of 5 arc minutes (0.083 degrees) at the eye, and each stroke of a 20/20 letter subtends an angle of 0.017 degrees (our old familiar 1 arc minute). Thus, if you can read a 20/20 letter, you can discern detail that subtends 1 minute of arc. If you have to be at 20 feet to read a letter that someone with normal vision can read at 40 feet, you have 20/40 vision (worse than normal). Although 20/20 is often considered the gold standard, most healthy young adults have an acuity level closer to 20/15.

Figure 33.2 Snellen acuity chart.

Illiterate E and Landolt C charts are based on the same principles as the Snellen chart.

Although Snellen's notation for visual acuity is commonly used, there are other schemes for specifying acuity (Table 33.2). For example, the Minimum Angle of Resolution (MAR) is the angular size of detail of the visual acuity letter in minutes of arc – it is the Snellen denominator (the number below the line, e.g. 40) over the Snellen numerator (the number above the line, e.g. 20). Thus, for example a Snellen acuity of 20/20 is equivalent to an MAR of 1'; 20/40 to an MAR of 2' and 20/100, an MAR of 5'. Another method for specifying acuity is the Snellen fraction (the Snellen numerator divided by the denominator or 1/MAR). Acuity is sometimes specified as LogMAR (the logarithm of the minimum angle of resolution) and sometimes as Log Visual Acuity (the logarithm of the Snellen fraction). Snell & Sterling⁴ developed a metric for quantifying visual loss due to injury or disease. The Snell–Sterling efficiency scale sets 20/20 (MAR = 1') as 100% efficiency, and reduces the efficiency by a fixed percentage ($\approx 84\%$) for every 1 minute loss of acuity.

There are many stimulus and subject variables that influence the minimum recognizable visual acuity (discussed below).

Minimum discriminable acuity

- Minimum discriminable acuity refers to the angular size of the smallest *change* in a feature (e.g. a change in size, position or orientation) that one can discriminate.

Perhaps the most studied example of minimum discriminable acuity is our ability to discern a difference in the relative positions of two features. Our visual systems are very good at telling where things are. Consider two abutting horizontal lines, one slightly higher than the other (Fig 33.3A). It is very easy to discern that, for example the right line is higher than the left (i.e. discriminate the relative positions of the two lines) even from a long way away. This is an example of a class of visual tasks that have been given the label "*hyperacuity*" by Gerald Westheimer.⁵ These tasks all have in common that they involve judging the relative position of objects, and Westheimer coined the term hyperacuity, because, under ideal conditions, humans can make these judgments with a precision that is finer than the size or spacing of foveal cones.

The smallest misalignment that we can reliably discern is known as Vernier acuity – named after the Frenchman, Pierre Vernier, whose scale, developed in the 17th century, was widely used to aid ship's navigators. The success of the Vernier scale was based on the fact that humans are very adept at judging whether nearby lines are lined up or not. Thus, Vernier alignment is still widely used in precision machines, and even in the dial switches in modern ovens.

Table 33.2 Different acuity notations

Snellen (Imperial)	Notation (Metric)	MAR	logMAR	Decimal	SF (c/deg)
20/200	6/60	10	1	0.1	3
20/20	6/6	1	0.0	1.00	30
20/10	6/3	0.5	-0.3	2	60

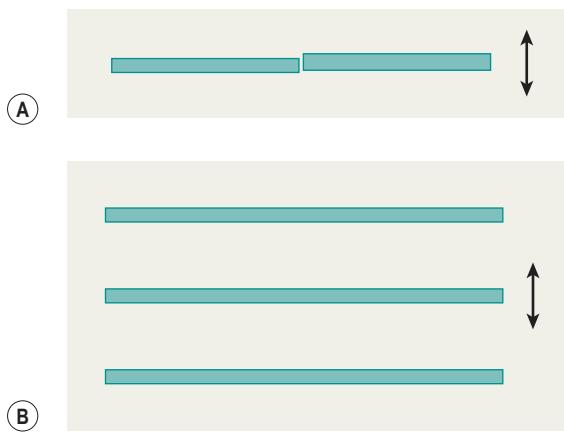

Figure 33.3 Two “hyperacuity” configurations: Vernier acuity (**A**) and bisection acuity (**B**). In both cases, the subject’s task is to judge the relative position of the features.

Under ideal conditions, Vernier acuity may be just three arc seconds (≈ 0.0008 degrees)! This performance is even more remarkable when you consider that it is about ten times smaller than even the smallest foveal cones. Note that the optics of the eye spread the image of a thin line over a number of retinal cones, and that the eyes are in constant motion, and this performance appears even more remarkable.

Vernier acuity is not the most remarkable form of hyperacuity. Guinness World Records 2005 describes the “highest hyperacuity” as follows: In April 1984, Dr. Dennis M. Levi (yes – that’s yours truly) “...repeatedly identified the relative position of a thin, bright green line within 0.8 seconds of arc (0.00024 deg). This is equivalent to a displacement of some 0.25 inches (6 mm) at a distance of 1 mile (1.6 km).” This “remarkable” position acuity was accomplished with a bisection task (Fig. 33.3B), but can actually be understood based on a straightforward model of human spatial vision.⁶

As remarkable as the other hyperacuities (sometimes also called “position” acuities) might seem, they do not defy the laws of physics. Geisler⁷ calculated that if you placed a machine (known as an ideal discriminator) at the retina, and this machine knew precisely the pattern of photons absorbed by the retinal photoreceptors when the stripes were aligned, and the pattern of photons absorbed when they were misaligned, that this machine could actually perform an order of magnitude better than even the best humans. So, the information about the Vernier offset is present in the pattern of photons absorbed by the photoreceptors; however, humans must be able to interpret the information despite the constant motion of the eyes. Thus hyperacuity must ultimately be limited by neurons in the visual cortex that are able to interpolate positional information with high resolution.

There is a good deal of evidence that different mechanisms limit position judgments for closely spaced (or abutting) targets, and for widely separated targets. In the nearby case, both contrast and contrast polarity are important. For example, in a two-line Vernier target Vernier acuity is better when the lines are both either bright or dark than if one line is bright and the other dark. For longer-range position judgments where the targets are well separated, neither contrast nor contrast polarity nor the local stimulus details matter

very much. For long-range position judgments the visual system must localize each of the features, and then compare the position labels of separate cortical mechanisms. The idea that cortical receptive fields have position labels (in addition to labels for other stimulus dimensions) is consistent with the topographical mapping of visual space in the brain (i.e. each point in space is systematically mapped on to the visual cortex). More than a century ago, Hermann Lotze⁸ wrote:

“So long as the opinion is maintained that the space relations of impressions pass as such into the soul, it must of course, in the interest of the soul, be further held that each impression is conveyed to it by a distinct fibre, and that the fibres reach the seat of the soul with their relative situation wholly undisturbed.”

Although we now know much more about the anatomy and physiology of the visual system than was known in the 1880s, Lotze clearly recognized that there must be a topographical representation of the world in the visual nervous system (if not the soul!), and that each “fibre” must carry a label about the position of the “impression” that it carried. For this reason, position labels were called “Lotze’s local signs”. Lotze also concluded that local signs played an important role in directing eye movements toward stimuli in the peripheral field of vision. So how accurate is “local sign” information? It turns out that humans can localize the position of a single peripheral feature to within about 1–2 percent of the eccentricity of the target, a little more precisely than we can make saccadic eye movements to peripheral targets.⁹

Limiting factors in visual acuity

In this section we explore the optical, anatomical and physiological factors that limit visual acuity. In the fovea, optics anatomy and neural mechanisms conspire to limit our visual acuity.

Optical quality of the eye

The optics of the eye spread the retinal image. Consider the retinal image of a distant star. Because stars are really far away, they are considered to be a “point source”, i.e. if they were in perfect focus and the eye’s optics were perfect, they would subtend an infinitely small angle at the eye. Point sources are useful if you want to learn about the quality of the eye’s optics. As it turns out, the eye’s optics are far from perfect; in fact your camera might have better optical quality. The eye’s optics spread the image, so that a point in space forms a distribution (like a Gaussian) on the retina, as illustrated in Figure 33.4A. This distribution, like the office football pool, is known as the **point spread function** (if the source is a line it’s called the **line spread function**). Figure 33.4B–D shows the retinal light distribution for a pair of nearby stars. As the stars become closer and closer together, their images overlap to a greater and greater degree, so that when they are very close, they look like a single distribution. When the separation between the stars on the retina is less than half the spread of each image, they will appear as a single star. This is known as the Rayleigh limit (Fig. 33.4D). The Rayleigh limit is determined mainly by the wavelength

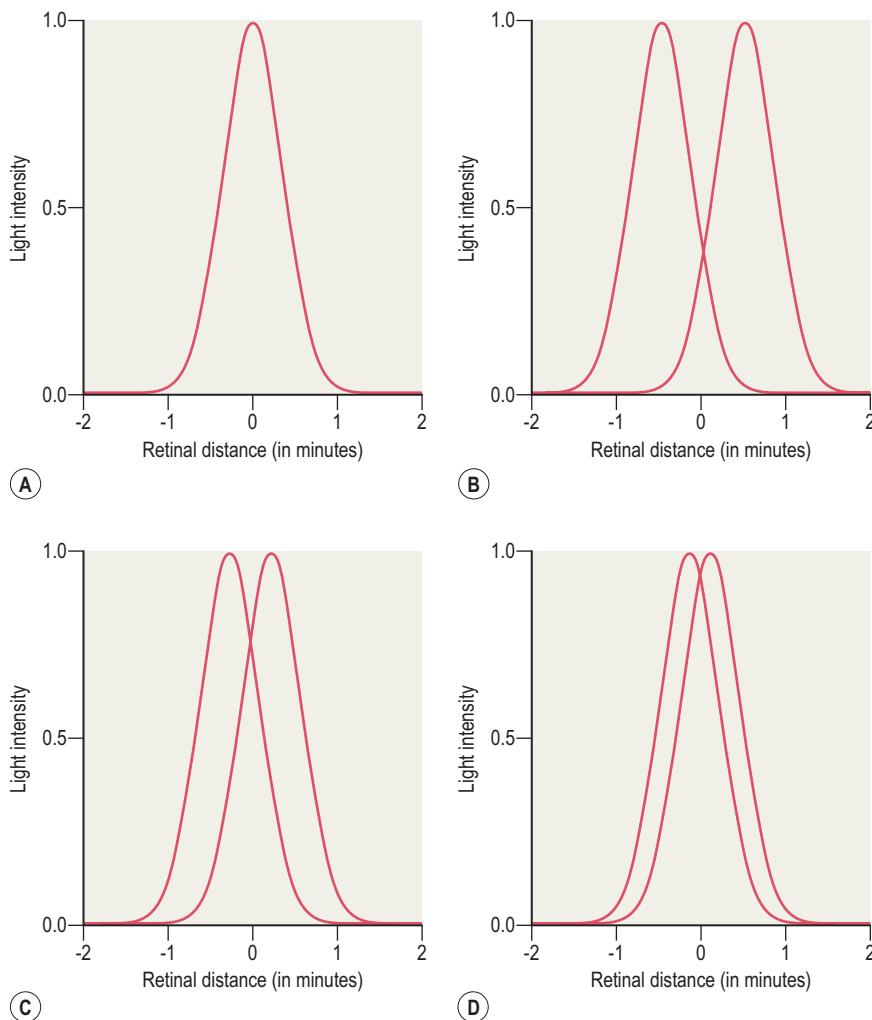

Figure 33.4 (A) Retinal image of a single point. Although the point is infinitesimally small, its image is spread on the retina. (B–D) Retinal image of a pair of nearby points, separated by distances equal to two (B), one (C) and half (D) the spread of each image. The latter case is known as the Rayleigh limit.

of the light and the size of the pupil (we'll soon discuss why). As noted earlier, the ability to distinguish double stars was one of the earliest measures of visual acuity, used by the Egyptians more than 5000 years ago.¹

Another way to determine the quality of an optical system is to measure its **modulation transfer function**. This is typically done by passing test patterns of sinusoidal gratings (Fig. 33.5) of known contrast through the optical system, and measuring the contrast in the image. Sinewaves are characterized by their **spatial frequency** (i.e. the number of stripes in a given distance, usually specified in cycles per degree), their **contrast** (i.e. the difference in the luminance of the peaks and troughs divided by the sum of the luminance of the peaks and troughs), and their **phase** (the position of the peaks). Sinewaves are especially useful because even after they are degraded by an optical system, they maintain their characteristic shape (i.e. once a sinewave always a sinewave) they just become smaller in amplitude (and they may shift in phase). The ratio of image contrast to object contrast is a measure of image quality. By measuring the ratio of image contrast to object contrast for a range of object spatial frequencies, we can measure the modulation transfer of any optical system. The red line in Figure 33.6A shows the average modulation transfer functions of a large group of

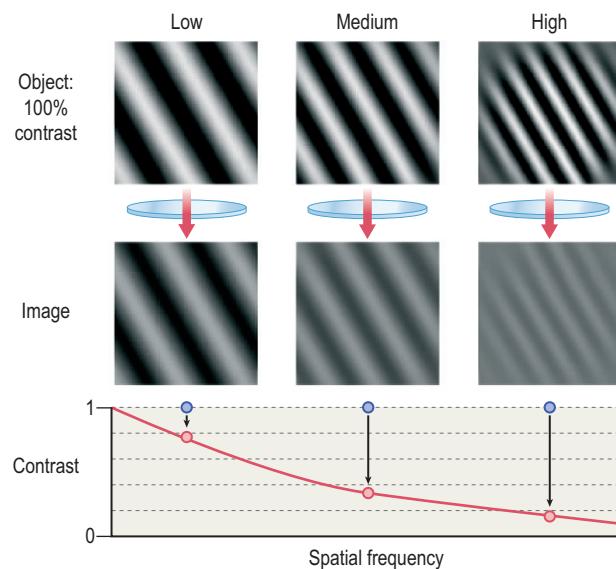

Figure 33.5 The modulation transfer function.

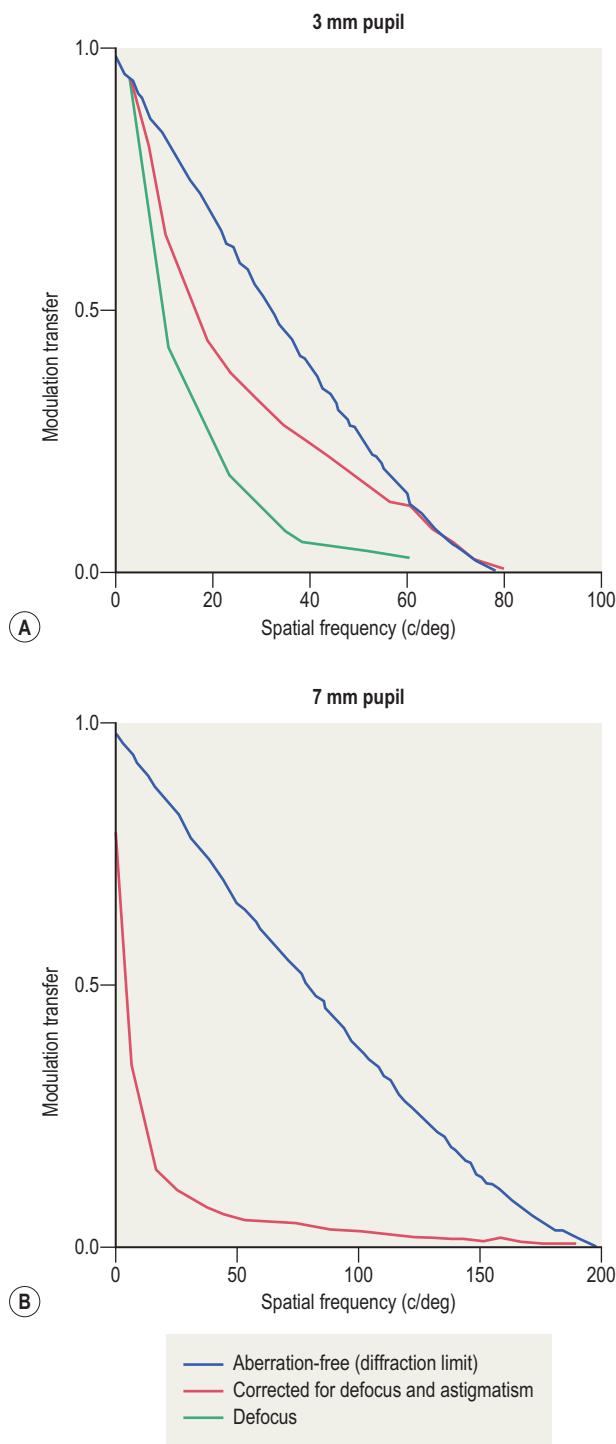

Figure 33.6 The modulation transfer function of the human eye. (A) The red line is the mean MTF of 12 eyes with a 3-mm pupil with refractive error corrected. The blue line is the MTF of an aberration-free eye (i.e. limited by diffraction only). The green line shows schematically the effect of uncorrected refractive error. (Adapted from Liang J. & Williams, D.R. (1997). Aberrations and retinal image quality of the normal human eye. *J Opt Soc Am A Opt Image Sci Vis.*, 14, 2873–83.¹⁰) (B) The red line is the mean MTF of 14 eyes with a 7.3-mm pupil with refractive error corrected. The blue line is the MTF of an aberration-free eye (i.e. limited by diffraction only). (Adapted from Campbell, F. W., and Green, D. G. (1965). Optical and retinal factors affecting visual resolution. *J Physiol* 181: 576–593.⁵⁵)

observers with 3-mm pupils (about the average size of the pupil in a well-lighted room). As the object spatial frequency increases the modulation transfer declines, falling to near zero at a spatial frequency of around 80 cycles per degree. The spatial frequency at which the modulation transfer function falls to zero is called the **cutoff spatial frequency**. At this spatial frequency the optics do not transmit the sinusoidal variations in the luminance of the object. The theoretical cutoff spatial frequency (in cycles/degree), like the Rayleigh limit, is determined mainly by the wavelength of the light (λ), and the diameter of the pupil (d):

$$\text{Cutoff SF (c/deg)} = \pi/180 * d/\lambda$$

where d and λ are both specified in millimeters (mm). For red light (630 nm or 0.000630 mm as used by Liang & Williams¹⁰) and a 3-mm pupil (about as small as they get) the predicted cutoff spatial frequency is 83 c/deg.

What limits optical image formation of the eye?

As noted above, the optics of the human eye are imperfect. Why do the eye's optics not match up to a fine camera? One limitation is **diffraction** produced by the pupil of the eye (or the lens aperture of a camera). For example, when light passes through the aperture, instead of staying in a straight line, the light from each ray will be scattered into different directions. This scatter is known as diffraction, and its consequence is to spread or defocus the image and to reduce the transfer of high spatial frequencies in the modulation transfer function. The blue lines in Figure 33.6 show the diffraction limit (i.e. the modulation transfer of an aberration free optical system). As noted above, the cutoff spatial frequency in the modulation transfer function depends on the pupil diameter. The red line in Figure 33.6B shows the modulation transfer function of a large group of human eyes for a large (7-mm) pupil size. Note that for the large pupil diameter the modulation transfer function is much poorer than predicted by the theoretical limit set by diffraction.

In both panels of Figure 33.6, the eye's optics are always worse than the theoretical limit, especially when the pupil is large. One important reason is that the eye exhibits **aberrations**. One form of aberrations in the eye is known as **spherical aberrations**, in which light rays passing through different parts of the eye's optics are focussed at slightly different points in the image plane. Larger pupils will result in more aberrations because more peripheral rays of light will enter the eye. There are also **chromatic aberrations**. If the light source (like starlight) is a mixture of light of different wavelengths, then not all of the wavelengths will be in focus on the retina (at any given time), so the eye will have different point spreads for different wavelengths.

Refractive error and defocus results in a marked loss of image quality

The refractive error of the eye is determined by the refractive power of the optical components of the eye (i.e. the power of the cornea and lens) and the length of the eyeball. To focus a distant point source on the retina, the refractive power of the optical components of the eye must be perfectly matched to the length of the eyeball. This perfect match is known as **emmetropia**. If there is an uncorrected refractive error or the optics of the eye are defocused, the image of a distant object on the retina will be spread out (i.e. the point

spread function will widen) and the modulation transfer function will be low (green line in Fig. 33.6A).

For myopes, the power of the optical components is too strong for the length of the eyeball, causing the light rays to converge too much to focus on the retina. Myopia cannot be remedied through accommodation because accommodation will increase the convergence of the light. The amount of image spread depends on the amount of defocus, and the pupil size. Reducing pupil size increases the depth of focus, so that defocus has less effect with small than with large pupils. As a rule of thumb, 1 diopter of uncorrected simple myopia will result in a decrease of Snellen acuity, on average, to $\approx 20/60$.

Myopia can be corrected with negative (minus) lenses, which diverge the rays. On the other hand, hyperopia (farsightedness) occurs when the power of the optical components is too weak for the length of the eyeball, causing the light rays to not converge enough to focus on the retina (the image plane lies behind the retina in an unaccommodated hyperopic eye). If the hyperopia is not too severe, a young hyperope can compensate by accommodating, and thereby increasing the power of the eye.

The most powerful refracting surface in the eye is the cornea, which contributes about two-thirds of the eye's refracting power. When the cornea is not spherical the result is astigmatism. With astigmatism, a point source would not have a single point focus on the retina (i.e. the pointspread function would be asymmetric), and lines of different orientations would be focussed in different planes. Although there are other causes for astigmatism, it is usually caused by asymmetry of the front surface of the cornea. Cylindrical lenses that have two focal points can correct astigmatism (e.g. they have different power in the horizontal and vertical meridians).

Photoreceptor size and spacing; aperture size; the "Nyquist" limit; aliasing

Retinal anatomy plays a very important role in setting the limits for foveal resolution acuity. Foveal cones are arranged in a regular arrangement (sometimes called a triangular array) and are densely packed (see Fig. 33.7). This dense packing is critical to fine resolution. The reason is simple. The visual world is represented by continuous variations in light intensity. However, our visual system "samples" the world discretely, i.e. by looking at the light distribution through many small individual photoreceptors. The more closely packed the photoreceptors, the better the light distribution can be represented to the visual nervous system. As illustrated in Figure 33.1, there is a sampling limit. In order

to properly represent the peaks and troughs in the intensity profile of a sinewave, there must be at least two cones for each cycle of the grating. This is known as the **Nyquist limit** and is represented in Figure 33.1B. More formally, the Nyquist limit occurs when the sinewave has a spatial period (i.e. the peak to peak distance) that is two times the cone spacing. When the spatial period is smaller than twice the cone spacing (i.e. when the sinewave spatial frequency is higher than the Nyquist frequency) the phenomenon known as "aliasing" may occur, i.e. rather than the cones signaling a perfect replica of the sinewave on the retina, the signal is distorted – it appears to be a sinewave with a lower spatial frequency than the original (Fig. 33.8). Since cones in the fovea have a center to center separation of around 0.5 arc minutes, the cone sampling (or Nyquist) limit is a grating spatial period of about 1 minute (i.e. a grating spatial frequency of 60 cycles per degree). Note that because the cones have triangular packing, geometry dictates that the Nyquist frequency will actually be about 15 percent higher or roughly 69 c/deg. This represents a fundamental limitation set by the spacing of the foveal cones, and it is not far off the limitations set by the eye's optics. Thus, in the fovea, the cone spacing is nicely matched to the eye's optics. As we'll see later in this chapter, in peripheral vision cone spacing changes dramatically, while the optics change only a little.

The notion that there is a "highest" spatial frequency that can be accurately represented by the visual system (the Nyquist frequency) raises the interesting question of whether aliasing actually occurs in human vision. Fortunately for us, our optics "protect" us from the effects of aliasing in the fovea by reducing the contrast of high spatial frequencies. Interestingly, it is possible to create a very high spatial frequency pattern on the retina bypassing the optics of the eye (this can be accomplished using lasers to create interference patterns). Under these conditions, humans report the appearance of aliasing – fine gratings appear coarse (and often appear to change their orientation). Figure 33.8 illustrate how viewing a grating through too coarse a grid produces the kind of wavy, coarse appearance produced by aliasing.

Cone to ganglion cell convergence

If many cones converged on a single ganglion cell, the advantage of having closely spaced cones would be lost. Recall however that in the fovea each cone effectively has a "private line" to the brain via the midget bipolar and ganglion cells. So, the receptive field centers of midget ganglion cells are effectively one cone wide. In peripheral vision resolution is limited by the retinal ganglion cells that are widely

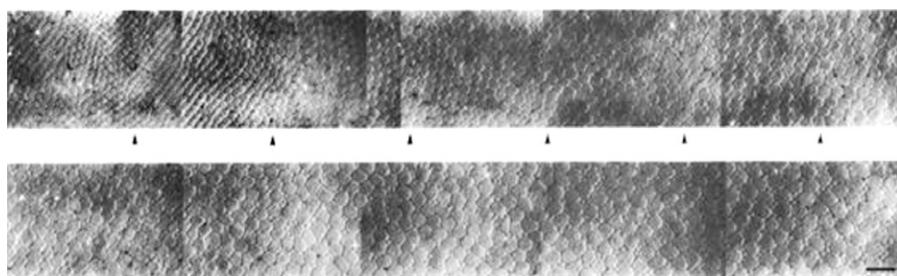

Figure 33.7 Inner segments of a human cone mosaic in a strip extending from the foveal center (upper left arrow) along the temporal horizontal meridian. The large cells are cones and the small cells are rods. The horizontal scale bar indicates 10 μm . (From Hirsch, J, Curcio, C. The spatial resolution capacity of human foveal retina. Vision Research, 29, 1095–1101; 1989.²⁴)

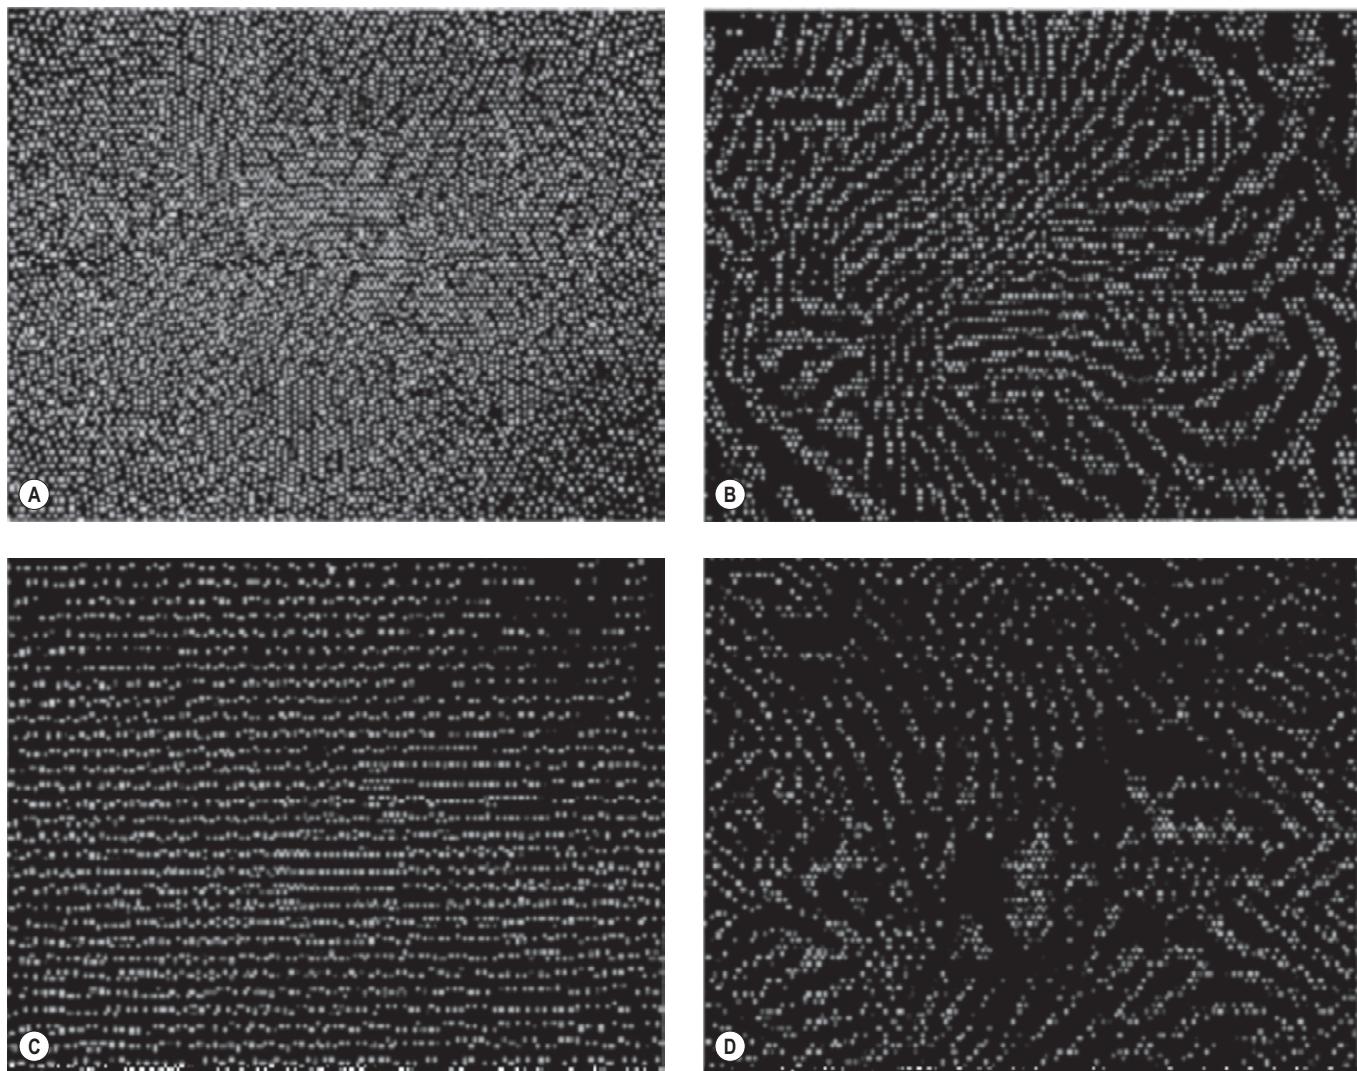

Figure 33.8 (A) The foveal cone mosaic is represented as sample points (bright dots). In the other panels it has been sandwiched with gratings of 40 cpd (C), 80 cpd (B) and 110 cpd (D). (From Williams DR. Topography of the foveal cone mosaic in the living human eye. Vision Research, 28, 433–54; 1988. Copyright Elsevier 1988.⁹⁵)

spaced (sparsely sampled) and that pool information from many cones.

Eccentricity

In contrast to the tight packing of cones in the fovea, cone density decreases dramatically with retinal eccentricity, and there is substantial convergence of cones to ganglion cells (Chapter 32). Humans have many more rods (about 90 million) than cones (about 4–5 million), and they have very different geographical distributions on the retina (Fig. 33.9). The cones are most concentrated in the center of the fovea, and their density drops off dramatically with retinal eccentricity. Rods are missing from the center of the fovea, and their density increases to a peak at about 20 degrees, and then declines again. As can be seen in Figure 33.7, the cones in the fovea are much more densely packed than in the peripheral retina, and there are no rods in the section from the foveal center. This “rod-free” area (about 300 micrometers on the retina) subtends a visual angle of

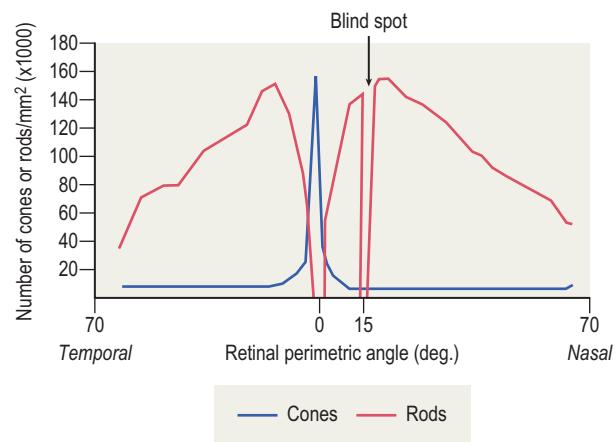

Figure 33.9 Distribution of cones (blue) and rods (red) across the retina. (Adapted from Osterberg, G. (1935). Topography of the layer of rods and cones in the human retina. Acta Ophthalmologica, Suppl. 6, 1–103.⁹⁶)

about 1 degree. Moreover, unlike the fovea, in the retinal periphery there is considerable convergence of cones onto ganglion cells.

Almost 140 years ago, Aubert & Forster¹¹ demonstrated that visual acuity declines in an orderly fashion with eccentricity – an important observation that has been often repeated and extended to a multiplicity of tasks over the years. About 100 years later, Weymouth¹² showed that many visual functions degrade approximately linearly with eccentricity, and we can characterize the rate of fall-off of many visual functions (as well as the anatomical structures that limit performance) by the gradient, which can be represented by a single number called E_2 . E_2 represents the eccentricity at which the foveal value has doubled.^{13,14}

Daniel & Whitteridge¹⁵ coined the term “cortical magnification factor” or CMF, to describe the cortical distance (usually specified in mm) devoted to one degree in the visual field. Although there are still uncertainties about the precise CMF of the fovea, in humans, the best estimates (based on functional imaging) suggest that it is about 20 mm/deg (i.e. 1 degree in visual space is represented over a distance of about 20 mm in the cortical representation of the fovea). In contrast, at an eccentricity of 10 degrees, 1 degree in visual space is represented over a distance of only about 1.5 mm in the cortex.

The CMF is generally specified in mm/deg. A convenient simplification is that the inverse CMF (i.e. the number of degrees per millimeter) varies approximately linearly with eccentricity (Fig. 33.10A). Thus, in the human fovea, approximately 0.05 degrees of visual space (3') is represented in 1 mm of striate cortex, while at 10 degrees eccentricity about 0.67 degrees is represented in 1 mm. The red line in Figure 33.10B shows the gradient (i.e. the rate of variation of inverse magnification with eccentricity), by plotting the ratio of peripheral to foveal inverse magnification at each eccentricity. Essentially, this normalizes inverse magnification at each eccentricity by the foveal value. An advantage of using the gradient is that it makes it simple to compare changes in anatomy or performance with eccentricity for different structures and functions.

For inverse cortical magnification (the red line in Figure 33.10B) the gradient is steep and E_2 is ≈ 0.77 degrees.¹⁴ In contrast, the gradient for midget retinal ganglion cell size (the blue line in Figure 33.10B – from Peterson & Dacey¹⁶) is shallow, and E_2 is about 3.7 degrees. The importance of the gradients of performance is that they may provide clues as to the structures, at various levels of the visual pathway, which limit performance. Indeed, one of the reasons Polyak¹⁷ gave for undertaking his classical study of the retina was to obtain a better understanding of the “striking difference between central and peripheral acuity”. Different psychophysical tasks also have different gradients. For example Vernier acuity has a steep gradient, while contrast sensitivity (discussed below) has a shallow gradient.

Figure 33.11 shows a visual acuity chart in which the letters are “scaled” in size, so that each letter covers an approximately equal cortical distance, and interestingly, the letters should be approximately equally visible!

Why is the foveal representation in the cortex so highly magnified? The visual system must make a trade off. High resolution (like our foveas) requires a great deal of resources – a dense array of photoreceptors; a one-to-one line from

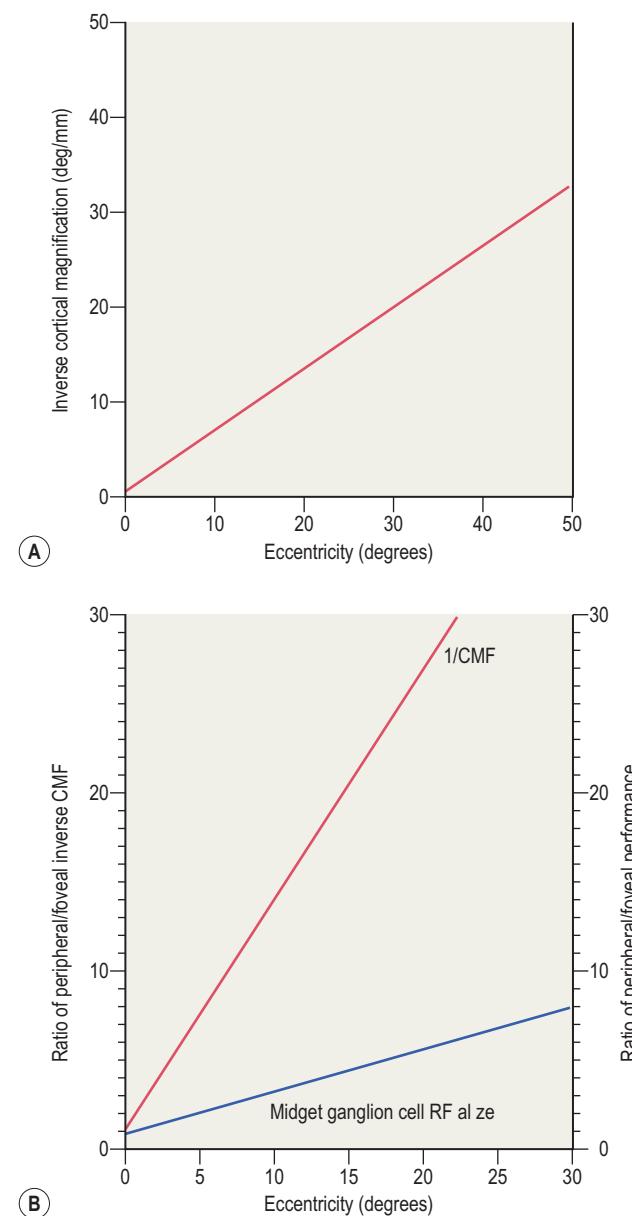

Figure 33.10 (A) The inverse cortical magnification factor (CMF in degrees per millimeter) versus eccentricity. (B) The red line shows the gradient (i.e. the rate of variation) of inverse magnification with eccentricity, by plotting the ratio of peripheral to foveal inverse magnification at each eccentricity. For inverse cortical magnification the gradient is steep. In contrast, the gradient for midget retinal ganglion cell size (the blue line) is shallow.

photoreceptors to retinal ganglion cells, and a large chunk of cortex. If we could see the entire visual field with such high resolution, we might need to have eyes and brains too large to fit in our heads! Thus, we have evolved a visual system that provides high resolution in the center, and lower resolution in the periphery. In large part, the high foveal magnification in the cortex reflects the topography of the retina¹⁸ (see Fig. 33.7); however, there appears to be additional magnification of the foveal representation in the cortex,¹⁹ and the striate cortex contains more than 100 times more cells than LGN.

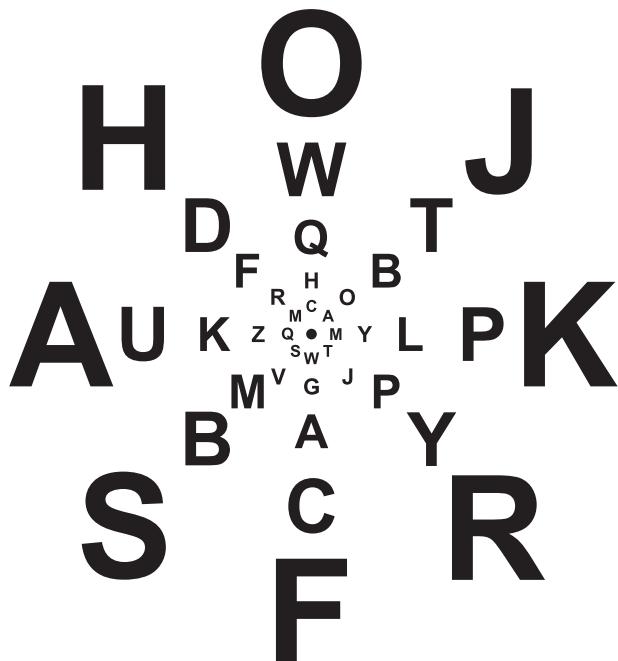

Figure 33.11 A visual acuity chart in which the letter size has been “scaled” according to the cortical magnification factor. (From Anstis SM. A chart demonstrating variations in acuity with retinal position. *Vision Research*, 14, 589–92; 1974. Copyright Elsevier 1974.⁹⁷)

Box 33.2 Crowding

In peripheral vision and in the central field in strabismic amblyopia, the identification of a letter, which can be easily identified in isolation, is severely impaired by neighboring letters. This “crowding” phenomenon has been discussed scientifically for some 60 years, but is only beginning to be understood. Crowding represents an essential bottleneck for object recognition and reading.

Crowding in peripheral vision

In peripheral vision, the identification of a letter is severely impaired by neighboring letters (Box 33.2). This “crowding” phenomenon²⁰ has been discussed scientifically for some 60 years, but is only beginning to be understood (see recent reviews^{21,22}). The reader can experience this phenomenon by viewing Figure 33.12. When looking at the fixation point, the letter R is clearly legible in the top panel, where it is presented in isolation. However, it is much more difficult to read in the lower panel, when flanked by other letters.

Inspection of Figure 33.12 makes it obvious that crowding does not result in reduced apparent contrast – rather, crowded letters are high contrast but indistinct or jumbled together. Tyler & Likova²³ also note their strong subjective impression of a “gray, or inchoate, smudge between the two outer letters, including the inner parts of those letters.”

In peripheral vision, the spatial extent of crowding depends on eccentricity, and can be as large as ≈ 0.5 times the target eccentricity. Several recent studies have varied both target size and eccentricity, and show that the extent of peripheral crowding is more or less invariant to target size.^{24–27}

Figure 33.12 Crowding. The reader can experience crowding by fixating the dot, and trying to identify one letter: in isolation (A), surrounded by 4 random flanking letters (B), surrounded by 2 horizontally placed random flanking letters (C), surrounded by 2 vertically placed random flanking letters (D). (From Levi DM. Crowding—An essential bottleneck for object recognition: A mini-review. *Vision Res.*, 48, 635–54; 2008. Copyright Elsevier 2008.²¹)

The strength and extent of peripheral crowding are much greater than the strength and extent of masking,^{24,28} so that in peripheral vision, the suppressive spatial interactions due to nearby flanks are not likely to be a consequence of simple contrast masking.

A number of studies, using very different stimuli and tasks, have shown convincingly that crowding is indifferent to whether the target and flanks are presented to the same eye or to different eyes (target to one eye, flanks to the other^{14,29–31}). The fact that crowding occurs when target and flanks are presented to separate eyes immediately places the site of the interaction at or beyond the site of combination of information of the two eyes. Remarkably, this dichoptic interaction even occurs when the flankers are presented around the blindspot of one eye, and the target in the “monocular” region corresponding to the blindspot of the other eye.³² This is both surprising and interesting because

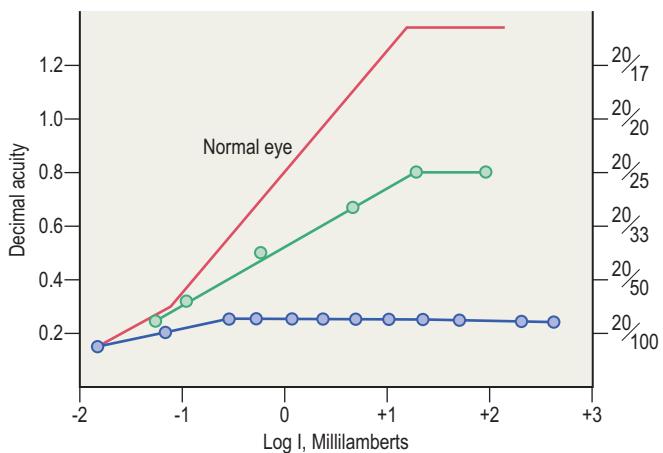

Figure 33.13 Acuity vs log luminance for normal fovea (red) and for patients with retinal lesions due to a disease of Bruch's membrane (green) and macular toxoplasmosis (blue). (Modified from Doc Ophthalmol.⁴⁰)

there is a complete absence of direct retinal afferents from one eye to this region of cortex.

Note that there is no evidence of crowding when looking directly at the letters in Figure 33.12. Except near the limit of resolution³³ in the normal fovea the extent of "crowding" is proportional to stimulus size and cannot easily be distinguished from ordinary masking.^{34,35} At the limit, foveal crowding extends over a tiny distance just 4–5 minutes of arc.^{33,36–38}

We will return to the issue of crowding in the section on amblyopia.

Luminance

Visual acuity is usually measured under moderate photopic luminance conditions (80 to 320 cd/m²), and under those conditions (and indeed luminance levels ranging from full moonlight to a bright sunny sky) visual acuity remains fairly constant.^{2,39,40} At very low luminance levels, visual acuity is markedly reduced. Under very low (scotopic) luminance conditions visual acuity is mediated by rods, and rod acuity asymptotes at an acuity level between 20/100 and 20/200. Figure 33.13 shows the acuity vs log luminance function for normal fovea (red) and for patients with retinal lesions due to a disease of Bruch's membrane (green) and macular toxoplasmosis (blue). Retinal disease lowers both the upper asymptote and the slope of the acuity vs luminance function.

Similarly, Vernier acuity for abutting lines is markedly reduced at low luminance levels.⁴² Reducing luminance alters the visibility of a stimulus. For example, the contrast ($\Delta I/I$) necessary to detect a thin line increases as retinal illuminance is reduced. Specifically, both line detection thresholds and (abutting) Vernier thresholds decrease with the square root of retinal illuminance, suggesting that photon statistics may be the main source of information loss.^{7,41,42} Interestingly, when the effect of luminance on target visibility is taken into account (by making the target contrast a fixed multiple of the detection threshold at each luminance level) Vernier acuity becomes independent of target luminance.⁴²

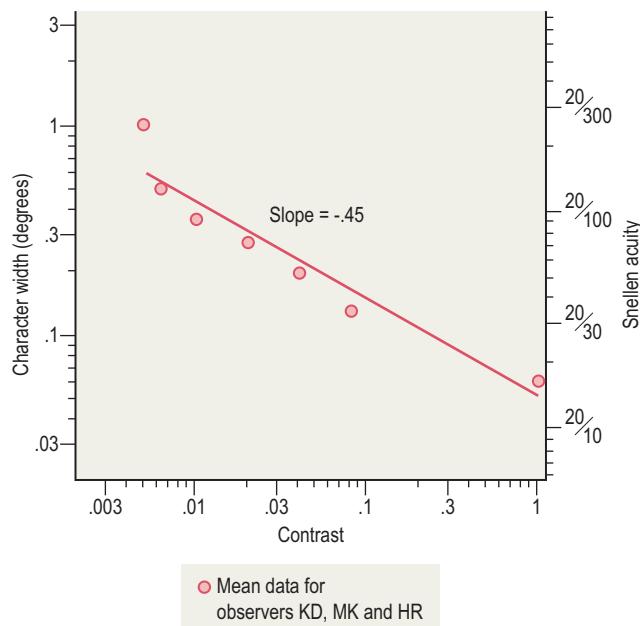

Figure 33.14 The effect of contrast on Snellen acuity. (From Legge GE, Rubin GS, Luebker A, et al. Psychophysics of reading—V. The role of contrast in normal vision. Vision Res., 27, 1165–77; 1987. Copyright Elsevier 1987.⁴⁷)

Contrast

Visual acuity is generally tested with high contrast ($\approx 100\%$ contrast) optotypes, and reducing the contrast results in a systematic reduction of acuity.^{43–46} Figure 33.14 (from Legge et al⁴⁷) shows that one's visual acuity for Sloan letters varies linearly on log-log coordinates, with a log-log slope of ≈ -0.5 . In other words, visual acuity improves in proportion to the square root of the target contrast. Similarly, other types of acuity (e.g. abutting Vernier acuity) depend strongly on target contrast. Interestingly, relative position judgments with widely separated targets show little dependence on contrast, luminance, or polarity, as might be expected if these judgments are limited by a local sign mechanism (discussed earlier).

Time

For many visual tasks including visual acuity and abutting Vernier acuity, performance is degraded when the stimulus presentation is brief.^{48,49} This effect can largely be understood on the basis of stimulus energy or visibility, i.e. reducing the duration below a "critical" duration, reduces the number of quanta and the visibility of the stimulus. This effect of duration can be cancelled by increasing the illumination or contrast of the stimulus to maintain a constant visibility (or a constant number of absorbed quanta^{2,49,50}).

Motion

Even when you try to hold your eyes completely stationary, they continue to execute small but important movements. These involuntary eye drifts and small jerks keep the retinal image "fresh"; if the eye muscles are temporarily paralyzed – say, as a result of taking curare⁵¹ – the entire visual world gradually fades from view. Using retinal image stabilization, Keesey⁵² showed that these small involuntary eye

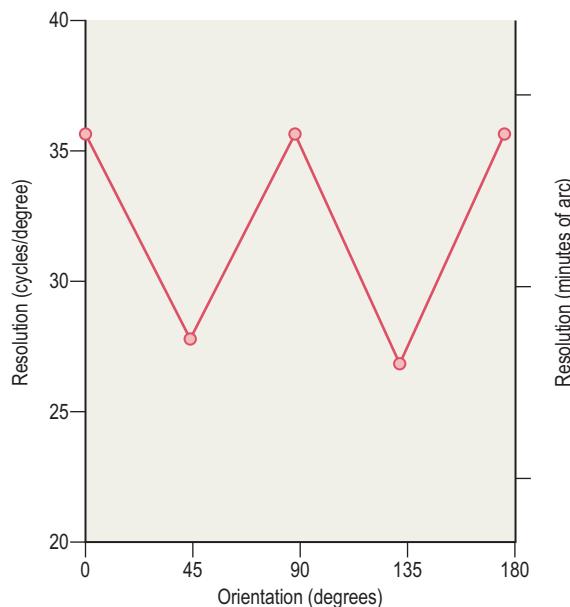

Figure 33.15 Oblique effect. (Modified from J Physiol.⁹⁸)

movements have little or no effect on visual acuity. Indeed, visual acuity measured with Landolt C's and Vernier acuity are unaffected by retinal image motion of up to ≈ 2.5 degrees/second.⁵³ Beyond that, Vernier acuity for targets consisting of closely spaced dots or lines is strongly degraded by fast motion. For very large blurred stimuli (low spatial frequency sinusoids), Vernier acuity is quite robust to even very high velocities.⁵⁴

Anisotropies

There are anisotropies in visual acuity. For example, in the fovea visual acuity and contrast sensitivity at high spatial frequencies are better for horizontal and vertical gratings than for oblique (Fig. 33.15). The W-shaped function shown in Figure 33.15 is known as the oblique effect.⁵⁵ It is not an optical effect since it occurs when interference fringes are imaged directly on the retina, thus bypassing the optics of the eye.⁵⁶ In peripheral vision the oblique effect gives way to a radial organization, with acuity being better for gratings oriented along a line connecting the fovea to the peripheral location (radial orientation) and worse for the orthogonal orientation. The most profound anisotropy is found under conditions of crowding. Crowding in peripheral vision is much more extensive when the flankers are radially arranged than when they are tangentially arranged (Fig. 33.16).^{27,38} The reader can see this effect for themselves in the lower two panels of Figure 33.12. In panel (D), the flanks are arranged radially, in panel (C), tangentially.

Visual acuity and reading

The ability to read quickly and accurately is crucial in our society, and difficulty in reading is one of the most frequent reasons that patients visit their eye doctor. Clearly, if acuity is substantially reduced, reading will be impaired. However, recent work shows that it is text spacing not text size that limits reading speed. When the text spacing is closer than a critical spacing, reading is slowed. The critical spacing for

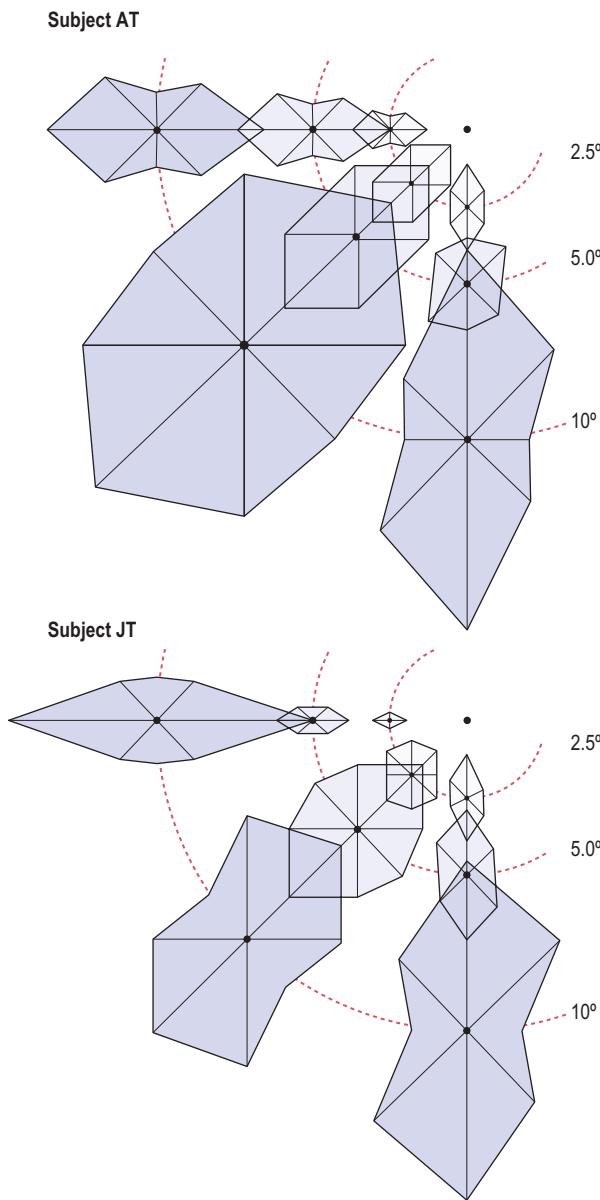

Figure 33.16 The 2-dimensional shape of "crowding" in foveal (the small dot in the center) and peripheral vision (at 2.5, 5 and 10 degrees). (From Toet A, Levi DM. The two-dimensional shape of spatial interaction zones in the parafovea. Vision Research, 32, 1349–57; 1992. Copyright Elsevier 1992.³⁸)

reading is equal to the critical spacing for crowding^{22,27,57} (Fig. 33.17). The notion that crowding limits reading is surprising and perhaps controversial, because reading rate has generally been thought to be linked to letter size rather than spacing. Changing the viewing distance for normal reading material changes both size and spacing; however, experiments measuring reading performance versus letter size with normal and doubled letter spacing (i.e. 1.1 and 2.2 times the letter size) reveal that it is spacing that matters.⁵⁷ Thus crowding appears to represent a limit for reading in normal and amblyopic central vision.⁵⁷ This is consistent with the conclusions of Legge and his co-workers that the "visual span" (i.e. the number of letters in a line of text that can be recognized reliably without moving the eyes) represents a sensory bottleneck for reading.^{58–60}

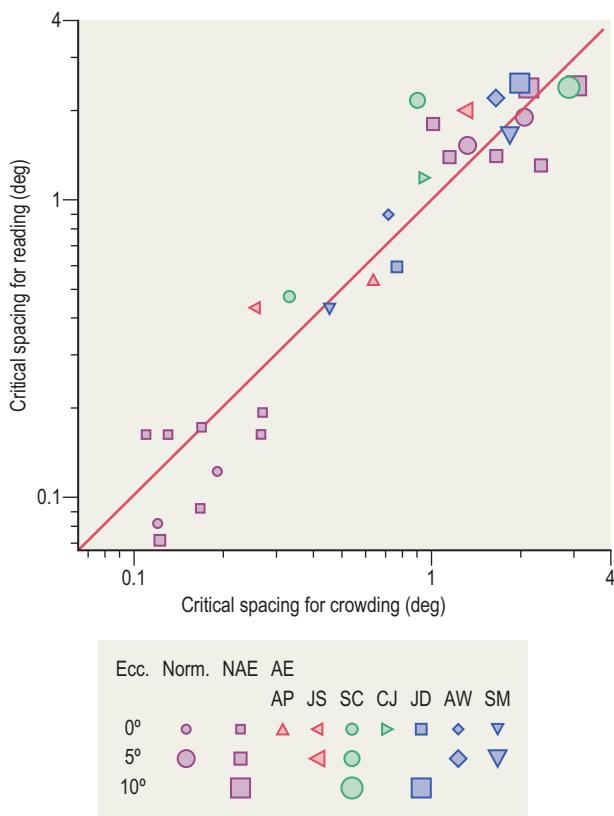

Figure 33.17 The critical spacing for reading is equal to the critical spacing for crowding for normal foveal, peripheral and amblyopic vision. (Reproduced with permission from Association for Research in Vision and Ophthalmology⁵⁷)

While the critical spacing for crowding and reading are also identical in peripheral vision (suggesting that crowding represents one limit to fast reading in the periphery), reading slows with increasing eccentricity even when crowding is controlled for (by scaling with eccentricity), for reasons that remain mysterious.

Spatial vision with low contrast

Up until now we've been discussing the smallest, high-contrast details that we can resolve; however, most of the objects in our world are larger than the resolution limit, and have lower contrast.

How can we measure and quantify how well we see objects that are larger than the resolution limit? Recall how the performance of an optical system was measured earlier in this chapter. Test patterns consisting of sinusoidal gratings (see Fig. 33.5) of known contrast and a range of sizes (spatial frequencies) were passed through the optical system, and the ratio of image contrast to object contrast was used as a measure of modulation transfer of the optical system. Sinusoidal gratings have some important advantages for testing optical systems, and therefore should be useful in characterizing human pattern vision. There is, however, a problem. In an optical system, it is relatively easy to measure the contrast of the image; however, that's not so easily done in

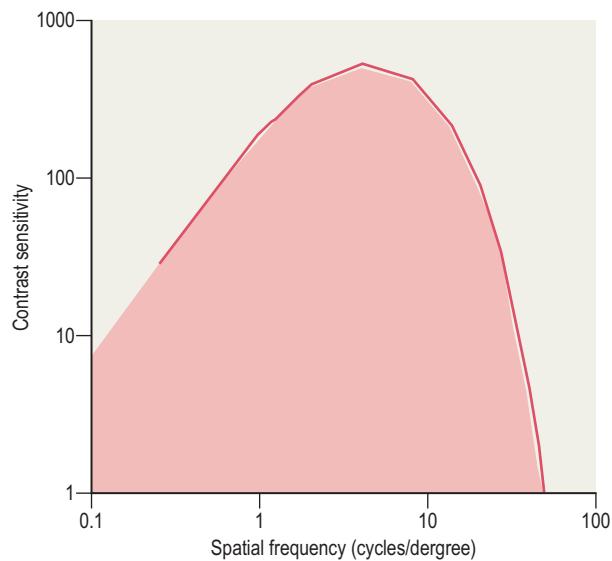

Figure 33.18 The contrast sensitivity function: our window of visibility.

human vision, because the image is on the retina. More importantly, how well we see sinusoidal gratings will be determined by both the optical components of the eye, and by any neural processing in the visual pathway. Thus, what we really want to know is about the quality of the image that reaches the brain and gives rise to perception. Schade⁶¹ first addressed this by showing people sinusoidal gratings and asking them to adjust the contrast of the gratings until they could just be detected. By repeating these measurements for a wide range of different spatial frequencies (stripe widths), Schade was able to describe the "contrast sensitivity function" – i.e. contrast sensitivity for gratings of different spatial frequencies. Almost 10 years later, Campbell & Green⁵⁵ published what is widely regarded as a classical paper, describing a relatively simple method for measuring the contrast sensitivity function, and showed that both optical and neural processes influence the function.

The contrast sensitivity function represents our window of visibility

The red line in Figure 33.18 shows a contrast sensitivity function (CSF). The vertical axis shows the observer's contrast sensitivity plotted as a function of the spatial frequency of the sinusoidal gratings (with low spatial frequencies, or broad stripes represented on the left, and high spatial frequencies or fine stripes, on the right). Surprisingly, the function is shaped like an upside-down U. The modulation transfer of the eye (or any other optical system) reduces the contrast of high spatial frequencies, so the fall-off of sensitivity at high spatial frequencies is to be expected based on the optics of the eye. However, the fall-off of sensitivity at low spatial frequencies is unexpected. Poor optics will not reduce sensitivity at low spatial frequencies, so this low spatial frequency fall-off must be due to neural factors (we'll discuss these later).

Contrast sensitivity is obtained by measuring the smallest amount of contrast needed to detect the target (the contrast threshold), and sensitivity is defined as the reciprocal of the threshold contrast. Thus, if the contrast at threshold is 0.01,

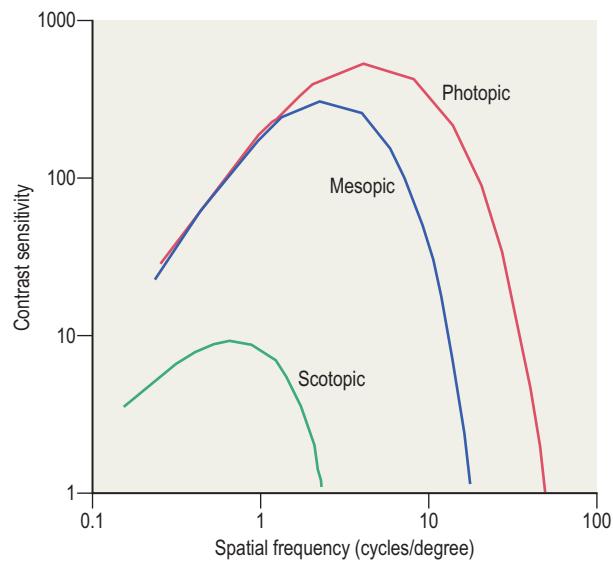

Figure 33.20 The CSF at photopic, mesopic and scotopic luminance levels.

Figure 33.19 Contrast and SF modulated grating (Robson & Campbell). (From Robson, J., and Campbell, F. (1997). A quick demonstration of your own contrast sensitivity function. In D. G. Pelli and A. M. Torres, *Thresholds: Limits of Perception*. New York: NY Arts Magazine.⁹⁹)

contrast sensitivity will be 100, and a contrast threshold of 0.1 will give a contrast sensitivity of 10. Thus, the red line in **Figure 33.18** corresponds to the lowest contrast one can see, and the pink region under the curve represents the window of visibility. Any pattern whose spatial frequency and contrast fall within the pink region will be visible, while any combination of spatial frequency and contrast in the region above the curve will be invisible. For example, a spatial frequency of 1 c/degree will be invisible if its contrast is less than 0.01 and will be visible with any contrast greater than 0.01. For this spatial frequency, the contrast sensitivity is 100. Note that contrast sensitivity equal to 1 corresponds to a contrast of 100 percent. This is the rightmost point on the CSF (at around 50 c/degree), and corresponds to the observer's resolution limit. It is the finest grating the observer can detect with 100 percent contrast.

Figure 33.19 allows you to visualize your own CSF. This figure shows a sinusoidal grating whose contrast increases continuously from the top of the figure to the bottom, and whose spatial frequency increases continuously from the left side of the graph to the right side. If you hold the figure at a distance of about 50 cm, you will notice the inverted U shape where the grating fades from visibility to invisibility. This is your own CSF – because it tells us how your sensitivity varies over a wide range of target sizes, it is more informative than visual acuity.

Figure 33.18 illustrates a typical CSF, obtained with foveal viewing of stationary gratings at high levels of illumination (i.e. using cone vision). The CSF changes its shape at low luminance (**Fig. 33.20**). For example, at very low (scotopic) luminance levels, sensitivity is markedly reduced at all spatial frequencies, and the low spatial frequency fall off is

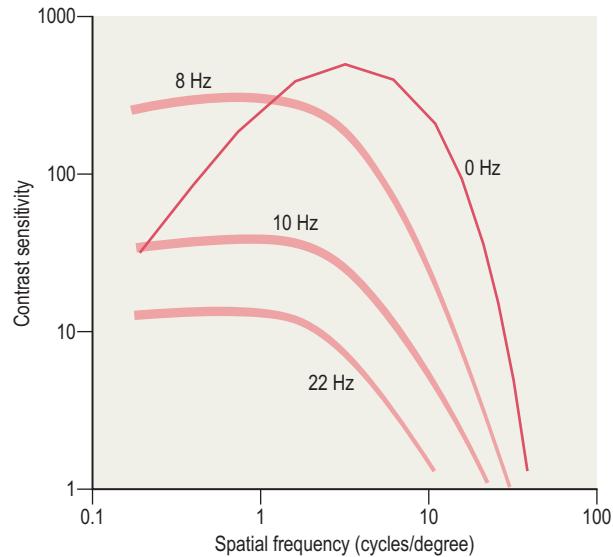

Figure 33.21 The CSF at 3 temporal frequencies. Note that it changes its shape at higher temporal frequencies.

less pronounced. At intermediate (mesopic) luminance levels, CSF is reduced mainly at high spatial frequencies. The CSF also changes its shape when the gratings are moved, flickered on and off or temporally modulated in other ways (**Fig. 33.21**). These changes in the shape of the CSF reflect neural changes.

The CSF in peripheral vision

Visual resolution declines with eccentricity. How the CSF changes with eccentricity depends in large part on how it is measured. In early studies, peripheral CSFs were measured with a patch of gratings that was fixed in size (say 1 degree). As illustrated in **Figure 33.22A**, when a fixed-size patch is viewed in the periphery, contrast sensitivity decreases dramatically at all spatial frequencies – with the most marked

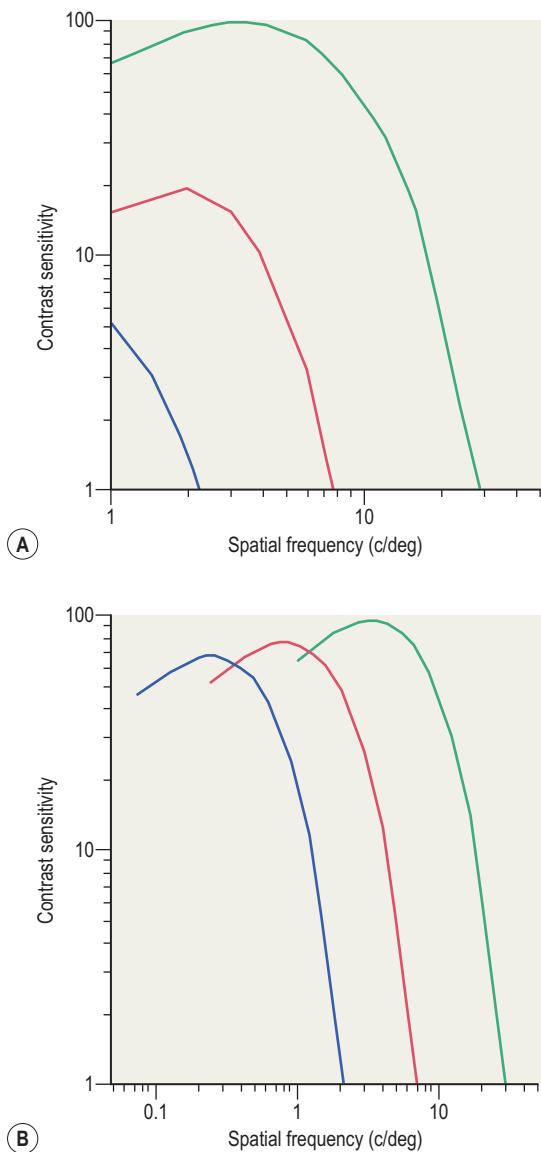

Figure 33.22 Contrast sensitivity functions at 3 eccentricities: fovea (green), 7.5 degrees (red) and 30 degrees (blue). (A) With fixed field size (2 degree half circle). (B) With field size scaled in proportion to ganglion cell density at each eccentricity. (Modified from Rovamo, J., Virsu, V. & Näsänen, R. (1978). Cortical magnification factor predicts the photopic contrast sensitivity of peripheral vision. *Nature*, 271, 54–6. By permission from Macmillan Publishers Ltd.⁶²)

effect at high spatial frequencies. Based on these types of measurements, it was commonly assumed that the periphery was basically able to function to detect light and movement, but not to be capable of making useful judgments about patterns or form. However, Rovamo et al⁶² showed that the peak contrast sensitivity of the periphery could be almost (but not quite) as high as that of the fovea, if the stimulus size was magnified in order to compensate for the reduced representation of the periphery in the visual nervous system. This basic idea, now widely known as **magnification theory**, has been shown to apply to a wide variety of visual stimuli and tasks. Rovamo et al⁶² magnified the stimulus size by a scale factor that was actually based on retinal ganglion cell density at each eccentricity, so in essence, they equated the number of ganglion cells that were stimulated by the patch

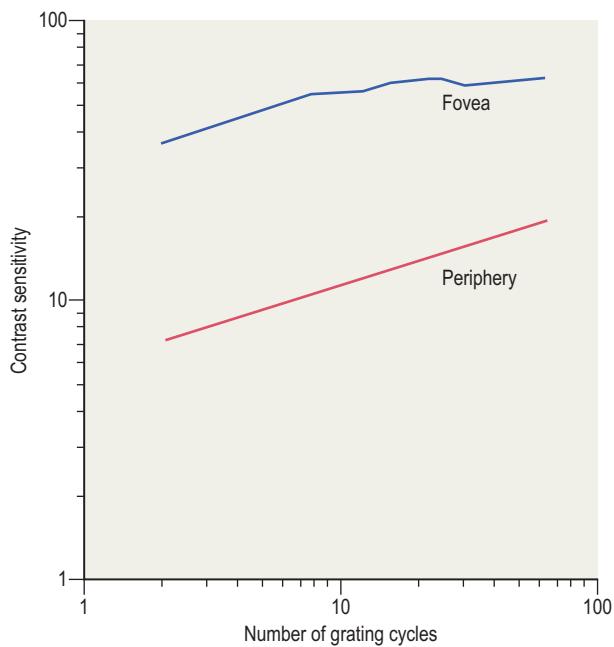

Figure 33.23 Contrast sensitivity vs number of cycles for fovea (blue) and periphery (red). (Modified from Robson JG, Graham N. Probability summation and regional variation in contrast sensitivity across the visual field. *Vision Res.*, 21, 409–18; 1981. Copyright Elsevier 1981.⁶³)

of grating at each eccentricity. (This “scaling” was accomplished by viewing the same patch on the screen from successively closer viewing distances as the eccentricity increased, thus increasing the angular size of the stimulus patch.) The result is that peak contrast sensitivity is almost the same at each eccentricity (Fig. 33.22B). Note, however, that even with the larger field size, both the peak of the CSF and the cutoff spatial frequency shift toward lower spatial frequencies as eccentricity increases.

How is it that peripheral contrast sensitivity improves so much at low spatial frequencies when the patch size is increased? Robson & Graham⁶³ showed that the improvement could largely be explained by a process known as **probability summation**. They measured contrast sensitivity for patches with different numbers of grating cycles. They found that contrast sensitivity improved as they added cycles, and the improvement followed a power function (i.e. a straight line on log-log axes). In the fovea, the function saturated when there were around 8 cycles, so that adding yet more cycles did not improve sensitivity much (Fig. 33.23 – blue line). However, in peripheral vision sensitivity improved up to 64 cycles (the maximum number they tested; see Fig. 33.23 – red line). Recall that the scaling method of Rovamo et al increased the field size when testing the periphery. Thus, the periphery would get the benefit of having more cycles of the grating than the fovea, and as Robson & Graham showed the periphery uses every cycle it gets! Robson & Graham argued that the improvement in sensitivity as more cycles are presented, accrues from having more opportunities to detect the pattern. Their notion of probability summation across space was that the grating would be detected if it landed on a mechanism (receptive field) that was sensitive to the target, and signaled its

presence, and they further assumed that each receptive field acted independently. Based on these simple assumptions, they were able to predict the effect of the number of cycles by simply pooling the responses of independent mechanisms sensitive to the target.

Clinical testing of visual acuity

Visual acuity chart design considerations

The original Snellen chart consisted of seven letter sizes, with a single (20/200) letter at the top, two (20/100) letters on the next line, with the number of characters (letters and numbers) increasing on each subsequent line, and the inter-letter spacing varying from line to line see (Fig. 33.2). Moreover, the change in letter size between the 20/200 and

20/100 lines is very coarse (50%), while the change from 20/50 to 20/40 is much finer (20 percent), so that testing accuracy varies depending on the acuity level.

Most contemporary charts incorporate some or all of the design principles (Box 33.3) proposed by Bailey & Lovie;⁶⁴ the same number of letters on each line; a constant ratio from one letter size to the next (i.e. each line is a fixed percentage smaller than the previous line); spacing between letters and lines proportional to letter size, and nearly equal legibility to the optotypes (or nearly equal average legibility at each letter size). A distinguishing feature of charts that incorporate these principles is the V-shaped appearance, since each line is proportionally smaller than the preceding line. Figure 33.24 shows two such charts, the Bailey–Lovie chart and the Early Treatment of Diabetic Retinopathy Study

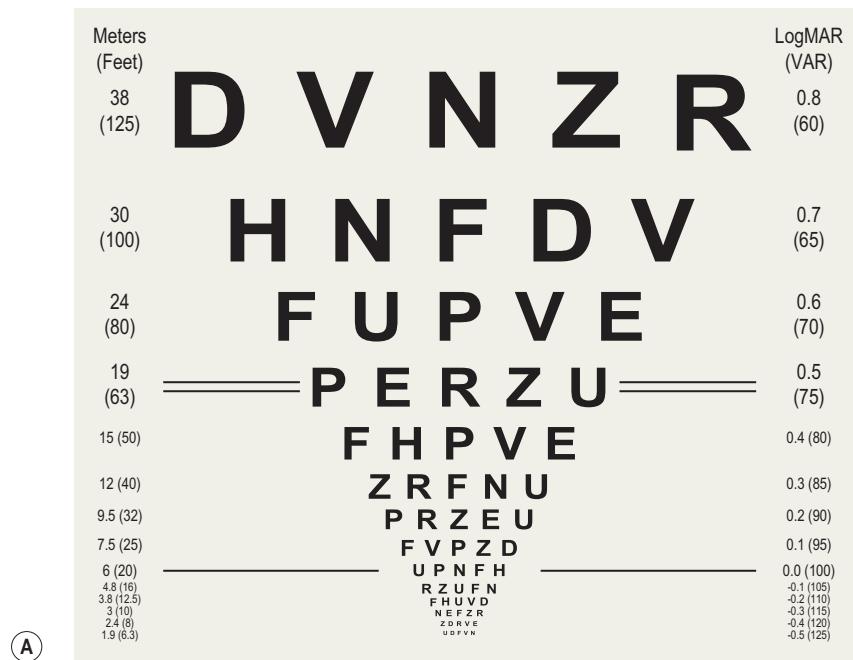

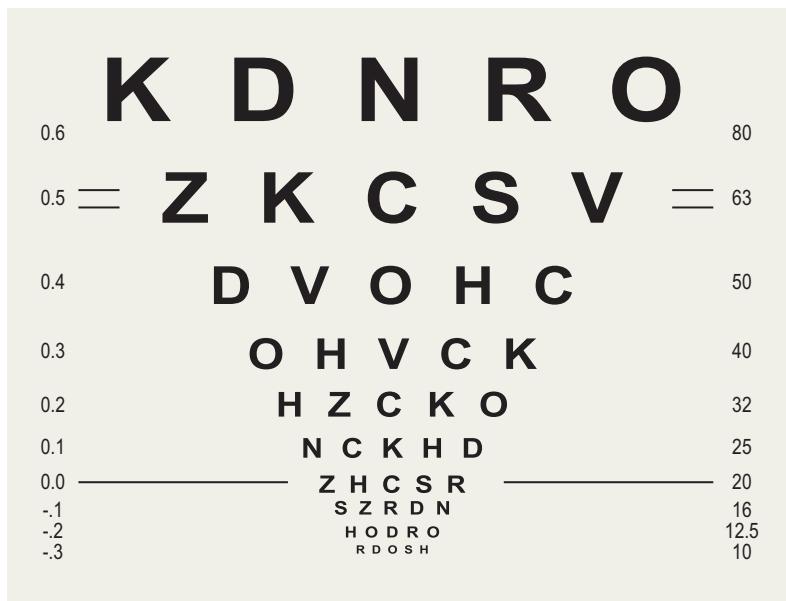

Figure 33.24 The Bailey–Lovie chart (**A**) and the Early Treatment of Diabetic Retinopathy Study (ETDRS) charts (**B**). Courtesy of Dr. Ian Bailey.

Box 33.3 Chart Design

Most contemporary charts incorporate some or all of the following design principles: the same number of letters on each line; a constant ratio from one letter size to the next (i.e. each line is a fixed percentage smaller than the previous line); spacing between letters and lines proportional to letter size, and nearly equal legibility the optotypes (or nearly equal average legibility at each letter size). Clinically, acuity can be measured with a variety of optotypes and charts. These include illiterate E's; Landolt C's and letters. Operationally, visual acuity charts come in several formats: printed, projected and computer-generated.

(ETDRS) charts. The constant ratio (logarithmic) size scaling is based on the psychophysical principle that just-noticeable differences and their variability scale logarithmically.⁶⁵

One impetus for using proportional spacing is the idea that letter spacing should be proportional to letter size in order to keep the effect of contour interaction consistent across acuity levels.³⁶ However, in peripheral vision²⁴ and in the central field of strabismic amblyopes crowding⁶⁶ is a fixed spatial distance, not a fixed multiple of the target size.

Clinically, acuity can be measured with a variety of optotypes and charts. These include illiterate E's; Landolt C's and letters. One of the great advantages of using letters for measuring acuity is that the likelihood of randomly guessing the correct letter is low ($\approx 4\%$ or 1 out of 26 if all the letters are used). Many charts used a reduced letter set, and for these the guess rate will be higher. For example, the ETDRS chart uses the Sloan letter set (C,D,H,K,N,O,R,S,V,Z), while the Bailey-Lovie chart uses the British letter set (D,E,F,H,N,P,R,U,V,Z). For both of these, the guess rate is 10 percent (1 out of 10). Operationally, visual acuity charts come in several formats: printed, projected and computer-generated.

There is a wide range of special methods for testing infants, toddlers and others who have limited capacity to respond to standard acuity charts. These run the gamut from objective tests such as visual-evoked potentials (VEP), optokinetic nystagmus (OKN) and preferential looking (PL), often used for infants and discussed in Chapter 38, to symbol and picture charts.

Clinical tests for CSF

Contrast sensitivity is not routinely measured in the clinical setting; however, there are now several methods available for doing so. These include the Functional Acuity Contrast Test (FACT CS Test – Stereo-Optical Co) that replaced the original Vistech chart.⁶⁷ This chart has 5 different sinusoidal grating frequencies, each presented at 9 contrast levels, allowing determination of the full CSF. A more popular approach is the Pelli-Robson CS chart⁶⁸ (Fig. 33.25) which consists of 16 "triplets" of letters. The letters in each triplet have the same contrast, with the contrast between successive triplets decreasing by 0.15 log units. Since the patient's task is to simply read the letters as far down the chart as they can, it is essentially identical to other visual acuity measures. What is different is that letter size is constant (0.5 degrees at 3 meters or 20/120) and contrast varies. There are also several conventional charts (varying letter size) that are available in both high- and low-contrast

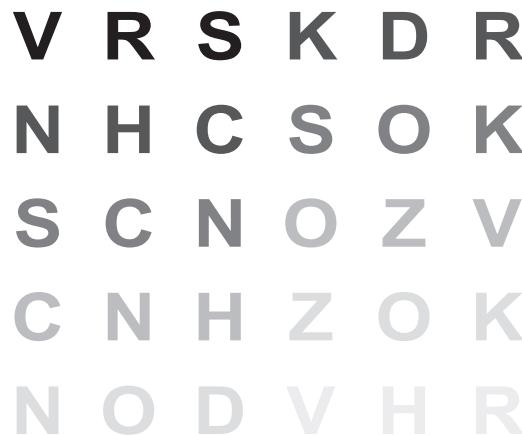

Figure 33.25 The Pelli-Robson chart for measuring contrast sensitivity. (From Pelli, D. G., Robson, J. G., & Wilkins, A. J. (1988) The design of a new letter chart for measuring contrast sensitivity. Clinical Vision Sciences 2, 187–199. Copyright Elsevier 1988.⁶⁸)

versions (e.g. the Bailey-Lovie chart and the Regan low contrast chart). It should be noted that different clinical contrast sensitivity tests measure different aspects of vision. For example, the Pelli-Robson test (fixed large letter size) provides information about the sensitivity near the peak of the CSF, while the low-contrast variable letter size tests (e.g. Bailey-Lovie and Regan charts) provide information about sensitivity along the high-frequency limb of the CSF (i.e. the smallest letter size that can be resolved at a fixed low contrast). Although contrast sensitivity testing provides useful information for clinical trials, assessing treatment outcomes, etc., it is not clear how widely used it is in clinical practice. For example, fewer than 20% of eye-care practitioners who responded in a survey, frequently or always measured contrast sensitivity in pre-operative cataract patients.⁶⁹

Glare

Glare – the effect of a bright or dazzling light source can be uncomfortable and can lead to a loss of visual function (known as disability glare). Disability glare is a consequence of excessive light scatter which reduces the contrast of the retinal image. Clinically, disability glare can be estimated by measuring the reduction in visual acuity or contrast sensitivity in the presence of a peripheral glare source, and there are several clinical tests available (e.g. the Miller-Nadler Glare tester; the Brightness Acuity Tester; the Optec 3000 and Vistech MCT8000). Disability glare tests have proved useful in clinical trials (e.g. ref. 70) and research on aging (discussed below) but the utility of glare testing in routine practice is not clear.

Development of spatial vision

We used to think of infant vision as "a buzzing, blooming, confusion".⁷¹ However, studies over the past 20 years or so have shown that the visual system is much more developed at birth than we used to think (see Chapter 38).

Development of visual acuity and CSF

The emerging picture suggests that peak contrast sensitivity increases, and the peak of the CSF shifts toward higher

spatial frequencies, with increasing age. Low spatial frequency sensitivity develops much more rapidly than high spatial frequency sensitivity. Thus, peak contrast sensitivity may reach adult levels as early as about 9 weeks of age, whereas sensitivity at higher spatial frequencies continues to develop dramatically, and there remains a roughly 20-fold difference in the contrast sensitivity of adults and 8-month-olds.⁷² Visual acuity is only adult-like around 3–5 years post-natal.⁷³

Development of hyperacuity

The early development of Vernier actually appears to be somewhat delayed, compared to resolution. Shimojo and co-workers^{74,75} suggested that Vernier acuity is initially worse than grating acuity, and then shows a dramatic improvement (relative to grating acuity) between about 2 and 8 months. At 8 months, Vernier acuity was about twice as good as grating acuity. The Vernier acuity of very young infants remains controversial. However, the important point is that Vernier acuity and grating acuity reach adult levels of performance at different ages. The attainment of adult levels of hyperacuity – which is 6 to 10 times better than grating acuity is delayed compared to resolution.

It is interesting to speculate why Vernier acuity has a slow late development, reaching adult levels considerably later than resolution. If we consider that Vernier acuity is limited by the precision with which the brain “knows” the position of each afferent, then it is perhaps not so surprising that intrinsic positional uncertainty can only reach adult levels after retinal development is fully complete. The primary postnatal changes in the retina concern differentiation of the macular region.⁷³ After birth, foveal receptor density and cone outer segment length both increase, as foveal cones become thinner and more elongated. There is a dramatic migration of ganglion cells and inner nuclear layers from the foveal region, as the foveal pit develops during the first 4 months of life, and it is not until about 4 years of age that the fovea is fully adult-like.⁷⁶ From birth to beyond 4 years of age, cone density increases in the central region, due to both migration of receptors, and decreases in their dimensions. Both of these factors result in finer cone sampling (by decreasing the distance between neighboring cones). It is likely that alterations in cone spacing and the light-gathering properties of the cones during early development contribute a great deal toward the improvements in acuity and contrast sensitivity during the first months of life. The massive migration of retinal cells, and the alterations in the size of retina and eyeball (along with changes in interpupillary distance), may necessitate the plasticity of cortical connections early in life. It seems reasonable to speculate that the brain cannot “know” the positions of foveal cones with high levels of precision, until after these changes in the retina are complete. Interestingly, the peripheral retina appears to develop much more rapidly than the fovea.⁷⁶

Visual acuity through the lifespan

Visual acuity reaches adult levels around 3–5 years of age, and remains rather constant until around 55–60 years of

Figure 33.26 The letter m sized in proportion to the median acuity for 4 measures of visual acuity in 60–65-year-olds and in 85–90-year-olds.⁷⁸

age, after which it begins to decline.⁷⁷ The decline is important because the graying of the population of the US. According to US Census 2000, 35 million Americans are 65 years and over (12.4 percent of the population). Those over 85 years are growing at roughly three times the rate of the general population – 50,000 Americans are over 100 years old.

There are a number of reasons why one might expect visual function to decline with age. These include:

- decreased pupil size particularly in dim light
- decreased lens transmission particularly for short-wavelength (blue) light
- increased intraocular light scattering.

All of these result in reduced retinal image contrast (particularly for small targets) and reduced retinal illumination. Thus, one might expect that visual performance is impaired most under low-contrast and low-light conditions NOT the high-luminance and high-contrast conditions normally used to test visual acuity.

Until ~10 years ago, only high-contrast acuity was known in elders. However, the SKI study, which has followed some 900 elderly persons from Marin county, CA over a period of about 7 years, suggests that high-contrast acuity greatly underestimates the loss of visual function in the elderly.⁷⁸ Figure 33.26 shows this graphically by presenting the letter m sized in proportion to the median acuity for 4 measures of visual acuity in 60–65-year-olds and in 85–90-year-olds.

For high-contrast, high-illumination targets, acuity is reduced by about a factor of 1.8 in the older group (i.e. the “m” must be about 1.8 times larger). Low-contrast acuity with glare is reduced by about a factor of 3 in the younger (60–65) group, but by almost a factor of 7 in the older group. Although the SKI study population is probably not representative of the population at large (it is primarily white, well educated with high socioeconomic status) it has important implications for understanding the visual problems of the elderly. Specifically, it shows that high-contrast visual acuity greatly underestimates the true age-related decline in vision, and that older persons with good standard visual acuity may be visually impaired under conditions of reduced contrast, reduced lighting, changing light level, or reduced contrast in the presence of glare.

Box 33.4 Amblyopia

Amblyopia is a developmental disorder of spatial vision usually associated with the presence of strabismus, anisometropia or form deprivation early in life.⁷⁹ Reduced visual acuity in an apparently healthy eye, despite appropriate optical correction is the sine qua non of amblyopia. However, there is a great deal of evidence showing that amblyopia results in a broad range of neural, perceptual, and clinical abnormalities.

Amblyopia

Amblyopia is a developmental disorder of spatial vision usually associated with the presence of strabismus, anisometropia or form deprivation early in life (Box 33.4).⁷⁹ Amblyopia is clinically important because, aside from refractive error, it is the most frequent cause of vision loss in infants and young children,⁸⁰ and it is of basic interest because it reflects the neural impairment which can occur when normal visual development is disrupted. The damage produced by amblyopia is generally expressed in the clinical setting as a loss of visual acuity in an apparently healthy eye, despite appropriate optical correction; however, there is a great deal of evidence showing that amblyopia results in a broad range of neural, perceptual, and clinical abnormalities.^{81–84} Currently there is no positive diagnostic test for amblyopia. Instead, amblyopia is diagnosed by exclusion: in patients with conditions such as strabismus and anisometropia, a diagnosis of amblyopia is made through exclusion of uncorrected refractive error and underlying ocular pathology.

In humans, amblyopia occurs naturally in about 2–4 percent of the population⁷⁹ and the presence of amblyopia is almost always associated with an early history of abnormal visual experience: binocular misregistration (strabismus), image degradation (high refractive error and astigmatism, anisometropia), or form deprivation (congenital cataract,

ptosis). The severity of the amblyopia appears to be associated with the degree of imbalance between the two eyes (e.g. dense unilateral cataract results in severe loss), and to the age at which the amblyogenic factor occurred. Precisely how these factors interact is as yet unknown, but it is evident that different early visual experiences result in different functional losses in acuity and contrast sensitivity amblyopia⁸⁵ (Fig. 33.27), and a significant factor that distinguishes performance amongst amblyopes is the presence or absence of binocular function. Amblyopes who lack binocularity (primarily strabismic amblyopes) show much greater losses in Vernier and Snellen acuity than in grating resolution.^{86,87}

Crowding and amblyopia

Extensive crowding occurs in the central field of strabismic amblyopes. As first reported by Irvine,⁸⁸ “single letters or direction of ... an E could be identified by the amblyopic eye, if viewed one letter at a time, but when placed in conjunction with other letters in a line, confusion affected the interpretation.” The ophthalmologist Hermann Burian noted that his orthoptist recorded better visual acuities in amblyopic patients than he did. The orthoptist used isolated letters to measure acuity, whereas he used letters arranged in a row.⁸⁹ The phenomenon of crowding in strabismic amblyopia has been repeatedly confirmed.^{20,35,36,66,86,87,90–93}

While the extent of crowding in the central field of amblyopic observers was originally thought to be proportional to the amblyope’s uncrowded acuity, and similar to normal observers when the resolution deficit was taken into account,³⁶ the story seems to be a bit more complicated. Recent studies suggest that crowding is qualitatively different in strabismic and anisometropic amblyopes.^{88,89} In anisometropic amblyopes crowded acuity is proportional to the amblyope’s uncrowded acuity, similar to normal vision with blur, whereas in strabismic amblyopes it is worse, often very much so, similar to normal peripheral vision.

Color Vision

Jay Neitz, Katherine Mancuso, James A. Kuchenbecker & Maureen Neitz

The ability to perceive color is a highly valued sensory capacity, and it has been a subject of experimental inquiry for over 200 years. Prior to the development of modern biological techniques, breakthroughs in color vision research stemmed from careful consideration of perceptual experiences. From color-mixing and matching experiments it was deduced that three different receptors in the eye, each maximally sensitive to a different region of the visible spectrum, were required to explain normal color vision. Thus, the three-component theories of Young and Helmholtz, as well as Hering's conflicting hypothesis of three paired, opponent color processes were developed in the 1800s, long before the three types of retinal cone photopigment were isolated and characterized. It is now understood that normal, or trichromatic, color vision is mediated by three types of cone photoreceptor – designated short- (S), middle- (M), and long- (L) wavelength-sensitive – the activities of which are, indeed, combined in later opponent organization to provide color perception. The first direct measurements of the absorption properties of primate cone photopigments occurred in the 1960s using a technique called microspectrophotometry. Since then, additional techniques including the electroretinogram and molecular genetics have allowed for refinement of the spectral sensitivity curves for the S, M, and L pigments, shown in [Figure 34.1](#).

The fact that most humans have trichromatic color vision explains why computer monitors and televisions mix just three primary colors, red, green, and blue, in order to produce colors that match almost all those seen in the real world. Likewise, if humans were tetrachromat, having four cone photopigments, televisions with four primaries would be required. The presence of three classes of cone photoreceptor also explains color blindness. That is, loss of function of each individual cone class is associated with an inherited form of color vision deficiency: protan defects involve loss of L cone function, deutan defects with loss of M cone function, and tritan defects with loss of S cone function ([Box 34.1](#)). Each type of color vision defect results from rearrangements, deletions, or mutations in the genes encoding the corresponding L, M, or S photopigment, and color vision tests have been developed which can detect changes in the cone complement. Observations that cannot be explained by the presence of three types of cone photoreceptor, however, involve the appearance of color. The neural

circuitry for color vision extracts signals from only three cone types, and yet gives rise to six hue percepts arranged in opponent pairs: blue-yellow, red-green, and black-white. These topics, including the molecular genetics of color vision deficiencies, tests of color vision, and the neural circuitry of color perception, will be discussed in detail in the following sections.

Molecular genetics of color vision and color deficiencies

Although the tendency for color vision defects to run in families and to be more prevalent among men had long been recognized, a major advancement in understanding the biological basis of color vision and its defects came in 1986 when Jeremy Nathans and colleagues cloned and sequenced the genes encoding the S, M, and L cone opsins and verified that the L and M opsin genes are in adjacent positions on the X-chromosome.¹⁻³ Further breakthroughs in understanding differences in the quality of color vision among individuals with anomalous trichromacy followed, with identification of the amino acids involved in spectral tuning, which are responsible for the ~30 nm difference in peak sensitivity of the L and M pigments underlying normal color vision.^{4,5}

The majority of inherited red-green color vision defects are caused by rearrangement and deletions of the L and M opsin genes on the X-chromosome that come about by meiotic recombination during oogenesis in females. A dichromatic phenotype results in males who inherit an X-chromosome in which all but one of the opsin genes have been deleted. A protanopic type defect is characterized by the absence of L opsin genes, and a deutanopic type defect is characterized by the absence of M opsin genes ([Box 34.2](#)). Although humans often have more than just two opsin genes on the X-chromosome, only two are typically expressed, and these determine color vision phenotype. If meiotic recombination creates an array in which the first two genes encode pigments with identical spectral properties, a male who inherits the array will be dichromatic, either protanopic or deutanopic. However, a male with an array in which the first two genes encode opsins of the same class (M or L), but differ slightly in spectral sensitivities, will be an anomalous trichromat. He will be protanomalous if the genes encode

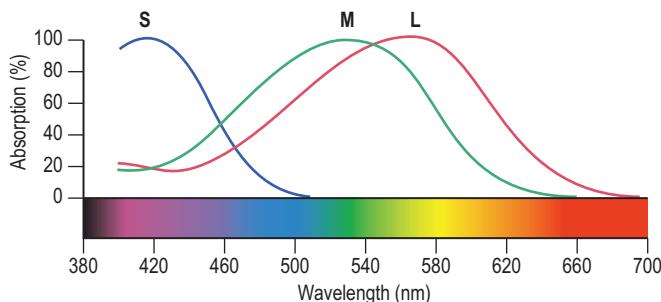

Figure 34.1 Absorption spectra of the three types of cone photopigment, short- (S), middle- (M), and long- (L) wavelength sensitive. The S photopigment is maximally sensitive to wavelengths near 415 nm, the M pigment to wavelengths near 530 nm, and the L pigment to wavelengths near 560 nm. Neural comparison of the rates of quantal absorption by the three cone types gives rise to four unique hue percepts – blue, yellow, red, and green – in addition to hundreds of intermediate colors in the visible spectrum.

Box 34.1 Nomenclature for inherited color vision deficiencies

Protan defects are the least common form of red-green color vision defects affecting about 2 percent of males in the US. There are two categories: dichromatic (protanopia), and anomalous trichromatic (protanomaly), each affecting about 1 percent of males. The severity of protan defects varies over a relatively narrow range. Protan comes from the Greek root for ‘the first.’ Protan color vision is mediated by S cones and M cones.

Deutan defects are the most common form of red-green color vision defects, affecting about 6 percent of males in the US. There are two categories: dichromatic (deutanopia) and anomalous trichromatic (deutanomaly). Deutanomaly and deutanopia affect ~5 percent and ~1 percent of males, respectively. The severity of deutan defects varies over a relatively broad range, from nearly normal to nearly dichromatic. Deutan comes from the Greek root for ‘the second.’ Deutan color vision is mediated by S cones and L cones.

Tritan defects are relatively rare and are characterized by impaired blue-yellow color vision. There is only one category, dichromatic (tritanopia). Tritan defects display incomplete penetrance, meaning there is variability in the degree to which color vision is impaired among individuals with the same underlying gene defect, even within a family. Tritan comes from the Greek root for ‘the third.’ Tritan color vision is mediated by M and L cones.

two M opsins, or deutanomalous if they encode two L opsins. The extent of color vision loss in anomalous trichromats is determined by the degree of similarity in the spectral peaks of the two pigments.⁶⁻⁸

It has been assumed that the 30 nm spectral separation between the L and M pigments was optimized during evolution, and that there is also an optimal ratio of L and M cones. However, recent studies have shown that much smaller spectral separations between, and skewed proportions of, L and M cones still provide robust red-green color vision. For example, red-green chromatic sensitivity was recently demonstrated to exhibit a non-linear relationship with photopigment proximity, and observers did not show a reduction in

Box 34.2 Visual pigments, cone opsins, and official gene designations

Visual pigments, also known as photopigments, are composed of an apoprotein and an 11-*cis* retinal chromophore. The genes, OPN1LW, OPN1MW, and OPN1SW, each encode an apoprotein (termed opsin). The chromophore is a vitamin A derivative that absorbs ultraviolet light; when covalently bound to an opsin, the chromophore absorption spectrum is shifted to longer wavelengths. Amino acid differences among the opsins are responsible for the differences in the absorption spectra of the three cone classes (Fig. 34.1). Within the L and M classes, variations or polymorphisms in the amino acid sequences produce relatively small spectral shifts giving rise to variants of L and M photopigments.

- OPN1MW: middle-wavelength sensitive cone opsin, expressed in M cones, commonly referred to as ‘green’ cones. OPN1MW is on the X-chromosome at location Xq28. Deutan defects are most commonly associated with the absence or lack of expression of the OPN1MW gene(s).
- OPN1LW: long-wavelength sensitive cone opsin, expressed in L cones, commonly referred to as ‘red’ cones. OPN1LW is on the X-chromosome at location Xq28. Protan defects are most commonly associated with the absence or lack of expression of the OPN1LW gene(s).
- OPN1SW: short-wavelength sensitive cone opsin, expressed in S cones, commonly referred to as ‘blue’ cones. OPN1SW is on chromosome 7 at 7q32.1. Tritan defects are caused by a missense mutation in one copy of the OPN1SW gene. A missense mutation is a change in the amino acid coding sequence of a gene that substitutes one amino acid for another in the encoded protein.

color discrimination that could be reliably classified as just outside the normal range until the L/M separation was reduced to about 12 nm or less.⁹ Another surprising finding occurred with the development of adaptive optics, a technique that allows resolution of the cone photoreceptor mosaic in living humans. Selective bleaching allowed identification of the different cone types and revealed that individuals with normal color vision have roughly the same number and arrangement of S cones, but there is tremendous variation in the ratios of L and M cones.^{10,11} This was startling in light of the widely held belief that the quality of red-green color vision would be affected by extreme cone ratios, and it is a testament to the fact that the visual system is tuned for detecting very small differences.

Inherited blue-yellow color vision, or tritan, defects are considerably more rare than red-green defects. They are caused by mutations in the S opsin gene,¹²⁻¹⁵ and are inherited in an autosomal dominant fashion, meaning that an individual who is heterozygous for an S opsin gene mutation will often exhibit the phenotype. Recent evidence from adaptive optics imaging of tritan subjects suggests that the defect is an S-cone dystrophy, similar to rod dystrophy caused by heterozygous mutations in the rod pigment rhodopsin in retinitis pigmentosa.¹⁵ Tritan defects are said to be incompletely penetrant, meaning not everyone with an S opsin gene defect exhibits the phenotype, but this is perhaps due to a progressive loss of S cones which must reach a critical threshold before the phenotype is manifested.

Tests of color vision

As described above, color vision defects are the result of genetic changes that are responsible for either the alteration or loss of cone photopigments. Since color vision is based on neural comparisons between different classes of cone photoreceptor, both the loss of a photopigment type and changes in the peak sensitivity of a photopigment such that there is a reduction in the differential responses of the two cone classes, will result in a reduced ability to distinguish colors.

Pseudoisochromatic plate tests are perhaps the most familiar tool for diagnosing color vision deficiencies. Popular examples include Ishihara's test of color vision and the Hardy, Rand, and Rittler (HRR) pseudoisochromatic plates. The plates consist of printed pages with dots of various colors and shades of gray, each containing a colored symbol(s) that is visible to individuals with normal color vision, but invisible to those with certain color vision defects. Subjects are asked to identify the symbols, and the specific pattern of errors on a series of plates in a test allows for diagnosis of the likely presence or absence of a color vision defect, and for some tests, an indication of the type and severity.

A fundamentally different testing strategy is used with arrangement tests, in which subjects are asked to arrange a series of colored discs 'in order' so that each disk is placed adjacent to the discs that are most similar in color appearance. Misordering of the disks allows a diagnosis of the presence or absence of a color vision defect. Popular examples of arrangement tests are the Farnsworth-Munsell 100 Hue Test and its abridged version, the Farnsworth-Munsell Dichotomous D-15 Test.

The Rayleigh color match is often referred to as the 'gold standard' for color vision testing. It is performed on the anomaloscope, an instrument which contains an optical system that produces two side-by-side lighted fields. One field, the 'test light' is a monochromatic amber color, and the other is a mixture of red and green light. The person being tested adjusts the ratio of red-to-green light in the mixture until it exactly matches the amber test light. Setting a match with a higher or lower ratio of red-to-green light compared to the match made by a person with normal color vision is diagnostic of an inherited color vision abnormality caused by a shift in the spectral peak of either the L or M pigment. This test is extraordinarily sensitive and can detect genetic alterations in the spectral sensitivities of the photopigments, even in subjects in whom the alteration in the photopigment has little or no effect on the person's ability to discriminate between different colors. Its extreme sensitivity in detecting the presence of anomalous photopigments is why the anomaloscope has been widely adopted as the 'gold standard.' However, it must be emphasized that mild photopigment abnormalities may be associated with little or no loss in color discrimination ability. Even with shifted pigments, the quality of color vision may still be quite good. Combining genetic analysis with the Rayleigh match can provide a more precise assessment of the likely quality of color vision.

Each of the widely used color vision tests has its separate advantages and is considered to be best under different

circumstances. Because of this, for general diagnosis of color vision defects, the results from a battery of tests can provide the most complete picture from which to make a differential diagnosis. Ideally, for diagnosis of color vision defects, one should obtain information on the 'type' of problem. Is it a red-green or blue-yellow deficiency, or mixed? If it is red-green, is it a 'protan' or 'deutan' defect? Is it a genetic disorder or is it acquired? The test should also provide information about severity. Does the person have a severe dichromatic form, or a milder 'anomalous' form of deficiency? If it is an anomalous form, is it very mild, mild, moderate, or more severe? Under some conditions it is impractical to administer a battery of tests. Cole et al¹⁶ recently recommended the latest edition of the Richmond HRR Pseudoisochromatic test as the 'one of choice for clinicians who wish to use a single test for color vision.' It has plates for detecting protan, deutan, and tritan defects, and its classification of mild, medium, and strong categories for deutan and protan defects is useful. To absolutely distinguish dichromats from anomalous trichromats, the anomaloscope, the D15, or both should be used in conjunction with a pseudoisochromatic plate test.

Genetic testing is the most reliable means of distinguishing acquired color vision defects from inherited color vision defects. Presently, genetic tests are not commercially available; however, the technology exists to perform such tests because the molecular genetics of inherited color vision defects is well understood, as described in the previous section.

Color appearance

The neural circuitry for color vision receives input from only three cone types (Fig. 34.2) and yet gives rise to six hue percepts arranged in opponent pairs: blue-yellow, red-green, and black-white. The dogma has been that for blue-yellow opponency, signals from S cones are combined antagonistically with an additive signal from M and L cones, abbreviated as S-(M+L); and for red-green opponency, signals from L cones are combined antagonistically with those from M cones (abbreviated as L-M). However, color vision testing in humans has established that the spectral signatures of hue perception actually involve contributions from all three cone types in the following manner: blue = (S+M)-L; yellow = L-(S+M); red = (S+L)-M; and green = M-(S+L). Therefore, while much progress has been made in identifying neurons in the visual system with color opponent responses, those matching the spectral signatures of human perception remain to be found. Results from molecular biology have shed new light on the evolution of primate color vision, imposing constraints on the possibilities for the underlying circuitry. Evolutionary constraints coupled with recent observations from human subjects with a retinal circuitry deficit are leading toward a new understanding of the color vision circuits.

Blue-yellow circuitry

In order to understand the neural operations responsible for transforming the cone signals into perception, it is helpful to first consider reduced color vision systems with fewer cone types and fewer fundamental sensations.

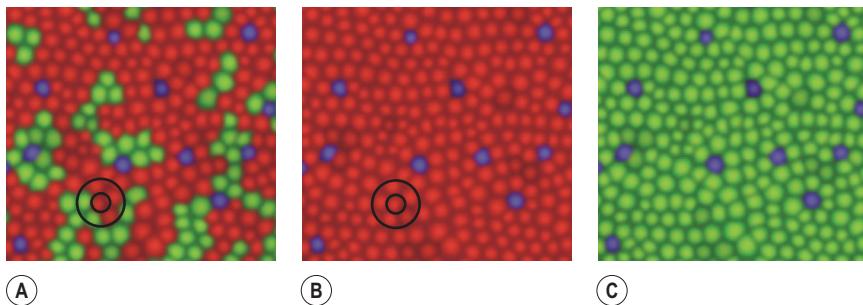

Figure 34.2 (A) Illustration of the arrangement of the three cone classes in a trichromat. S cones (colored blue) represent a minority, ~5 percent of the total, and are roughly evenly spaced across the retinal mosaic. The arrangement of L cones (colored red) and M cones (colored green) is very close to random for trichromats. Midget ganglion cells have center-surround receptive fields with the center derived from a single cone (for example, within the inner ring of the two concentric circles). The six adjacent cones are the most important contributors to the surround (enclosed by the outer ring). (B) Arrangement of cones in a deutanope, a dichromat with only two different cone classes, L and S. In a dichromat, usually all of the cones in the surround are of the same class as the center input to a midget ganglion cell. (C) Arrangement of cones in a protanope, a dichromat with only M and S cones.

Short-wavelength cones are an evolutionarily ancient photoreceptor type and blue-yellow color vision appears to be the ancestor from which all other color vision evolved. Our dichromatic primate ancestors had two types of cone, short- and long-wavelength-sensitive and, presumably, they also had similar circuits underlying their vision as modern-day dichromats, including a high-acuity spatial vision circuit served by the midget ganglion cell system (introduced in Chapter 21), in addition to the blue-yellow color vision circuit.

It is not completely clear which ganglion cell subtypes are specialized for carrying information corresponding to blue-yellow color vision. In primates, the S-cones have only two significant output pathways that have been described thus far (Fig. 34.3, left). One pathway is the straight-through output to the receptive field center of S-cone-specific ON bipolar cells which, in turn, output to the *small bistratified ganglion cells* providing a 'blue-on' signal.¹⁷ The second pathway from S-cones occurs through H2 horizontal cells to the terminals of adjacent L/M cones,¹⁸ which then output to *midget ganglion cells* via L/M specific bipolar cells; however, the physiological role of this anatomical connection has remained unclear. Historically, the small bistratified ganglion cells have been viewed as the major candidate to serve as a neural substrate for blue-yellow color vision. However, they all respond to blue and inhibit to yellow, leaving us without a physiological basis for the yellow half of this opponent system. Furthermore, recent assessment of human subjects with a genetic mutation that renders the ON bipolar pathways inactive seems to cast doubt onto the role of small bistratified cells in blue perception. Specifically, the mutation occurs in the metabotropic glutamate receptor expressed on the ON-bipolar cells, and clinically, these subjects present with congenital stationary night blindness¹⁹ (Box 34.3). If small bistratified cells were, indeed, the physiological substrate for blue perception, with no input from the S-cone ON bipolar, CSNB patients would be expected to have a tritan color vision defect. However, standard tests indicate that they have normal, trichromatic color vision. While the visual mechanisms associated with this ON-pathway deficit require further inquiry, these results suggest that blue perceptions may be mediated by a separate pathway, leading us now to consider the possible role of the second anatomical S-cone

Box 34.3 A clue for blue: Congenital Stationary Night Blindness (CSNB)

The two types of photoreceptor in the human eye, rods and cones, serve different functions. Rods provide vision only under very low light levels, such as at night when little light is available. In contrast, cones serve vision at relatively higher light levels, such as daylight and standard indoor lighting.

While L/M cones synapse with both ON and OFF bipolar cells, the S cones and rods synapse with only ON-type bipolar cells. The dendrites of ON bipolar cells express a metabotropic glutamate receptor, mGluR6, and mutations in this receptor result in ON-pathway deficit. Curiously, while rod-mediated vision is compromised in CSNB patients, producing loss of nocturnal vision, S-cone mediated (blue) color vision appears to be unaffected.

output, via H2 horizontal cells, to the midget ganglion cell pathway.

In the region of primate retina that serves highest visual acuity, the fovea, more than 90 percent of ganglion cells are of the 'midget' variety, so called because of their small dendritic arbors, which in the central 7–10 degrees connect to a single cone via a 'midget' bipolar cell. There are two types of midget ganglion cells, ON- and OFF-center, which receive input through a corresponding pair of ON- and OFF-midget bipolar cells, which have opposite responses to the neurotransmitter, glutamate, released by cones (Chapters 22, 23). Midget ganglion cells do not receive direct center input from S-cones, only from M/L cones. Thus, in a dichromatic ancestor to humans that had only S and L cones, the midget ganglion cell system's major function was to compare absorptions of S vs. L cones to provide achromatic luminance signals (Fig. 34.2b); presumably giving rise to white percepts through the ON-pathway and black percepts through the OFF-pathway (Fig. 34.3, top right). Because S cones are relatively sparse and roughly evenly spaced across the retina, and the signal strength to neighboring cones falls off exponentially with distance, only a small number of midget ganglion cells would receive significant input from S-cones in their receptive field surrounds, providing a

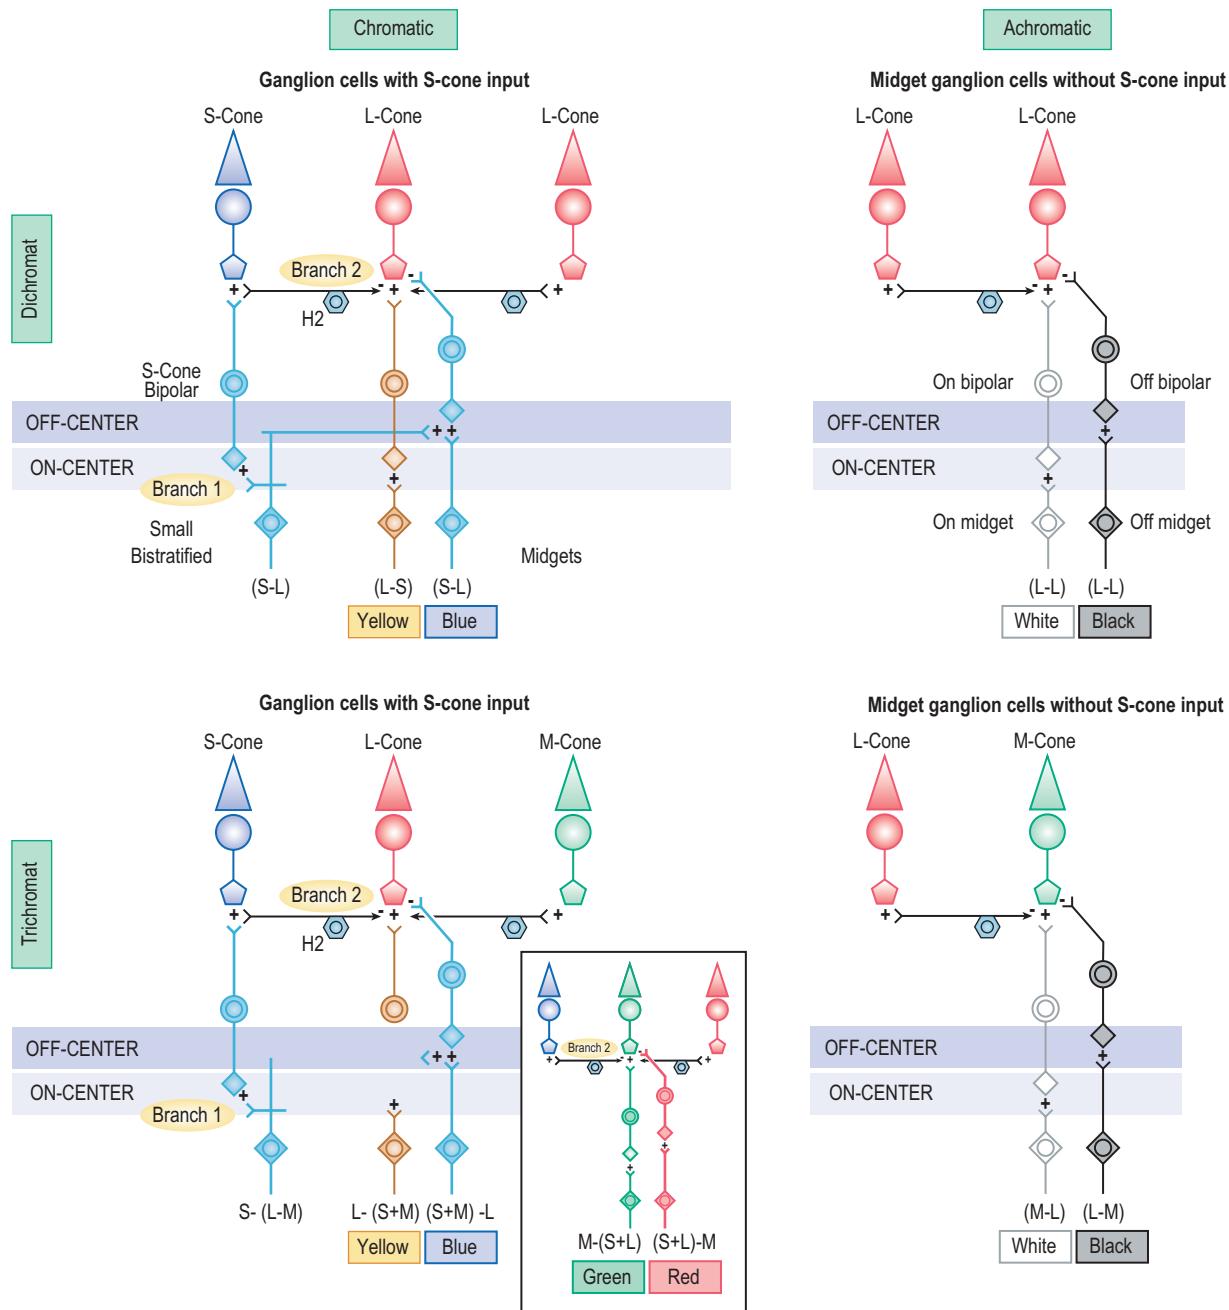

Figure 34.3 Retinal circuits based on known anatomical connections that would give rise to signals matching the spectral signatures of human perception following addition of a third cone type. ‘Branch 1’ indicates the straight-through S-cone output to the *small bistratified ganglion cell pathway*; ‘branch 2’ is a second known anatomical connection that may provide S-cone output to the *midget ganglion cell pathway* via H2 horizontal cells (see text). The addition of M cones to a dichromat only changes the ‘surrounds’ of small bistratified ganglion cell receptive fields, and they would continue to have similar spectral response properties, making them an unlikely substrate for hue sensations of red, green, blue, and yellow. In contrast, both the ‘center’ and ‘surround’ of midget ganglion cell receptive fields become altered by the addition of M cones, splitting the pre-existing blue-yellow circuit into two organizations with distinct spectral response properties, one for blue-yellow and one for red-green (inset). Even though midget ganglion cells in trichromats respond both to diffuse red or green lights and dark-light edges, ultimately the two percepts must be separated from each other at a higher level of visual processing; we have illustrated the idea that only the ‘black-white’ signals from purely L/M opponent circuits are propagated to the cortex (bottom right).

possible substrate for L vs. S cone comparisons required for blue-yellow opponency (Fig. 34.3, top left).

Red-green circuitry

The idea that midget ganglion cells with S-cone input in their receptive field surround may serve as a substrate for

blue-yellow perception seems plausible when considering the effects produced when a third type of cone was added during evolution. Results from molecular genetics indicate that trichromatic color vision arose relatively recently from a gene duplication event that added M cones. In order for this low-probability genetic event to get passed-on and eventually confer routine trichromacy to Old World primates,

including humans, it must have produced an immediate advantage for the primate ancestor by adapting a pre-existing visual circuit for a new dimension of red-green color vision. In ancestral primates with only S and L cones, the small bistratified ganglion cell circuitry would have been little affected in its spectral response characteristics by the addition of M cones (Fig. 34.3, bottom left); that is, the center would remain unaltered due to the S-cone specific connections made by small bistratified cells, and the surround would be transformed from 'L' to 'L+M'. Thus, the simple addition of a third cone type would not 'split' this ganglion cell class into two spectral types, one for blue-yellow and one for red-green color vision, as required by the evolutionary constraint that an immediate advantage was produced. In contrast, when M cones were randomly added to the pre-existing midget system, the small subset of spectrally opponent midget ganglion cells would have automatically become segregated into two different classes. The center of the receptive field would have become either 'L' or 'M'; accordingly, the receptive field surrounds would be transformed to either 'M + S' or 'L + S', automatically producing midget cells with two different spectral response characteristics – one corresponding to red-green and the other to blue-yellow color vision (Fig. 34.3, inset).

In summary, it appears plausible that midget ganglion cells receiving S-cone input in their receptive field surround may provide the physiological substrate giving rise to hue circuits in the cortex. The cone forming the receptive field center can be either L or M, and the ganglion cells can be either ON or OFF center. The resulting four possible combinations would correspond to the known spectral signatures of the four main hue percepts of trichromats. That is, an ON-center ganglion cell receiving input from an M cone center with S and L cones in the surround would provide M-(S+L)-green; this same receptive field through an OFF-center ganglion cell produces (S+L)-M-red. An L cone center with an M and S surround would result in L-(S+M)-yellow; this same receptive field through an OFF-center ganglion cell produces (S+M)-L-blue.

Black-white circuitry

A remaining unresolved mystery in color vision stems from the fact that addition of a randomly distributed long-to-middle wavelength sensitive cone type causes almost every midget ganglion cell in the retina, as well as the cells they project to in lateral geniculate nucleus (LGN), to respond to either spatially uniform red or green lights in addition to dark-light edges. Earlier color vision models thus attributed the red-green system to outputs of the L and M cones, about 95 percent of the cone population, while the whole blue-yellow system was considered to be centered on just the remaining 5 percent of cones, the S cones. Because an imbalance seems inherently implausible based on the similar perceptual acuities of both color systems, it has been proposed that the preponderance of L/M cones indicates that these cone types alone are used for luminance (dark-light) detection, suggesting that only a fraction of the spectrally opponent information from L/M cones actually contributes to color vision. While this idea seemed heretical at first, it has become more plausible in light of recordings from neurons in primary visual cortex (V1) which receive

direct input from the axons of color opponent neurons in the LGN.

The receptive field properties of V1 neurons are quite different from those of the LGN, in that few cortical neurons respond to spatially uniform stimulation and most are selective for the orientation of edges. Furthermore, most V1 neurons respond well to achromatic modulation and less well or not at all to chromatic modulation, which, in contrast, is a powerful stimulus to most LGN cells. Altogether, only about 5–10 percent of neurons in V1 respond robustly to purely chromatic modulation and little, if at all, to achromatic modulation.²⁰ This lends credence to the idea that even though LGN cells receiving input from purely L/M opponent receptive fields respond to both spatially uniform colors and black-white edges, most of the chromatic signals become subtracted-out and disregarded, perhaps by a second round of lateral antagonism at the level of the cortex, analogous to horizontal cell interactions at the level of the retina. A second round of cortical antagonism would have been serendipitous in preserving the neural outputs of the pre-existing achromatic luminance circuitry in primate ancestors when a third cone type was added, leaving this system dedicated to the original purpose for which it evolved, responding to edges (Fig. 34.3, bottom right). Accordingly, only the small subset of midget ganglion cells receiving input from all three cone types would be able to pass color signals to higher cortical levels (Fig. 34.3, bottom left), thereby rectifying the apparent imbalance between the inputs to the red-green and blue-yellow systems.

Future directions

Much has been learned about the neural types and their interconnections in the retina responsible for luminance and color, and there is a growing body of information about the higher visual centers; yet, how these ultimately operate to provide vision remains a fascinating puzzle. Many clues have come from information about the evolution of the visual system and about its anatomy and physiology, and continued progress will undoubtedly arise from rapidly emerging technologies. One such example has resulted from the development of viral vector-mediated gene therapy to address human visual disorders. Using recombinant adeno-associated virus containing cone-specific promoter elements, it is possible to target transgene expression to subclasses of mammalian cone,^{21,22} including in primates.²³ Introducing new cone photopigments into animal models with reduced color vision provides an experimental tool for probing the neural circuitry for color vision and understanding the evolutionary requirements for developing a new dimension of red-green color vision.

There is currently no cure for red-green color vision deficiency. However, in the majority of cases the cone photoreceptors are healthy and viable, and viral-mediated gene therapy is a feasible option for delivering the missing cone opsin gene to photoreceptors to rescue the deficit. If all of the neural circuitry required for taking advantage of a third cone type is present in dichromatic individuals, as was also possibly the case in dichromatic primate ancestors, gene therapy holds promise for providing red-green color blind adults with full trichromatic color vision.

The Visual Field

Chris A. Johnson & Michael Wall

Introduction

Perimetry and visual field testing have been used as diagnostic procedures for evaluation of visual function for nearly 200 years, and a historical review of these techniques may be found in several publications.^{1–5} During this period of time, a variety of new techniques have been developed, although the standard clinical procedure of detecting a small white target superimposed on a uniform background at different peripheral locations in the field of view is still the method that is most commonly used by eye care specialists. Perimetry is used clinically to detect functional losses produced by pathology to the visual pathways, for differential diagnostic purposes to identify the location of a visual deficit, to monitor the status of acute and chronic disease processes, and to evaluate the efficacy of treatment. In spite of the similarity of current test procedures to early techniques, significant progress has recently been made in the presentation, analysis and interpretation of visual field findings. This has resulted in the automation of procedures, standardization of methods, the immediate statistical evaluation of test results and enhanced efficiency of testing. In this chapter, we will provide an overview of the psychophysical basis for perimetry, a discussion of the types of perimetric test strategies, the data representation formats that are used for visual field testing, important factors for interpreting visual field results, recognition of patterns of visual field loss, strategies for monitoring progression of visual field changes, and guidelines for assessment of visual field information in a clinical setting. Additionally, we will briefly describe some of the new visual field test procedures that have been shown to provide salient information concerning the functional status of the visual system and have been reported by many investigators to be clinically useful.

The psychophysical basis for perimetry

For conventional perimetric testing, the patient's task is to detect a small white target superimposed on a uniform background luminance at different visual field locations. The detection task is based on the increment or differential light threshold, which determines the minimum amount of light that must be added to a stimulus (ΔL) in order to make it

distinguishable from the background (L) and is known as Weber's Law, or $\Delta L/L = C$.⁶ In order for Weber's Law to be valid, the background adapting luminance of the perimeter must be in the photopic range (typically 31.5 apostilbs, or 10/candelas per meter squared), pupil size must be sufficiently large (greater than 2 mm), ocular media must be relatively clear, and other test conditions (stimulus size, stimulus duration, etc.) must be within appropriate levels. Under these conditions of photopic adaptation in a normal eye and visual system, the fovea is the visual field location with the highest sensitivity. As eccentricity from the fovea increases, there is a significant drop in sensitivity out to about 3 degrees, then a more gradual sensitivity decline out to about 30 degrees radius, followed by a more rapid decrease beyond 30 degrees. The temporal visual field (away from the nose) extends farther than the nasal visual field, and the inferior visual field extends farther than the superior visual field. The three-dimensional shape of the sensitivity profile of the visual field has therefore often been referred to as the "hill of vision" or the "island of vision in a sea of blindness", as shown in Figure 35.1. Note that there is a "hole" in the island of vision that represents the blind spot, a location where the optic nerve exits the eye where no photoreceptors or other retinal neural elements are present. The blind spot is represented as an area of non-seeing by a dark solid oval located approximately 15 degrees from the center of view (fixation) in the temporal visual field extending one-third above and two-thirds below the horizontal meridian. From a clinical standpoint, one of the primary purposes of perimetry and visual field testing is to search for departures from this normal sensitivity profile (sensitivity losses) and determine the shape and location of the deficit.

As with all psychophysical assessments, there is variability in the values obtained for repeated measures in the sensitivity to light increments. Several laboratories have indicated that under clinical testing conditions, the standard deviation of repeated measures is approximately 3 dB for individual visual field locations with normal sensitivity.^{7–15} As sensitivity declines in damaged visual field areas, there is an increase in variability of about 300–400 percent that extends the 95 percent confidence interval to nearly the entire operating range of the perimeter.¹⁵ One method of quantitatively evaluating this variability is by obtaining a frequency of seeing (FOS) curve, which plots the percentage of stimuli seen as a function of the luminance of the stimulus. The FOS curve is

typically quite steep in areas with normal sensitivity, and becomes flatter at greater eccentricities and in damaged visual field areas. From a clinical perspective, it is important to minimize response variability so that subtle changes in sensitivity that are due to pathology can be more readily detected. This can be accomplished by using larger stimuli, modifying the type of stimulus used, adjusting the response estimate algorithm and several other procedures.^{7–15}

The physiologic basis for perimetry

Proper interpretation of visual field results requires knowledge of the anatomical arrangement of the visual pathways. As shown in Figure 35.2, a panoramic image of the visual field of view is formed on the retina by the optical

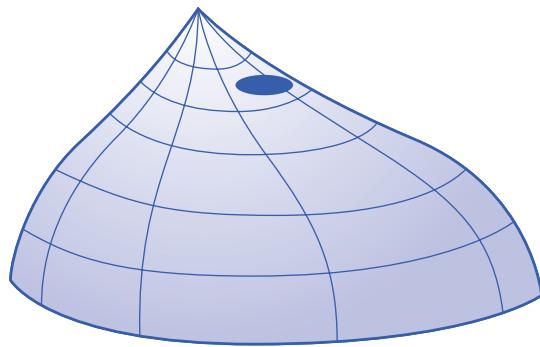

Figure 35.1 Three-dimensional representation of the eye's sensitivity to light throughout the visual field. An illustration for a right eye (OD) is presented.

components (cornea, lens, pupil) of the eye. The light image is converted into electrical impulses that are transmitted through more than 100 million photoreceptors to other retinal neural elements and eventually to approximately 1 million retinal ganglion cells. The retinal ganglion cell axons enter the optic nerve and travel back to eventually reach primary visual cortex. As the optic nerve fibers leave the eye and travel towards the brain, there is a separation of nerve fibers subserving the nasal and temporal visual field along the vertical meridian. This separation occurs at the optic chiasm, whereby the nasal visual field from one eye combines with the temporal visual field of the other eye, so that the left half of vision is represented in the right hemisphere and the right half of vision is represented in the left hemisphere. At this point in the visual pathways, there is not a point-for-point retinotopic mapping of locations between the two eyes. The nerve fibers continue on to a portion of the thalamus (the lateral geniculate nucleus) where they synapse with nerve fibers that convey information to primary visual cortex known as area 17 or V1. In primary visual cortex, there is a point-for-point mapping of retinotopic information from both eyes (under normal development) as a consequence of rearrangement of fibers traveling from the optic chiasm. Beyond primary visual cortex, there are complex interactions with other areas of the brain that are beyond the scope of this chapter.

Types of perimetric testing

Currently, there are three different forms of visual field testing that are performed clinically: kinetic perimetry, static perimetry, and suprathreshold static perimetry. Each of these procedures has particular advantages and disadvantages, as described below, and each of them serves distinct purposes

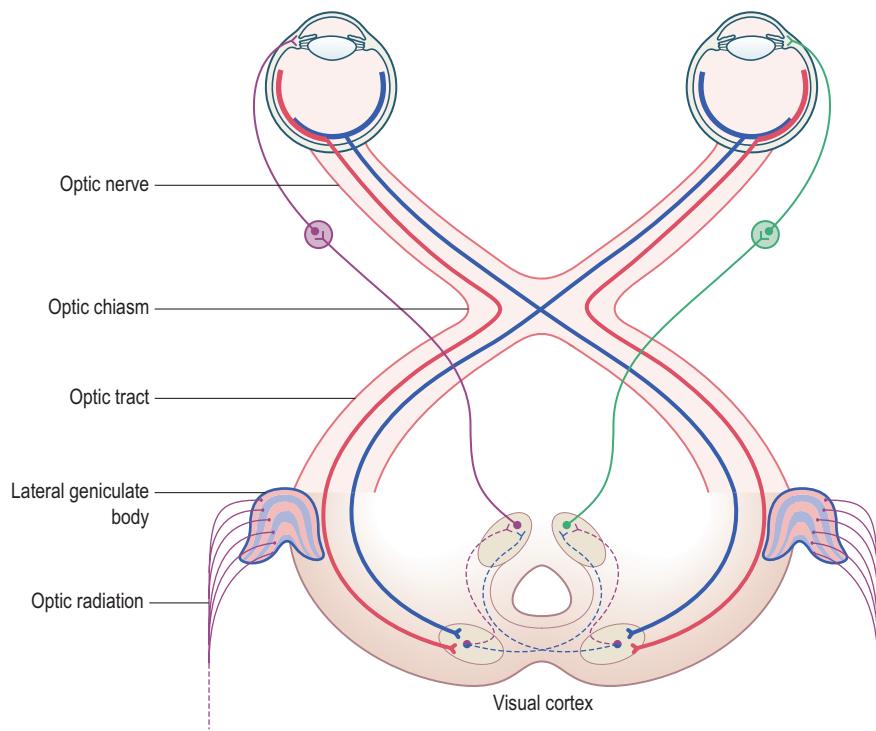

Figure 35.2 Schematic illustration of the human visual pathways.

for clinical diagnostic testing. In this view, it should be noted that these techniques should be regarded as complementary, with only moderate amounts of overlap in clinical performance.

Kinetic perimetry

As implied by its name, kinetic perimetry involves the movement of a small target on a uniform background consisting of a 1- or 2-meter dark tangent screen or a light hemispherical bowl perimeter (Goldmann or Goldmann-like perimeter). A skilled kinetic perimetrist usually requires a considerable amount of apprenticeship time (6–12 months) to become proficient in these techniques. A thorough description of kinetic perimetry strategies is beyond the scope of this chapter, although an excellent description of kinetic perimetric techniques and strategies may be found in the book by Anderson.⁴

Kinetic perimetry consists of mapping the hill of vision (boundary between seeing and non-seeing) by moving a target of predetermined size and luminance from the periphery towards the fixation point along successive meridians separated by approximately 15 degrees of angular extent. The rate of smooth movement should be 4–5 degrees per second for greater eccentricities, and 1–2 degrees per second for locations near fixation. For a particular target, the boundary locations are connected by a line of equal sensitivity known as an isopter. Multiple isopters can be generated by changing the size or luminance of the target. For the far periphery, target size is usually varied, whereas luminance is altered for evaluation of nearer eccentricities. A normal isopter is relatively egg-shaped, with the long axis of the egg extending to the temporal visual field and the short portion of the axis of the egg projecting to the nasal visual field. Similarly, the inferior visual field extends farther peripherally than the superior visual field. If an isopter corresponds to this shape, then no further evaluation is needed. However, if local indentations of an isopter are present, further moving target scans should be directed from the periphery in a direction perpendicular to an imaginary line drawn between the two points. If further definition of the isopter contour is needed, this process should be repeated. Typically, between 3 and 6 isopters are required to provide a thorough characterization of the visual field.

Within the central 30–40 degrees radius of the visual field, a series of arcuate “spot checks” are usually performed between isopters and in locations where one or more isopters show an indentation. Static spot checks are performed with the kinetic isopter stimulus, inside the isopter and consist of a brief flash of the target. A location where a spot check is missed should be checked again to confirm non-detection. In these missed spot check areas or regions with local recession or depression of isopters, scotoma mapping should be performed, beginning at the presumed center of the defect and moving outwards in 8 radial directions (horizontal, vertical and oblique). Additional intermediate scans can also be performed to better characterize the shape of the deficit, and multiple targets should be used to indicate the depth of the deficit and the slope of its borders. The final result is a topographic mapping of the hill of vision to provide a two-dimensional representation of the three-dimensional structure of the visual field.

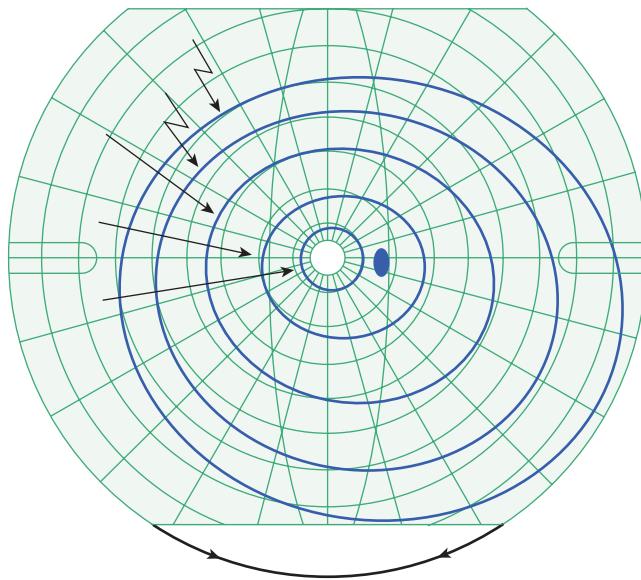

Figure 35.3 Representation of a normal visual field for kinetic visual field testing using a Goldmann-type perimeter.

Advantages of kinetic perimetry include the ability to characterize the entire central and peripheral visual field, enhanced flexibility and interaction between the examiner and the participant, the ability to accurately characterize the shape of visual field deficits, and a highly efficient method of evaluating the far peripheral visual field. Disadvantages consist of higher variability than other forms of perimetric testing, large individual differences in clinical performance among examiners, poorly standardized procedures, limited normative population characteristics, and difficulty in characterizing generalized or widespread visual field sensitivity loss for different age groups.

Although there are no specific quantitative features that can be easily described, Figure 35.3 presents an example of a normal visual field. Most kinetic perimetric testing is performed manually, except that several automated perimeters have recently incorporated kinetic testing procedures.^{16–20}

Static perimetry

To date, static perimetry is the most common method of clinical visual field testing, particularly for automated perimeters. Static perimetry involves the detection of a small stationary target that is superimposed on a uniform white background. At each visual field location that is tested, the measurement consists of the minimum amount of light increment (differential light threshold) that can be just distinguished from the background. Different visual field locations are tested along various radial meridians between the central point of fixation and eccentric locations, or according to a Cartesian grid of locations that usually bracket the horizontal and vertical meridians. A variety of test strategies have been developed for static perimetry, including the ascending method of limits,² bracketing or staircase procedures,^{21–23} forecasting (Bayesian) threshold estimation procedures,^{24–29} and other efficient and adaptive testing strategies.^{30–33} Most eye care specialists today use some form of adaptive forecasting procedure such as the Swedish Interactive Threshold

Algorithm (SITA), Zippy Estimation of Sequential Thresholds (ZEST), Tendency Oriented Perimetry (TOP) or a similar procedure.^{24–33} Additionally, methods of evaluating test performance (false positive responses, false negative responses, and blind spot fixation checks) and alignment (eye and head position) tracking have also been developed for static perimetry.^{34–39}

The representation of visual field results from automated static perimetry is typically displayed as numerical sensitivity values, general and pattern deviations from average expected normal values for a specific age group, gray scale sensitivity representations of visual field sensitivities, probability plots (deviations from average normal), and in some instances three-dimensional sensitivity density plots. Also, for the Humphrey Field Analyzer, summary statistics known as visual field indices are also determined to provide an indication of generalized or widespread sensitivity loss (mean deviation [MD]), localized sensitivity loss (pattern standard deviation [PSD]), visual field loss produced by asymmetric superior and inferior visual hemifield loss characteristic of glaucoma (glaucoma hemifield test [GHT]), and visual field progression (glaucoma progression analysis [GPA]) and rate of progression (glaucoma progression index [GPI]). Similar types of analyses are available for other automated perimeters.

Advantages of automated static perimetry include the use of a standardized test procedure, the ability to exchange information from one device and office to another, availability of an age-corrected normative database, immediate comparison of individual results to normal population characteristics, and methods for monitoring response reliability, attention and cooperation, proper alignment and greater reproducibility. Disadvantages of automated static perimetry consist of time-consuming and limited methods of evaluating the entire peripheral visual field, less flexible test procedures, a more demanding burden on the patient's attention and performance, and very high test-retest variability when sensitivity is less than 20dB for a size III target.

Figure 35.4 presents examples of gray scale plots of static perimetry conducted for (a) a normal visual field, (b) a generalized or widespread visual field loss and (c) a localized visual field deficit.

Suprathreshold static perimetry

Suprathreshold static perimetry is generally used as a rapid screening procedure to detect visual field deficits. However, there are several drawbacks to suprathreshold static visual field testing using standard automated perimetry: (1) with a few exceptions,^{40–46} the vast majority of basic research in this area has been directed towards threshold estimation strategies rather than suprathreshold screening procedures, (2) there are a limited number of clinical studies that have been performed to evaluate the performance characteristics of these procedures, (3) threshold estimation strategies have become considerably more efficient and can actually take less time than some suprathreshold screening procedures, and (4) there is no consensus as to which suprathreshold visual field screening procedures are most suitable for routine use.

There are a wide variety of forms of suprathreshold static perimetric methods that are currently in use. The stimulus

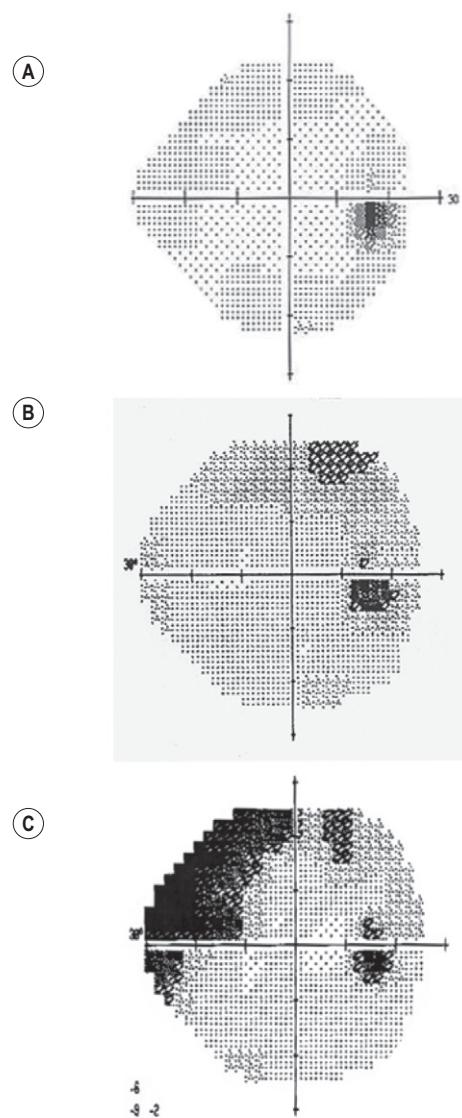

Figure 35.4 A gray scale representation of static perimetry test results obtained for (A) a normal visual field, (B) generalized or widespread visual field loss, and (C) localized visual field loss.

presentation patterns range from a small number of targets (less than 30) to nearly 200 locations. Some strategies present all targets at a fixed stimulus luminance, others use multiple stimulus luminance levels that are varied according to eccentricity, some perform threshold estimates for locations that have sensitivity below normal limits, some present multiple stimulus luminances in damaged locations to estimate the magnitude of sensitivity loss, some provide a retest of missed locations to confirm suspected sensitivity losses, and some use an adaptive strategy that provides greater spatial resolution of test points for suspicious visual field locations. Only a few studies have compared results obtained from different procedures or have evaluated screening results in comparison to threshold visual field techniques.^{40–46} This has created an opportunity for future investigations to determine methods that are appropriate for visual field screening in a clinical setting as well as population-based screening.

Suprathreshold static perimetry has the advantage of providing simple and efficient visual field screening techniques

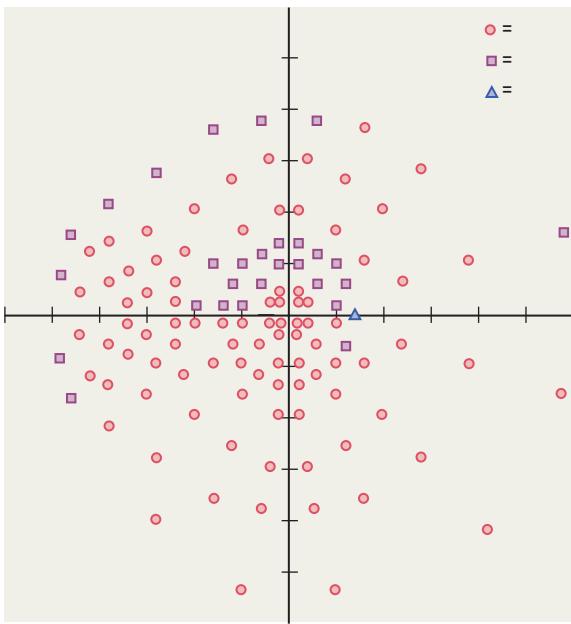

Figure 35.5 An example of a two-zone, threshold-related 120 point visual field screening test on the Humphrey Field Analyzer for the right eye of a primary open angle glaucoma patient with a superior arcuate defect.

for the patient and the examiner, standardized procedures and the ability to test the entire peripheral visual field. Disadvantages include limited quantitative information, lower sensitivity and specificity in comparison to threshold techniques, a lack of appropriate decision rules and scoring systems that have been validated, and limitations in the ability to monitor progressive changes.

Figure 35.5 presents visual field screening results for the right eye of a patient with superior arcuate glaucomatous visual field loss using a multiple stimulus luminance test strategy for the Humphrey Field Analyzer.

Detection of perimetric sensitivity loss and interpretation of results

Perhaps the best method of providing instruction about interpretation of visual field results is to conduct a systematic overview of the findings that are presented on the printed output. Figure 35.6 presents a single visual field analysis of the results for the left eye of a patient with an inferior arcuate glaucomatous visual field deficit that was obtained using the 24-2 SITA Standard test procedure on the Humphrey Field Analyzer II.

The top portion of the visual field printout shown in Figure 35.6 provides (from left to right and top to bottom) an indication of the patient's name, the eye that was tested, the patient's ID code and date of birth. Below this is information pertaining to the test conditions used (background luminance, stimulus size, fixation target, fixation monitoring method), the test strategy (SITA, Full Threshold, Suprathreshold screening), performance characteristics (false positive errors, false negative errors, fixation losses), the patient's age, and ocular conditions (distance refraction, pupil size,

visual acuity). False negative errors that exceed 33 percent are outside normal limits, although this occurs frequently in eyes with visual field loss.⁴⁷ Excessive false positives are infrequent, and are often associated with excessive fixation losses because patients are "trigger happy".⁴⁸ For the Full Threshold procedure a criterion of 33 percent is used, but for SITA a new algorithm is being used, and 15 percent is the appropriate criterion for excessive false positives.⁴⁹ Fixation losses that exceed 33 percent are considered to be excessive^{34,35} but methods can be employed to dramatically reduce excessive fixation losses, and head tilts can falsely elevate this percentage.⁵⁰

Below this information are the patient's foveal threshold (if it is enabled for the test), an XY graphical presentation of sensitivity values, and a gray scale representation of visual sensitivity. The sensitivity values are indicated in decibels (dB), which for standard automated perimetry is defined as the contrast (increment threshold or Weber fraction, $\Delta L/L$) needed to just detect a stimulus superimposed on the uniform background and reflects visual field sensitivity on a logarithmic scale. A value of 0 dB represents the brightest stimulus that can be produced by the instrument and superimposed on the background. Each 1 dB increment represents a 0.1 log unit increase in stimulus luminance. Thus, a 10 dB sensitivity represents an ability to detect a target that is 10 times dimmer than the maximum stimulus luminance, a 20 dB stimulus represents an ability to detect a target that is 100 times dimmer than the maximum stimulus luminance, and so forth. The gray scale representation of visual field sensitivity provides an immediate indication of the sensitivity properties of the hill of vision, and is able to convey areas of reduced sensitivity in the form of darkened portions of the graph. This provides a very rapid method of depicting the location, size, shape and depth of area of reduced visual field sensitivity.

Immediately below the gray scale representation are the values for the Mean Deviation (MD), Pattern Standard Deviation (PSD) and Glaucoma Hemifield Test (GHT) calculations. MD indicates the deviation of the patient's visual field from the average normal results for an individual of the same age. PSD is the departure (root mean square [RMS] deviation) from the average decline in sensitivity from the fovea to the periphery out to 30 degrees radius (0.6 dB per degree for a Size III target). In some ways, PSD may be regarded as a quantitative indicator of visual field perturbation (irregularities in visual field surface with eccentricity), particularly because the edges of scotomas provide a distinct transition from a smooth sensitivity profile. The Glaucoma Hemifield Test (GHT) compares the sensitivity of clustered points for mirror image regions of the superior and inferior hemifields, as shown in Figure 35.7. The five regions in the superior and inferior hemifields are designed to be representative of arcuate nerve fiber bundle areas that are most frequently involved in glaucomatous visual field losses (nasal steps, paracentral losses, partial arcuate and arcuate defects). In normal eyes, there are only minimal differences in sensitivity between these regions in the superior and inferior hemifields. However, in glaucoma and some other optic neuropathies, the damage to retinal locations corresponding to the superior and inferior hemifields is often asymmetric, resulting in large sensitivity differences between regions in the superior and inferior hemifields.

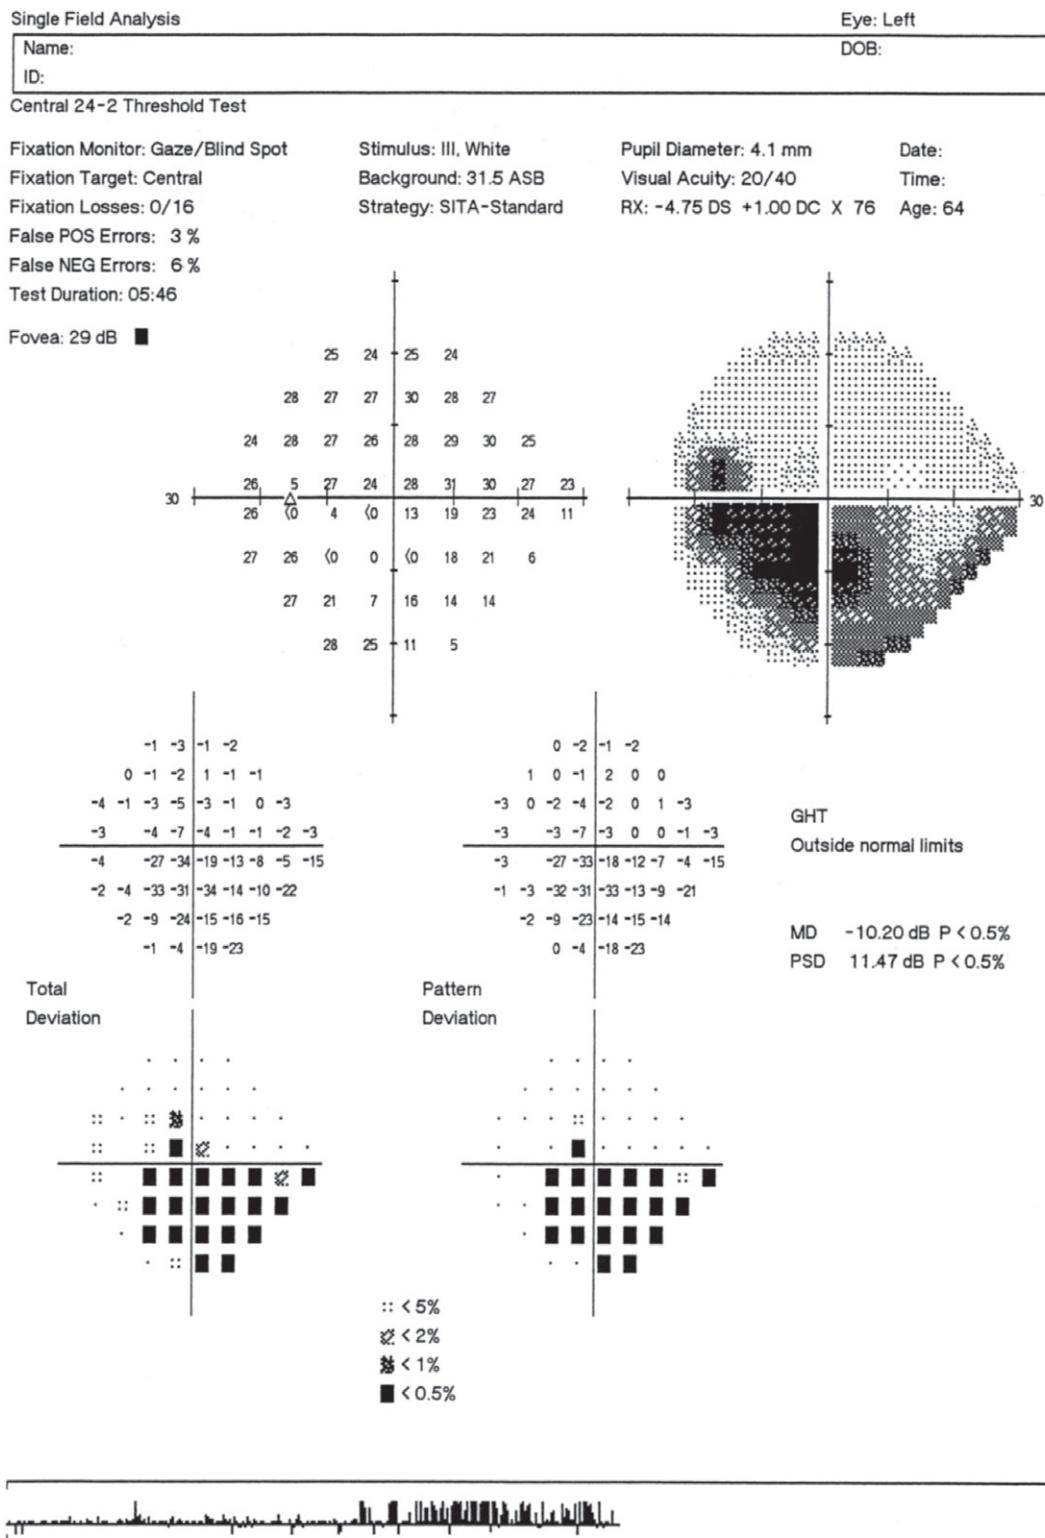

Figure 35.6 Standard Automated Perimetry (SAP) results using the SITA Standard 24-2 test procedure on the Humphrey Field Analyzer for the left eye of a patient with primary open angle glaucoma, depicting an inferior arcuate visual field defect. Note that eye alignment, as indicated by the gaze tracking presentation, became variable towards the end of the test procedure.

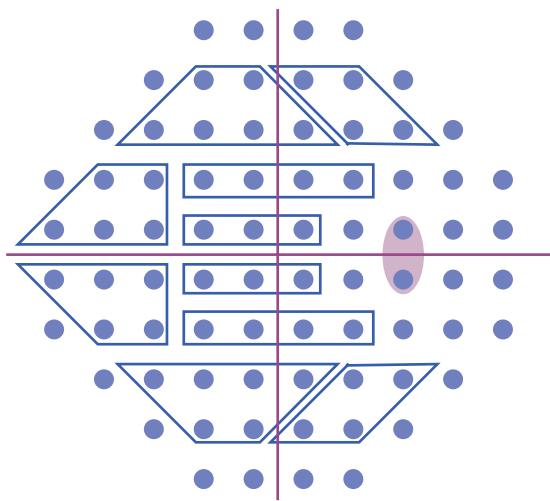

Figure 35.7 The clusters of visual field locations used to evaluate superior and inferior hemifield asymmetry as part of the glaucoma hemifield test. The clusters were selected to generally correspond to the pattern of nerve fiber bundles entering the optic nerve head.

To the left of the visual field indices are the Total Deviation and Pattern Deviation graphs. The upper left graph for Total Deviation indicates the deviation of the patient's threshold sensitivity from the average normal observer of the same age (plus values indicate higher than average normal sensitivity and minus values reflect lower than average normal sensitivity). The Pattern Deviation values to the right are derived by adjusting the patient's visual field according to the 85th percentile (7th most sensitive point for the 24-2 stimulus presentation pattern) to account for widespread or generalized sensitivity differences (i.e. higher sensitivity values for the patient are adjusted down and lower sensitivity values are adjusted up). Once this is accomplished, the deviation from average normal sensitivity for a person of the same age is calculated. Below the numerical values for the Total and Pattern Deviation calculations are the probability plot graphs. For each visual field location, these plots display single dots for values that are within the normal 95 percent confidence limits, and dithered symbols of increasing darkness and density to indicate locations with sensitivity below the average age-adjusted normal 5 percent, 2 percent, 1 percent and 0.5 percent probability levels, respectively. Comparison of the Total and Pattern Deviation probability plots can be very useful for interpreting the visual field.

Figure 35.8 presents four examples of visual field results represented by the Total and Pattern Deviation probability plots. Figure 35.8A displays a normal Total Deviation plot, with many abnormalities for the Pattern Deviation plot. This indicates that the patient's eye had sensitivity values that were above the 95 percent normal age-adjusted values, which is commonly caused by a "trigger happy" patient who inappropriately responds to targets that are not usually detected by normal individuals. Fixation losses and false positive errors are often outside normal limits in these cases as well. Figure 35.8B shows abnormalities that appear for the Total Deviation probability plot, but are not present for the Pattern Deviation probability plots. This is indicative of widespread or diffuse visual field loss. Figure 35.8C shows Total and Pattern Deviation probability plots that appear

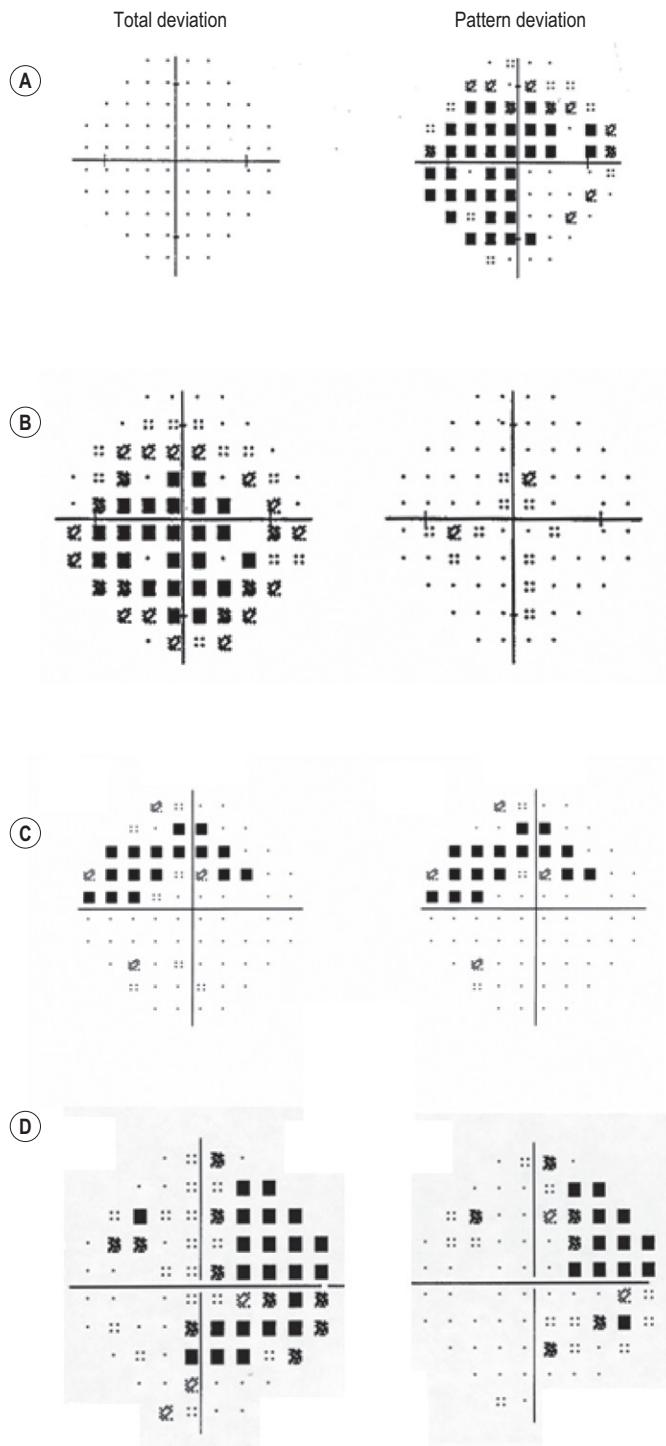

Figure 35.8 Examples of the results for Total and Pattern Deviation probability plots for (A) a "trigger happy" patient with abnormally high sensitivity related to pressing the response button too often, (B) generalized or widespread visual field loss, (C) localized visual field loss, and (D) mixed localized and widespread visual field loss. Note that these data representations provide highly useful clinical information.

to be nearly identical, which is indicative of localized visual field sensitivity loss. Finally, Figure 35.8D shows abnormal visual field locations for both the Total and Pattern Deviation probability plots, with some locations indicated as abnormal for both graphs and other locations

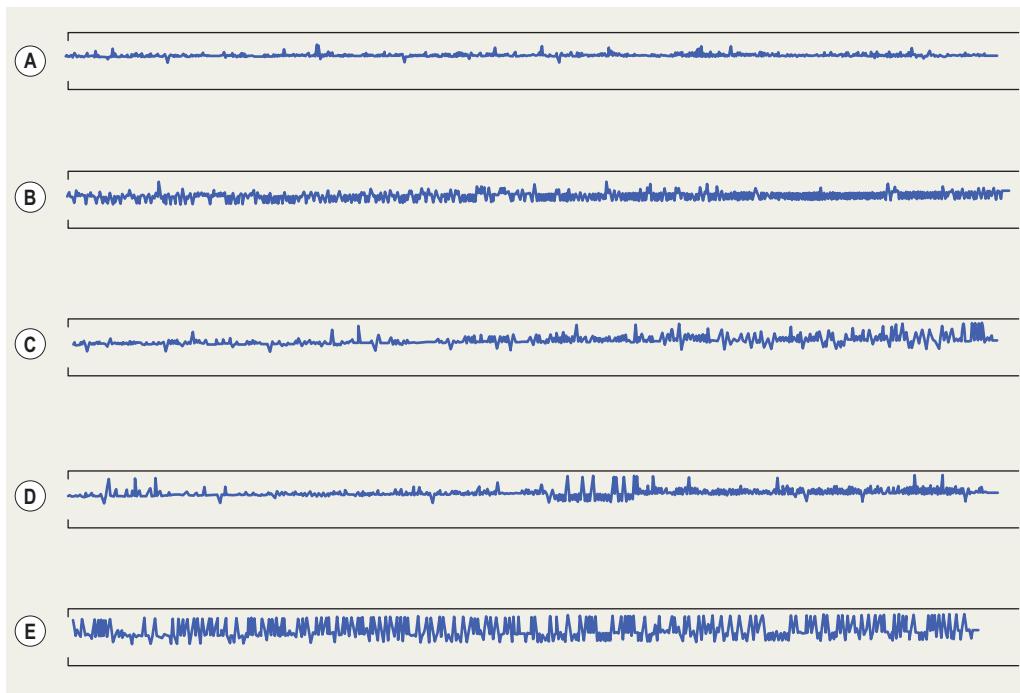

Figure 35.9 Examples of gaze tracking results for the Humphrey Field Analyzer. Upward deflections indicate alignment difficulties (eye and head movements) and downward deflections indicate blinking or droopy eyelid: (A) good gaze tracking, (B) excessive blinking, (C) droopy eyelid, (D) fatigue, and (E) alignment problems.

demonstrating an abnormality on the Total Deviation plot but not on the Pattern Deviation plot. This is a common presentation, which indicates a mixture of localized and widespread or diffuse visual field sensitivity loss.

Below this is the name and address of the eye clinic in the lower right, and a printout of gaze tracking from left to right. Gaze tracking is a valuable component of the visual field printout. During the test, a video camera is monitoring the location of the first Purkinje image (corneal reflex) relative to the edges of the pupil (retinal red reflex) from an infrared light source that does not interfere with the test procedure. This method can then be used to monitor eye and head alignment during the test, as well as eye blinks and droopy lids during the visual field test procedure. The visual field printout has a time line from left to right that presents eye blinks and upper eyelid drooping (a contiguous series of downward deflections) as well as eye and head alignment (upward tick mark deflections) throughout the test procedure. As shown in Figure 35.9, this information can reveal much about the attention and cooperation of the patient during the test procedure. Figure 35.9A shows the results for a patient with good fixation and blinking behavior throughout the test. Figure 35.9B shows the results for a patient who develops excessive blinking and tear film breakup that may be related to the tested eye drying out from exposure to the infrared light (a rest break can assist in minimizing this problem). Figures 35.9C–E present results for a patient who becomes sleepy (droopy upper eyelid) throughout the test, a patient that becomes fatigued as the test progresses, and a patient with head and eye alignment problems during the test, respectively.

It is important to keep in mind that all of the information provided on this printout is essential, and that proper interpretation of visual fields requires taking all of these results

into account. Often, there is a temptation to concentrate on portions of the printout and ignore or discount other information that is presented. This is not a good habit to establish, however, because it can lead to misinterpretation of the visual field findings and artifactual results due to specific testing circumstances that can be missed. It is also critical to remember that visual field testing is only one part of the vision examination, and that additional information from the patient's exam, ocular and medical history, family medical history, and other factors need to be included in the final assessment.

Patterns of visual field loss associated with different pathologic conditions

Proper evaluation of patterns of visual field loss is probably the most vital aspect of visual field interpretation. It is important to keep in mind the three-dimensional nature of visual field properties so that X (width), Y (height) and Z (depth) coordinates are all taken into account. The shape and extent of a visual field defect, whether it has steep or sloping boundaries, and whether it "respects" (terminates abruptly) certain anatomical borders are all important features to consider. Figure 35.10 presents some schematic representations of fibers at different levels in the visual pathways and the patterns of visual field loss that correspond to damage at these locations.

In this section, we will outline some key features and patterns of visual field loss that will be of assistance in visual field interpretation.

- *Generalized or widespread visual field sensitivity loss.* This can be produced by a variety of conditions, ranging

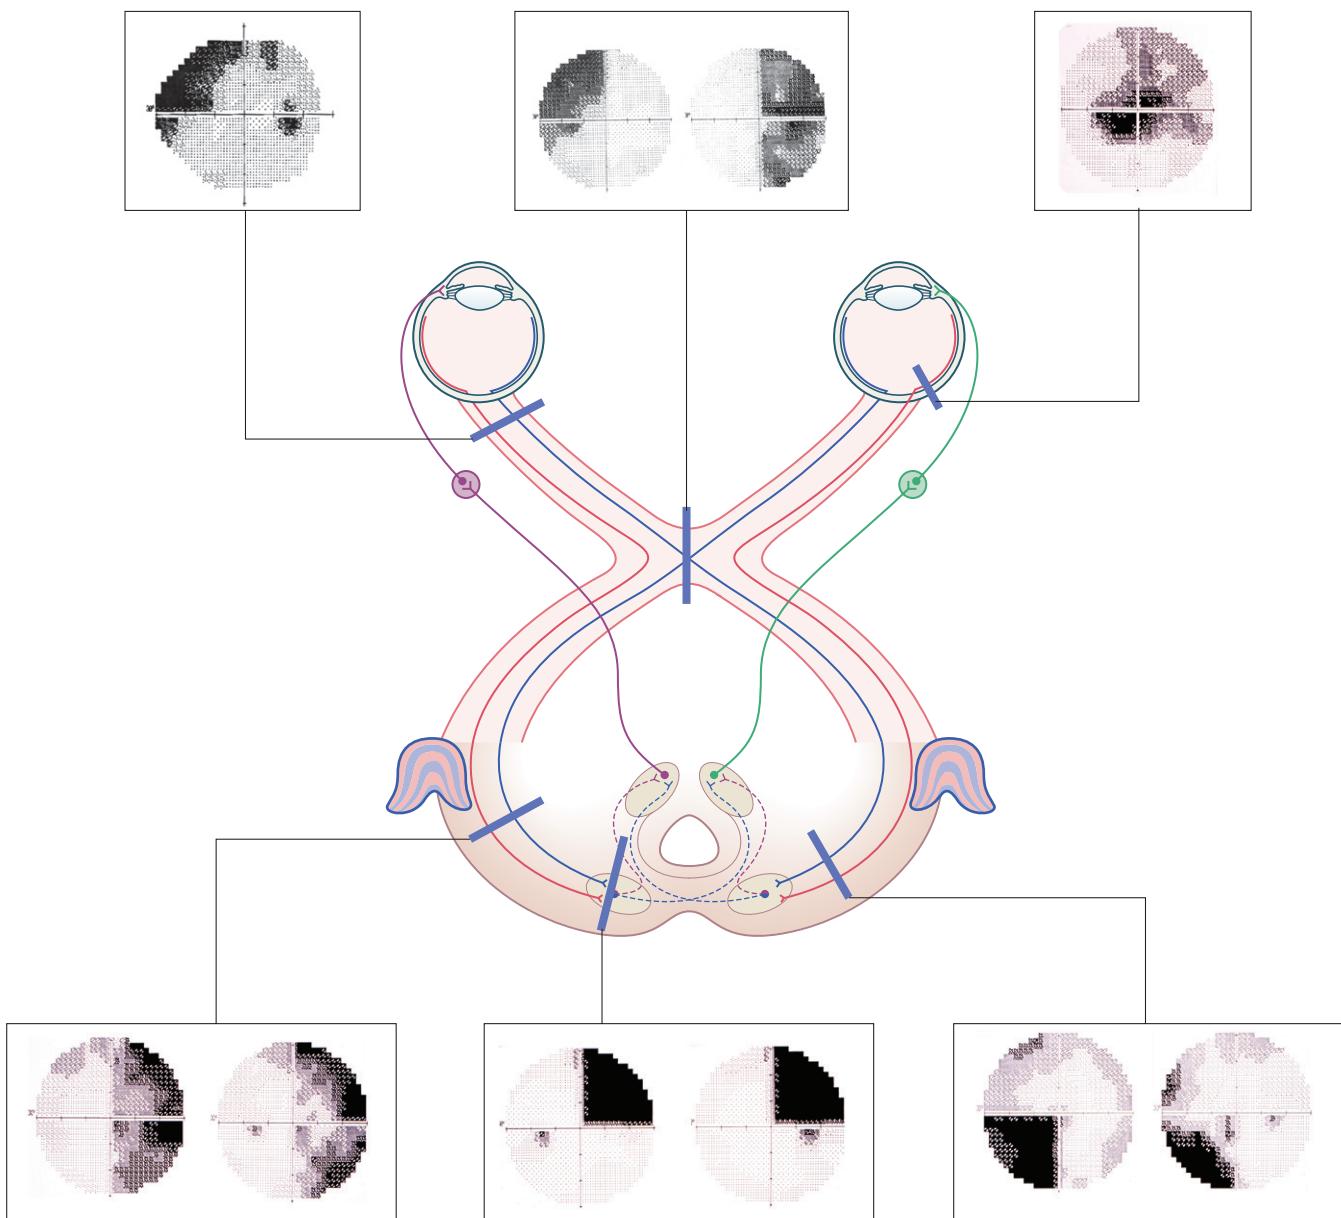

Figure 35.10 Examples of visual field loss produced by damage to the visual pathways at various locations from the retina to primary visual cortex.

from changes in the ocular media to pathology to various portions of the visual pathways to attentional and cognitive factors. It is therefore a rather non-specific diagnostic sign.

- **Ring scotomas.** These defects (either a total or a partial ring of sensitivity loss in the mid periphery surrounded by normal visual field locations) are typically indicative of retinitis pigmentosa or some other type of retinal degeneration.
- **Central scotomas.** Generally, these types of defects are associated with diseases of the macular region of the retina, although optic neuropathies can also produce central scotomas.
- **Defects that "respect" the nasal horizontal meridian.** Generally these types of defects are associated with the

retinal ganglion cell nerve fiber bundles, and are indicative of glaucoma or some other type of optic neuropathy. However, compromises of the retinal vasculature (e.g. a branch artery occlusion) can also produce this type of defect.

- **Arcuate scotomas.** These types of defects again typically affect either the arcuate nerve fiber bundles (glaucoma or other optic neuropathies) or the retinal vasculature.
- **Nasal steps.** These defects are primarily associated with glaucoma or other optic neuropathies.
- **Centrocecal scotomas.** These defects represent pathology to the papillomacular bundle of nerve fibers that subserve the region between the blind spot and fixation. Usually, the deficit is produced by optic neuropathies, but they can also be created by retinal

disease, particularly those that involve edema (e.g. central serous retinopathy).

- **Visual field constriction.** This is a deficit that can be produced by a variety of causes, ranging from retinal disease to optic neuropathies.
- **Defects that "respect" the vertical meridian.** Because of the separation of nerve fibers along the vertical border at fixation, these defects are found for damage to the visual pathways at the optic chiasm or after the optic chiasm.
- **Bitemporal defects.** In nearly all cases, a bitemporal visual field defect that respects the vertical meridian indicates damage to the visual pathways at the optic chiasm.
- **Defects that resemble a horizontal tongue.** This is an uncommon visual field deficit that is only infrequently seen. The deficit can be for the "tongue", or the tongue can be the only remaining visual field areas of seeing. It is produced by damage to visual pathway fibers at the level of the lateral geniculate body.
- **Homonymous visual field defects.** Damage to the visual pathways that is on the same side (right or left) of vision for both eyes is homonymous, and indicates a deficit that has occurred after the optic chiasm. A total homonymous hemianopic visual field defect (the entire right or left side of vision is missing) is indicative of a defect after the optic chiasm, but can be at any location within the optic radiations.
- **Congruous and incongruous defects.** In general, the greater the amount of incongruity of homonymous defects between eyes, the closer the site of damage is to the optic chiasm. Deficits for primary visual cortex (occipital lobe) are highly congruous, parietal lobe and temporal lobe deficits are semi-congruous.
- **Pie in the sky defects.** A homonymous visual field deficit that resembles a piece of pie missing from the superior visual field of both eyes is usually associated with a temporal lobe lesion.
- **Pie on the floor defects.** A homonymous visual field deficit that resembles a missing piece of pie that has fallen to the floor is more often the result of a parietal lobe lesion.
- **Cookie-cutter punched out lesions.** Visual field deficits that look as though one used a hole punch or cookie cutter to represent loss in both eyes is highly indicative of an occipital lobe (primary visual cortex) lesion.

We hope that these guidelines will assist you in the interpretation of visual field information.

Determination of visual field progression

The ability to accurately determine visual field progression and the rate of visual field progression is a vital component in following the functional visual status of patients over time. However, there is currently no general agreement or consensus concerning the best method of following visual field progression. This is best depicted by the fact that every multicenter clinical trial that has employed visual field

results as an outcome measure has used a different method of defining progression.^{14,51–55} A review of the various methods used to determine visual field progression has been reported by several sources.^{14,51–55} Basically, visual field progression techniques can be divided into the categories of clinical judgment methods, classification systems, event analyses and trend analyses.⁵¹ Each procedure has its advantages and disadvantages. It should also be noted that most of the procedures for determining visual field progression have been directed towards glaucoma.

Clinical judgment consists of a practitioner using his/her knowledge and experience to make a determination of whether or not the visual field has undergone systematic changes over time. The main advantage of this procedure is that it is an easy, efficient method of evaluating visual field progression. The primary disadvantage is that there is a large amount of variability among eye care specialists for interpreting visual field progression. Previous investigations have demonstrated that even highly experienced, competent eye care specialists have a tendency to "overcall" visual field progression.

Classification systems consist of staging the amount of visual field damage into a series of categories. A historical review of visual field staging and classification systems for glaucoma has recently been published.⁵⁶ In general, most classification systems use between 5 and 7 different levels of visual field damage to characterize the spectrum of loss. Exceptions to this include the systems derived by the Advanced Glaucoma Intervention Study (AGIS) and the Collaborative Initial Glaucoma Treatment Study (CIGTS), which use 20 stages.^{57,58} Advantages of classification systems include their use by several multicenter clinical trials and the ability to assign a quantitative value to visual field damage, whereas disadvantages consist of the use of a discrete outcome rather than a continuous function, and the lack of knowing the measurement scale (linear, non-linear, etc.) that the system is based upon.

Event analysis is most commonly performed by comparing the most recent visual field to those obtained at baseline visits. For this type of analysis, the intent is to determine whether visual field changes from baseline (progression or improvement) are within or outside expected limits. This technique has been used by several multicenter trials and is available on commercially available automated perimeters.^{57–60} Advantages of this procedure are that it is able to monitor visual field changes over time, and the application of more rigorous statistical procedures to analyze results. Included for disadvantages are the absence of evaluating interim visual fields between the current and baseline results, and the large influence of spurious results (meaningfully higher or lower sensitivity values for a single visit).

Trend analysis has also been used for many multicenter clinical trials, most commonly as a linear least-squares regression.^{61–65} This procedure analyzes all visual fields that have been obtained over time and determines the best fitting equation (usually a linear function) to describe the data. The slope of the line can then be used to provide an estimate of visual field change. Advantages of this procedure include the use of all the visual field data to obtain an estimate of change, based on a long-standing formal statistical model. Limitations of this procedure are related to a requirement for the slope to be statistically significantly different from

zero, and a minimum of 6 to 8 visual fields that are necessary to achieve appropriate high clinical performance. Recently, there have been several enhancements that have been introduced to improve the performance of trend analysis, but it still requires a minimum of 5 to 6 visual fields before satisfactory performance can be achieved (i.e. high sensitivity and specificity).^{66–68} Note that the requirement of at least 5 to 6 visual fields holds for all of the current procedures for analyzing visual fields, which means that an accurate, precise and reliable estimate of visual field status may require several years of follow-up before an informed decision can be made with existing techniques. Clearly from a clinical perspective, there is a strong need for new, innovative approaches to this perplexing problem.

How do the various methods of determining visual field progression compare? Several laboratories have made such comparisons using the same visual field data set to evaluate according to the various methods. In summary, these studies indicate that there are considerable differences in the amount of time to detect progression, the number of reliable visual fields that are determined to be progressing, the number of progressing visual fields that are determined to be unchanged, and the influence of variability (long and short term) on final outcomes.^{14,52–55} Moreover, there is agreement among the various methods only about 50–60 percent of the time.^{14,52–55}

Given these difficulties, what can be done to assist the eye care specialist in determining visual field progression at the present time? Here are a few helpful hints:

- Examine the complete visual field history of the patient, not just the current and the most recent previous results. Otherwise, false positives (inappropriate evaluation of change) and false negatives (inappropriate evaluation of stability) will frequently occur.
- Use all of the available methods of assessing longitudinal visual field status (e.g. Overview Analysis, Change Analysis, Glaucoma Change Probability, Glaucoma Progression Analysis, Glaucoma Progression Index, Progressor, etc.).^{63–65,68–71}
- Compare visual field results with other clinical examination findings, the patient's ocular and general medical history, and other pertinent information (visual fields alone do not provide all of the necessary information).
- When in doubt, perform an additional visual field test, use another type of visual field testing, and perform assessments of structural retinal, optic disc or neural (imaging) characteristics to confirm suspected visual field findings.⁷²
- Consult with colleagues to determine their analysis and interpretation of results.

In the future, what can be done to improve our ability to determine visual field changes over time? We believe that there are four factors that can assist us in this endeavor:

- (1) The development of visual field techniques that provide larger changes that are related to pathology. As described in a later section, several techniques have been developed that appear to detect changes earlier than standard automated perimetry.

- (2) The development of procedures to reduce variability in visual field measures, both within a single session and from one session to another. There have been some methods that have been introduced that appear to be of assistance in this regard.^{28,29,66–68}
- (3) Development of better, more sophisticated statistical analysis techniques. Again, there have been some advances in statistical, neural network and related analytical approaches that have been made in recent times.^{73–76} However, clinical demands on optimizing patient care would be tremendously advanced if more reliable, accurate, precise and efficient methods could be developed for evaluating a patient's visual field status over time.
- (4) Development of methods to analyze "noise" and variability to search for meaningful signals of pathology. Traditionally, visual field variability has been viewed as something that needs to be eliminated, and there has been little research directed towards a systematic analysis of this information to look for markers of pathology. There are many areas of medicine and ophthalmology that have shown value in seeking out such markers. It is likely that there are "signatures" of specific patterns of "noise" or variability that are indicative of pathology of a dysfunctional visual system.

In summary, each of these suggestions for the future is directed towards improving the ability to extract meaningful signals and markers of visual system pathology and changes in visual status that can be revealed through visual field testing.

Finally, one of the most important factors that eye care specialists must consider in the management of patients is the rate of visual field progression. This is a crucial issue in determining the management and treatment regimen for patients, and in assessing how their visual impairment may affect their quality of life and activities of daily living. In this regard, Progressor and the Glaucoma Progression Index provide a means of forecasting the future visual field characteristics for the patient.^{63,64,71} However, it should be kept in mind that these procedures are based on a linear regression model, and it is not clear whether this or non-linear methods would be most appropriate for predicting future visual field outcome for the patient. This topic has only recently received attention by the research community, and it is clear that much additional work is needed.

A guide for interpretation of visual field information

It is important to have a systematic approach for interpreting visual field information (Box 35.1). We recommend using a relatively simple analysis sequence, but emphasize that it is critical to maintain the proper order of this sequence to minimize errors of interpretation (false positives, false negatives, improper localization of the defect, and other difficulties).

- (1) Decide if the visual fields are reliable and if artifactual test results are present.

Box 35.1 Visual field interpretation guidelines

- Detection – Is the visual field of each eye within normal limits or does it have abnormalities?
- Identification – What is the pattern of visual field loss? Is the visual field loss in one eye or both eyes? What is the location or locations of damage to the visual pathways that could account for this loss (differential diagnosis)?
 - For each eye, is the visual field normal or abnormal?
 - If abnormal, is it in one or both eyes?
 - What is the general location of the defect (superior, inferior, nasal, temporal)?
 - What is the shape and specific visual field location of the deficit?
 - Does the deficit correlate with anatomical features and boundaries?
- Staging of visual field loss – What is the severity of visual field loss? Is the loss abrupt or gradual?
- Artifactual visual loss – Does the deficit resemble a lens rim holder, a droopy eyelid, or some other non-pathologic or physiologic result?
- Functional visual loss – Does the pattern and severity of visual field loss exceed that expected on the basis of other clinical findings?
- Longitudinal follow-up of visual field loss – Is the visual field defect remaining stable, improving or getting worse over time? If the visual field loss is changing over time, what is the rate of change over time?
- Practical visual field issues – How does the visual field loss affect the patient's quality of life and activities of daily living? Does it impair the ability to drive, navigate the environment, reduce employment effectiveness?

(2) Place the visual fields for both eyes in front of you, with the left eye on the left and the right eye on the right. For each eye separately, determine whether the visual field is within or outside of normal limits. Automated visual field testing provides assistance in this analysis by presenting a comparison of individual results to those of average findings for a person of the same age. If both visual fields are within normal limits, the analysis is complete.

(3) Determine if the visual field loss (outside normal limits) is in one eye or both eyes. If the loss is in one eye, then the source of the visual damage is before the optic chiasm. Visual field loss in both eyes can be due to insults affecting the visual pathways at the optic chiasm and beyond, or could be due to diseases influencing the optics, retinas or optic nerves of both eyes.

(4) For each eye, determine the general location of the deficit (superior, inferior, nasal or temporal), and if the visual field loss is extensive, assess the predominant location of the deficit. A deficit that is in the temporal visual fields of each eye (bitemporal) is often due to factors affecting the optic chiasm, deficits affecting the nasal visual fields of each eye are usually due to retinal or optic nerve disorders, and losses occurring in the nasal visual field of one eye and the temporal visual field of the other eye are usually related to damage occurring at locations after the optic chiasm. In this view, it is now possible to localize the most likely areas of damage to specific regions of the visual pathways.

(5) Determine the shape and specific location of the deficit. This particular aspect of visual field interpretation is probably the most difficult, but also most important part of the assessment. There are many physiologic and pathologic factors that can produce generalized or widespread visual field sensitivity loss (small pupils, lack of attention, fatigue, corneal opacities, lens opacities, ocular and neurologic disorders, etc.), making this a rather non-specific finding for localization of the etiology of visual field sensitivity loss.

Some retinal diseases can produce specific patterns of visual field loss: (a) scalloped edges of isopters in the far periphery, (b) ring or partial ring scotomas in the mid periphery produced by retinitis pigmentosa, (c) arcuate defects produced by branch artery occlusions, (d) central scotomas related to macular diseases, (e) multiple foci of visual field loss at scattered points the visual field from diabetic retinopathy or other retinal degenerative disease processes, and (f) irregular deficits that do not correspond to other anatomical landmarks throughout the visual pathways.

Diseases affecting the optic nerve can produce: (a) centrocecal scotomas produced by damage to the papillomacular bundle of retinal ganglion cells subserving the region between the macula and the blind spot, (b) arcuate defects created by damage to the superior and inferior arcuate nerve fiber bundles entering the top and bottom of the optic nerve head (often these defects will "respect" [terminate at] the nasal horizontal meridian), (c) central scotomas, (d) constriction of the visual field, (e) enlargement of the blind spot, and (f) temporal wedge defects produced by the radial fibers from the periphery that enter the nasal portion of the optic nerve head (corresponding to the temporal visual field).

Chiasmal deficits most commonly produce bitemporal visual field losses that "respect" (terminate at) the vertical meridian for both eyes. Sometimes, a deficit can be located at the anterior portion of the chiasm and produce a central scotoma in one eye (damage to the optic nerve of that eye) and a superior temporal defect in the other eye. Binasal deficits that "respect" the vertical midline can also occur, but they are very rare because they involve compression of the chiasm from both the left and right sides. Beyond the chiasm, visual field defects are homonymous (occurring on the left side of vision for both eyes or the right side of vision for both eyes). If the deficit is incongruous between the two eyes (greater loss in one eye than in the other, and only moderate overlap between the defective areas in the two eyes), the damage has occurred prior to primary visual cortex (area 17 or V1). The greater the congruity between deficits for the two eyes, the farther the insult is from the chiasm and the closer it is to primary visual cortex.

(6) If there are multiple visual fields that have been obtained for different visits, determine whether the results indicate improvement, stability or progression of visual loss. It is important to review all of the visual field results and not just rely on comparisons of the current results with those obtained for the most recent previous visit. Additionally, comparison of the visual field interpretation of multiple tests with other findings for the clinical examination is also essential.

(7) Finally, if there is uncertainty or doubt concerning the visual field interpretation, it is always helpful to get the opinion and assessment of colleagues. Different

practitioners do not always observe results in the same manner and may have various features that are regarded with greater or lesser importance.

New perimetric test procedures

Many new visual field test procedures have been introduced, particularly within the past 20 years (Box 35.2). Some of these techniques have been successful, while others have not been found to have sufficient clinical or basic research

Box 35.2 Visual field test procedures

Contrast sensitivity and incremental light detection

- Standard Automated Perimetry (SAP) – A method of determining the eye's sensitivity to light at different locations throughout the field of view.

Spatial visual field tests

- High Pass Resolution Perimetry (HPRP) – A procedure that determines the minimum size of a low-contrast stimulus necessary for it to be detected.
- Rarebit Perimetry – A method of providing fine detail mapping of visual field locations by determining the detectability of tiny light dots.

Temporal visual field tests

- Flicker perimetry – A visual field procedure for determining the highest rate of flicker that can be detected (critical flicker fusion or CFF perimetry), the minimum amplitude (contrast) of flicker that can be detected (temporal modulation perimetry), or the minimum light increment needed to detect an illuminated target as flickering on a uniform background (luminance pedestal flicker perimetry).
- Motion perimetry – A method for determining sensitivity to motion throughout the visual field by determining the minimum displacement needed to detect motion (displacement threshold perimetry), the amount of directional coherence needed to detect motion among a collection of random dots (motion coherence perimetry) or the size of visual field area needed to detect motion of a subset of random dots.

Spatio-temporal visual field tests

- Frequency Doubling Technology (FDT) perimetry and Matrix perimetry – A method for presenting a low spatial frequency sinusoidal grating flickering at a high temporal frequency to determine the amount of contrast needed for detection.

Color perimetry

- Short Wavelength Automated Perimetry (SWAP) – A visual field technique that isolates and measures the sensitivity of short wavelength mechanisms.

Electrophysiological perimetry

- Multifocal Electroretinogram (mfERG) – A method of measuring electrical retinal signals for localized visual field regions.
- Multifocal visual evoked potentials (mfVEP) – A technique that measures the electrical activity from primary visual cortex for alternating stimuli presented to small regions of the visual field.

value and have therefore been dropped from further consideration. We will provide a brief summary of the methods that have been shown to be important for clinical diagnostic purposes and for understanding the basis of underlying physiologic and pathologic mechanisms.

Short wavelength automated perimetry (SWAP)

Stiles reported the two-color increment threshold technique for psychophysically isolating and measuring the sensitivity of individual color vision mechanisms.⁷⁷ This procedure was adapted for clinical application by Kitahara⁷⁸ and Kranda and King-Smith,⁷⁹ although the procedures were too cumbersome and time consuming for routine clinical use. Subsequent studies by Sample and colleagues^{80–89} and Johnson and associates^{90–99} reported a modification of an existing automated perimeter (the Humphrey Field Analyzer) to permit the evaluation of short-wavelength-sensitive (blue) color vision mechanisms, which is referred to as Short Wavelength Automated Perimetry (SWAP) within a time frame that was comparable to standard automated perimetry (SAP). A collaborative study identified optimal test conditions for SWAP, which now serves as the basis for SWAP tests that are available on several commercially available perimeters.⁸⁴

Investigations now indicate that SWAP may detect glaucomatous visual field deficits an average of 3–5 years earlier than conventional SAP, and in some cases can occur up to 10 years earlier than SAP visual field deficits.^{80–100} SWAP can sometimes characterize glaucomatous patterns of visual field loss and predict the onset and location of future SAP deficits. Progression of visual field loss appears to be more rapid than for SAP deficits. Isolation of short wavelength mechanisms is maintained throughout the range of glaucomatous deficits, including regions of advanced visual field loss. Additionally, SWAP has been shown to be useful for characterizing visual field losses in other ocular and neurologic diseases affecting the visual pathways,¹⁰¹ and Bayesian forecasting procedures have been developed for more efficient testing and expansion of the dynamic range.^{102–105} Figure 35.11 displays an example of SWAP visual field loss for the right eye of a patient with inferior glaucomatous visual field loss.

Frequency doubling technology (FDT) perimetry

A low spatial frequency sinusoidal grating (less than 2 cycles/degree) that is rapidly counterphase (square wave) flickered at greater than 15 Hz produces a percept of twice as many light and dark bars than are physically present, known as "frequency doubling".^{106–108} This phenomenon has been incorporated into a clinical diagnostic test procedure known as Frequency Doubling Technology (FDT) perimetry, which has now undergone two generations of testing devices.^{109–110} However, the observer's task is not to evaluate the frequency doubled nature of the percept, but rather to determine the minimum contrast at which the stimulus can be detected. The first generation (FDT) perimeter presented 17 or 19 large (10-degree square) targets to various visual field locations, whereas the second generation device (the Humphrey Matrix) can provide a larger number of smaller targets

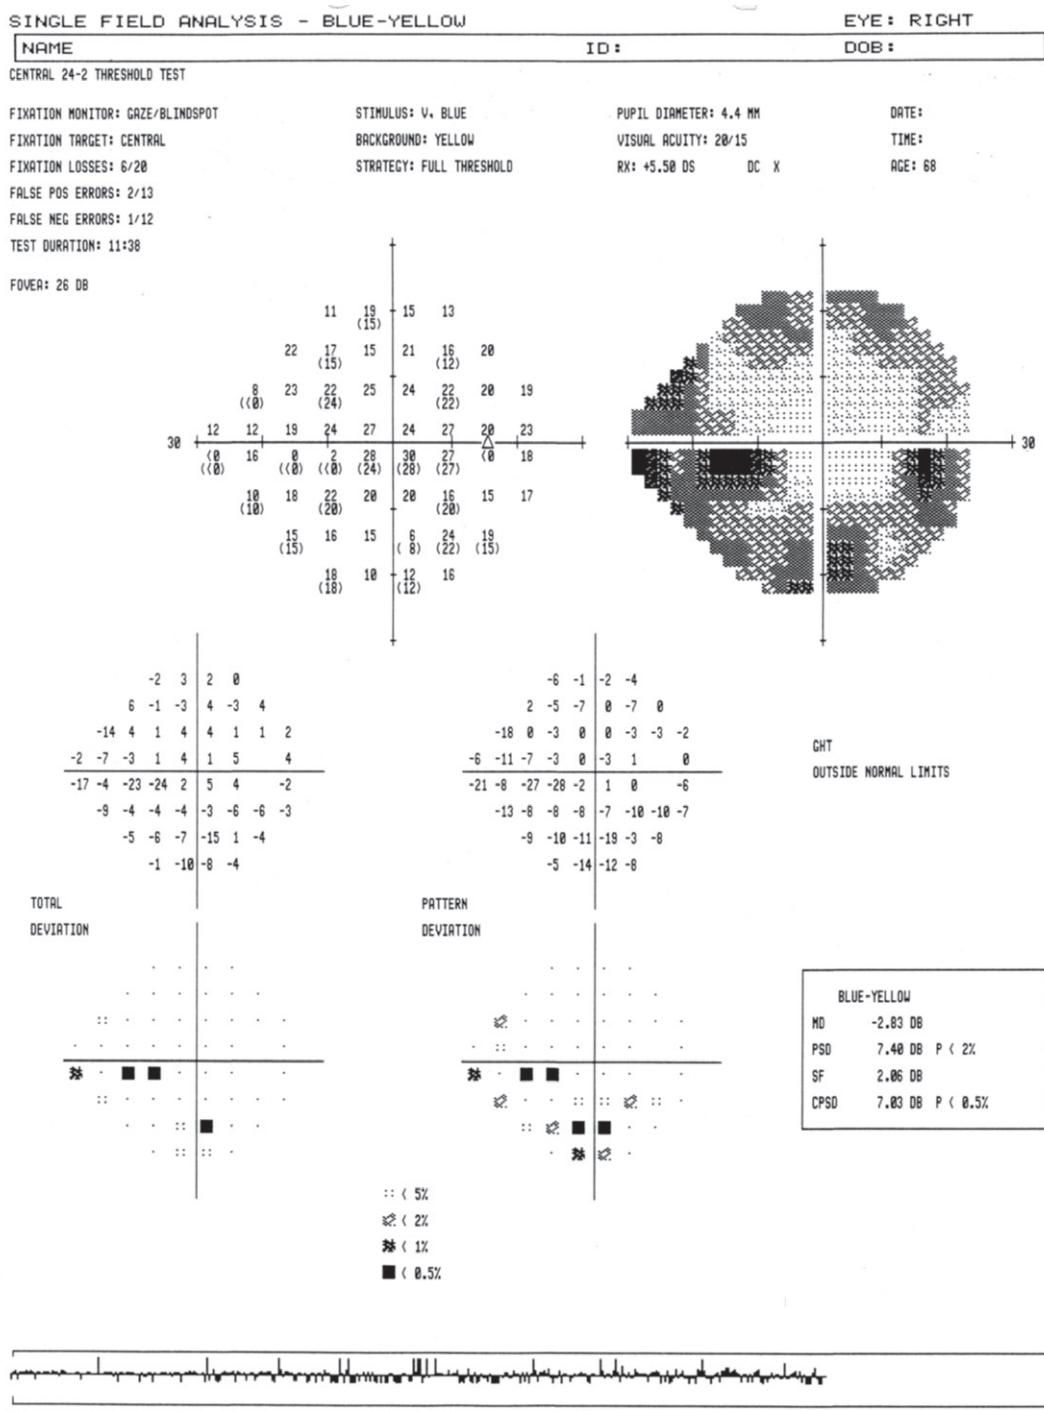

Figure 35.11 Short Wavelength Automated Perimetry (SWAP) results for the right eye (OD) of a patient with primary open angle glaucoma, revealing a partial inferior arcuate visual field defect.

(5-degree or 2-degree squares) to produce the 30-2, 24-2, 10-2 and macula presentation patterns. Details concerning these procedures and methods may be found in other publications.¹¹¹⁻¹²⁸

FDT perimetry has been found to be clinically effective in determining visual field loss that is produced by glaucoma and other ocular and neurologic diseases affecting the visual pathways.¹¹¹⁻¹²⁸ Additionally, some reports have indicated that FDT perimetry deficits can precede losses detected by

SAP, and that they may be predictive of future visual field outcomes.^{129,130} The recent advent of the Humphrey Matrix has provided a number of additional features for this procedure, and has also been reported to have uniform variability over the entire response range of the instrument, a distinct benefit for monitoring the status of moderate to advanced visual field loss. Figure 35.12 presents FDT results for the left eye of a patient with superior glaucomatous visual field loss, and Figure 35.13 shows the results for the same eye using

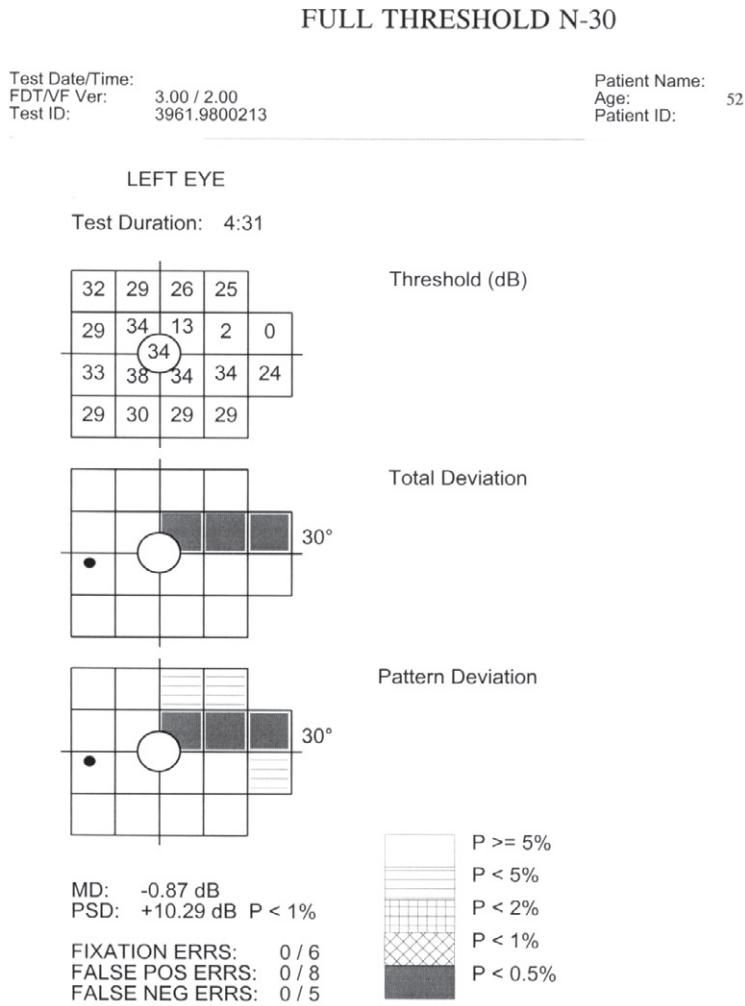

Figure 35.12 Frequency Doubling Technology results for the left (OS) eye of a patient with primary open angle glaucoma that displays a superior nasal step.

the Humphrey Matrix 24-2 test procedure obtained approximately one year after the initial FDT testing session.

Flicker and temporal modulation perimetry

Four forms of flicker perimetry have been developed in recent years: (1) determining the highest temporal flicker frequency that can be distinguished from a steady light (critical flicker fusion [CFF] perimetry), (2) evaluating the minimum amplitude of temporal alternation needed to detect flicker (temporal modulation perimetry [TMP]), (3) detection of a letter or shape of a series of rapidly alternating dots that are flickering in counterphase to other dots (flicker-defined form [FDF] perimetry) and (4) determining the minimum amount of flicker superimposed on a luminance increment needed to detect flicker from a steady light (luminance pedestal flicker [LPF] perimetry).¹³¹⁻¹⁴⁴

Each of these procedures has certain advantages and disadvantages, but no study to date has compared all four tests in normal controls and patients with ocular disease to determine their clinical merits and deficits. However, a comparison between CFF and TMP indicated that in glaucoma, TMP was more sensitive for separation of findings from normal controls and glaucoma patients.¹³¹ No systematic investigations of FDF or LPF perimetry in ocular and neurologic diseases have been reported to date.

Early investigations reported that high temporal frequencies were optimal for detection of glaucomatous visual field loss,¹³³ but subsequent studies indicated that a high temporal frequency sensitivity loss was characteristic of older normal controls, and that middle temporal frequencies (about 8 Hz) provided the greatest dynamic range, the lowest variability, and the best ability to detect early visual field losses.¹³⁶ Flicker perimetry also appears to be quite resistant to the influence of blur, and other test variables, but can sometimes be influenced by changes in pupil size and other stimulus presentation, physiologic and pathologic conditions.¹³⁴⁻¹³⁹ Several studies have reported that flicker perimetry is able to detect glaucomatous visual field loss prior to SAP and has clinical value in predicting the onset and location of subsequent SAP visual field loss.¹³⁴⁻¹⁴⁴ Figure 35.14 presents temporal modulation flicker perimetry results for the left eye of a patient with superior glaucomatous visual field loss.

Motion perimetry

As with flicker perimetry, motion perimetry is conducted according to several different methods: (1) detection of rapid movement of a single stimulus presented at various visual field locations (displacement threshold perimetry), (2) determination of a minimum proportion of dots moving

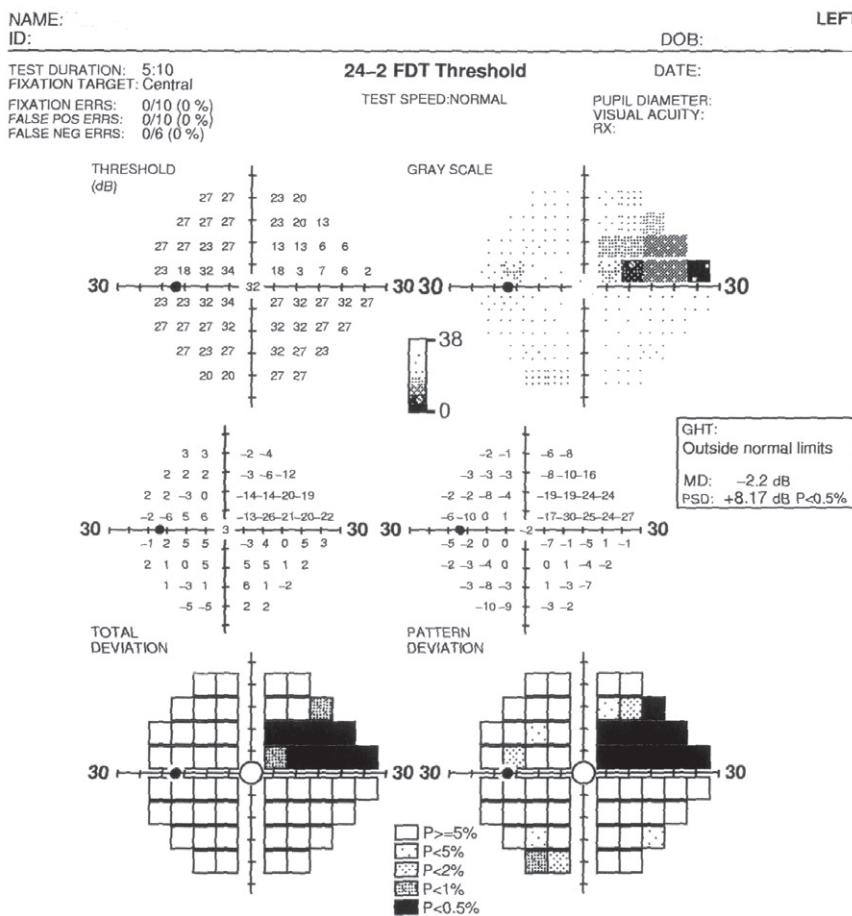

Figure 35.13 Humphrey Matrix Frequency Doubling Technology results for the same left eye (OS) of the patient with primary open angle glaucoma shown in Figure 35.12, exhibiting a superior nasal step. This test was performed one year after the results that were presented in Figure 35.12.

in the same direction that are embedded with a group of stationary dots or a group of dots that are moving in random directions (motion coherence perimetry), and (3) motion of a cluster of dots within a group of stationary dots.^{145–158} In these instances, the measurement variables are minimum position displacement, minimum proportion of coherently moving dots, and minimum size of clustered moving dots, respectively.

Similar to flicker perimetry, motion detection perimetry is a robust measurement, being resistant to the influence of varying degrees of blur, contrast variations and background luminances. In this view, motion detection is a very salient feature that can be easily processed by peripheral visual field mechanisms. Additionally, motion perimetry appears to have uniform variability across its entire dynamic response range, and has been reported to be quite effective in detecting early visual field loss in a variety of diseases affecting the visual pathways.^{145–158} Figure 35.15 presents the results for the left eye of a patient with inferior glaucomatous visual field loss.

High pass resolution perimetry

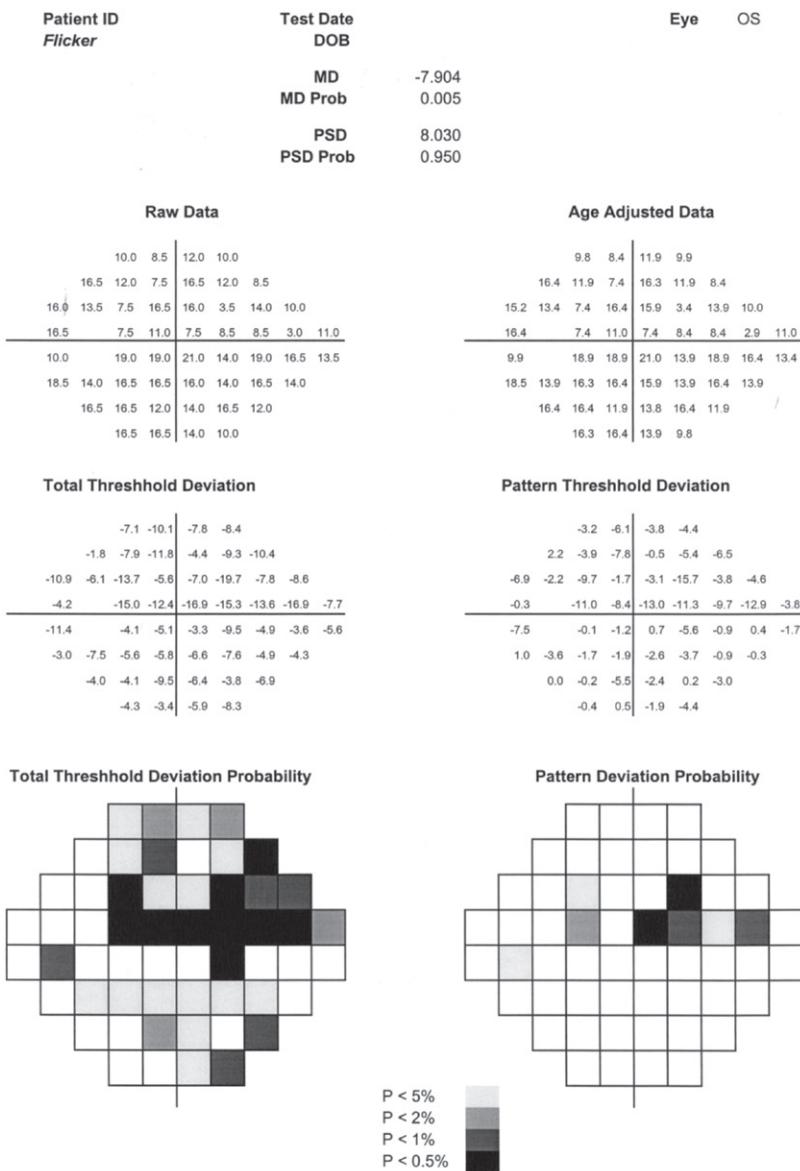

High pass resolution perimetry (HPRP) presents a series of ring stimuli consisting of a dark ring surrounding a circular central white stimulus to different visual field locations.^{159–169} The observer's task is to indicate when they are able to detect the ring stimulus, and the size of the ring is varied to determine a threshold measurement. The HPRP stimuli are presented at 85 percent contrast so that detection (distinguishing

a target from the uniform background) and resolution (distinguishing one target from another) thresholds are essentially equivalent. The test is presented on a computer-controlled video monitor, and is an adaptive, interactive procedure.

Studies performed in glaucoma and other ocular and neurologic disorders indicate that HPRP is a useful diagnostic test procedure for detection and characterization of visual field loss,^{159–169} has good test-retest reproducibility¹⁶⁵ and can detect progression of glaucomatous visual field loss an average of approximately 18 months earlier than SAP.¹⁶⁶ Although HPRP appears to have many advantages as a clinical diagnostic test procedure for characterizing visual field properties, it has limited commercial availability at the present time. Figure 35.16 presents results for the right eye of a patient with superior visual field loss due to glaucoma (left), with results from the Humphrey Field Analyzer also presented (right) for comparison.

Rarebit perimetry

Rarebit perimetry is a relatively new test procedure that uses a computer-driven video display to present one or two small white dots (pixels) on a uniform background.^{170–174} The observer is asked to respond whether they saw one or two small targets during each stimulus presentation. By using a high-density pixel map, Rarebit perimetry evaluates correct and incorrect responses to construct regions of normal and abnormal detection of stimuli in an effort to locate gaps and discontinuities in performance throughout the visual field.

In this manner, the intent of Rarebit perimetry is to identify areas of patchy sensitivity loss produced by glaucoma and other ocular and neurologic disorders that might be overlooked by SAP in the evaluation of early disease onset.

Information from clinical evaluation of Rarebit perimetry is somewhat limited to date, although these preliminary findings have been shown to be quite promising.^{170–174} Although many of the features of Rarebit perimetry are quite appealing, empirical findings from clinical studies will ultimately determine its utility for clinical evaluations. The sensitivity, specificity, reproducibility and ability to monitor visual field progression with Rarebit perimetry need to be assessed carefully. Figure 35.17 presents the results of Rarebit perimetry testing in the right eye of a patient with superior and inferior glaucomatous visual field loss.

Multifocal visual evoked potentials (mfVEP)

Until recently, electrophysiological evaluation of visual field deficits produced by ocular and neurological diseases have

Figure 35.14 Temporal modulation perimetry (flicker) perimetry for the left eye (OS) of a patient with primary open angle glaucoma, revealing a superior arcuate visual field defect and an inferior partial arcuate defect.

had a rather limited, narrow application to clinical diagnostic procedures. The recent advent of multifocal techniques to measure the electroretinogram (mfERG) and visual evoked potential (mfVEP) has made it possible to expand these capabilities.^{175–186} These techniques present rapidly alternating checkerboard patterns to various locations throughout the visual field according to a modified binary M-sequence, whereby the onset–offset characteristics of the checkerboard are the same for each location, but are subject to a delay in the initiation of the sequence at each of the visual field locations. An autocorrelation function is then used to extract localized signals from the complex waveform to obtain individual electrophysiologic recordings from a variety of visual field locations.^{175–186}

Although the mfERG is useful for evaluation of many retinal disorders,^{175–179} it has not been particularly beneficial for evaluation of glaucoma, and does not correlate well with traditional SAP visual field findings. On the other hand, mfVEP results have been shown to correlate quite well with SAP results, and have been reported to have signal to noise

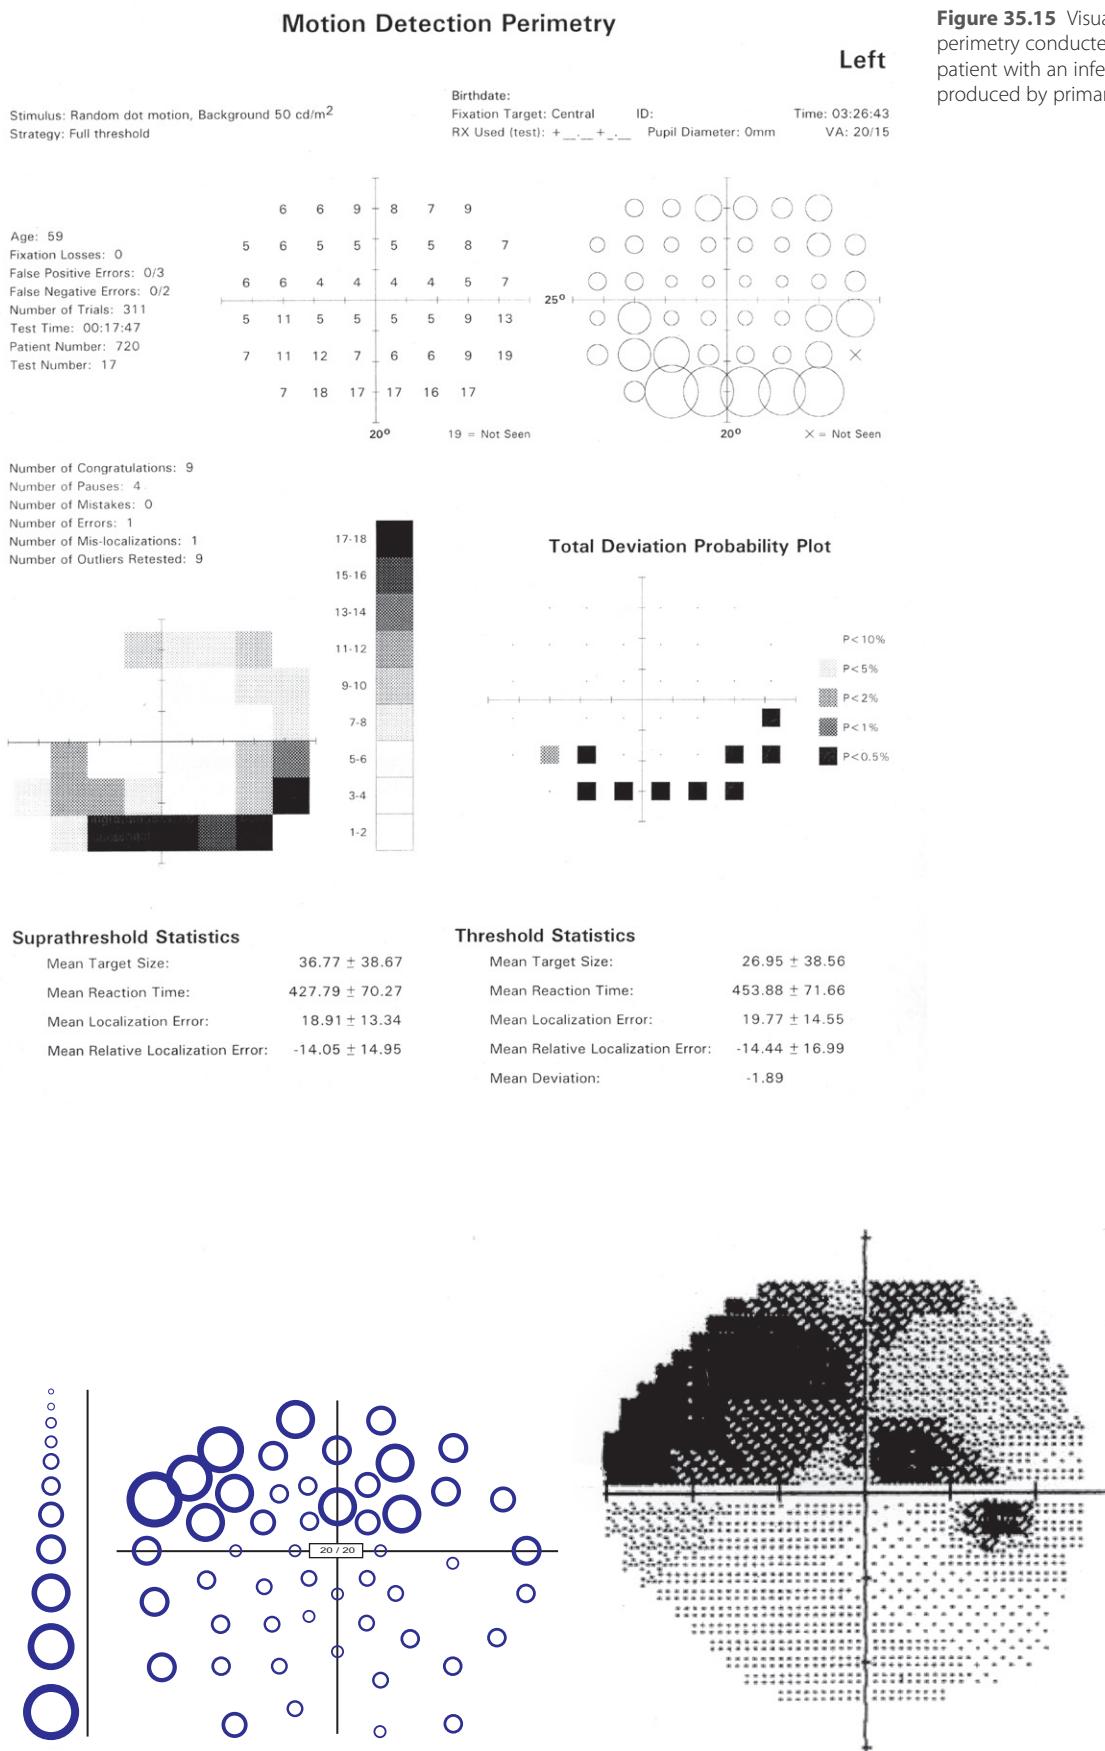

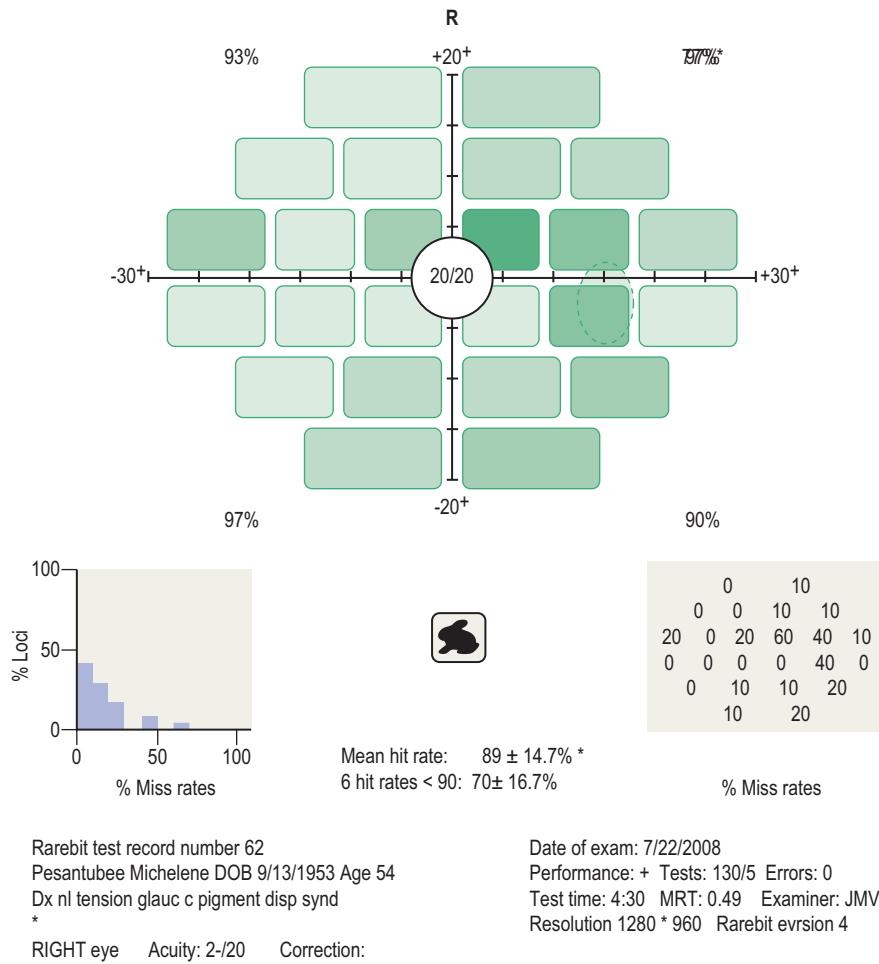

Figure 35.15 Visual field results for motion perimetry conducted on the right eye (OD) of a patient with an inferior arcuate visual field defect produced by primary open angle glaucoma.

Figure 35.16 A comparison of high-pass resolution perimetry (left) and standard automated perimetry conducted on the Humphrey Field Analyzer (right) for the right eye (OD) of a patient with primary open angle glaucoma. (Reproduced with permission from Birt CM et al. J Glaucoma 1998; 7:111.)

Figure 35.17 Superior and inferior arcuate visual field loss for the right eye (OD) of a patient with primary open angle glaucoma as determined with Rarebit automated perimetry.

ratios that remain relatively constant throughout its dynamic range, and to utilize the asymmetry between eyes to indicate subtle losses in glaucoma.^{180–186} Although this procedure has undergone tremendous advances in recent years, there are also a number of disadvantages that remain:

- (1) the response range is rather limited, so evaluation of patients with significant moderate to advanced glaucomatous damage cannot be performed,
- (2) testing and setup times are long when compared to SAP,
- (3) analysis of results is presently cumbersome and time-consuming, and
- (4) the procedure requires careful monitoring to minimize the influence of confounding variables (attention loss, daydreaming, presence of alpha waves, etc.).

Figure 35.18 presents the results of multifocal VEP testing in a patient with inferior glaucomatous visual field loss in both eyes.

Conclusions

Perimetry and visual field testing are important diagnostic procedures that can provide a wealth of useful clinical information concerning a patient's functional vision status, ability to detect objects in the periphery, and effectively

navigate through the environment. Additionally, visual field evaluation provides a useful guide concerning the location of damage to the visual pathways and the type of disease entity that is producing the visual field loss. The pattern of sensitivity loss and the relationship of visual field deficits between the two eyes can provide valuable insights about the locus of involvement for pathology that is affecting the visual pathways. In this view, it is useful to compare the diagnostic power of visual fields to other clinical test procedures. Measurement of visual acuity is undoubtedly the most common assessment of visual function. However, reduced visual acuity (e.g. 20/100) can be due to any factor influencing the visual pathways from the cornea to primary visual cortex and beyond. In this sense, visual acuity may be a sensitive measure of form vision that is important for reading, object identification and other related tasks, but it is not very specific in terms of where the anomaly is occurring in the visual pathways. Visual field testing, on the other hand, is able to provide specific information about the location of pathology by evaluating the shape, location and density of visual field sensitivity loss. Prior to the development and use of neurologic imaging procedures (CT, MRI, fMRI, PET, etc.), visual fields were used as a primary indicator of the location of ocular or neurological pathology.

It should be kept in mind that no single test procedure, including visual field testing, can provide the clinician with complete information about a patient's functional visual

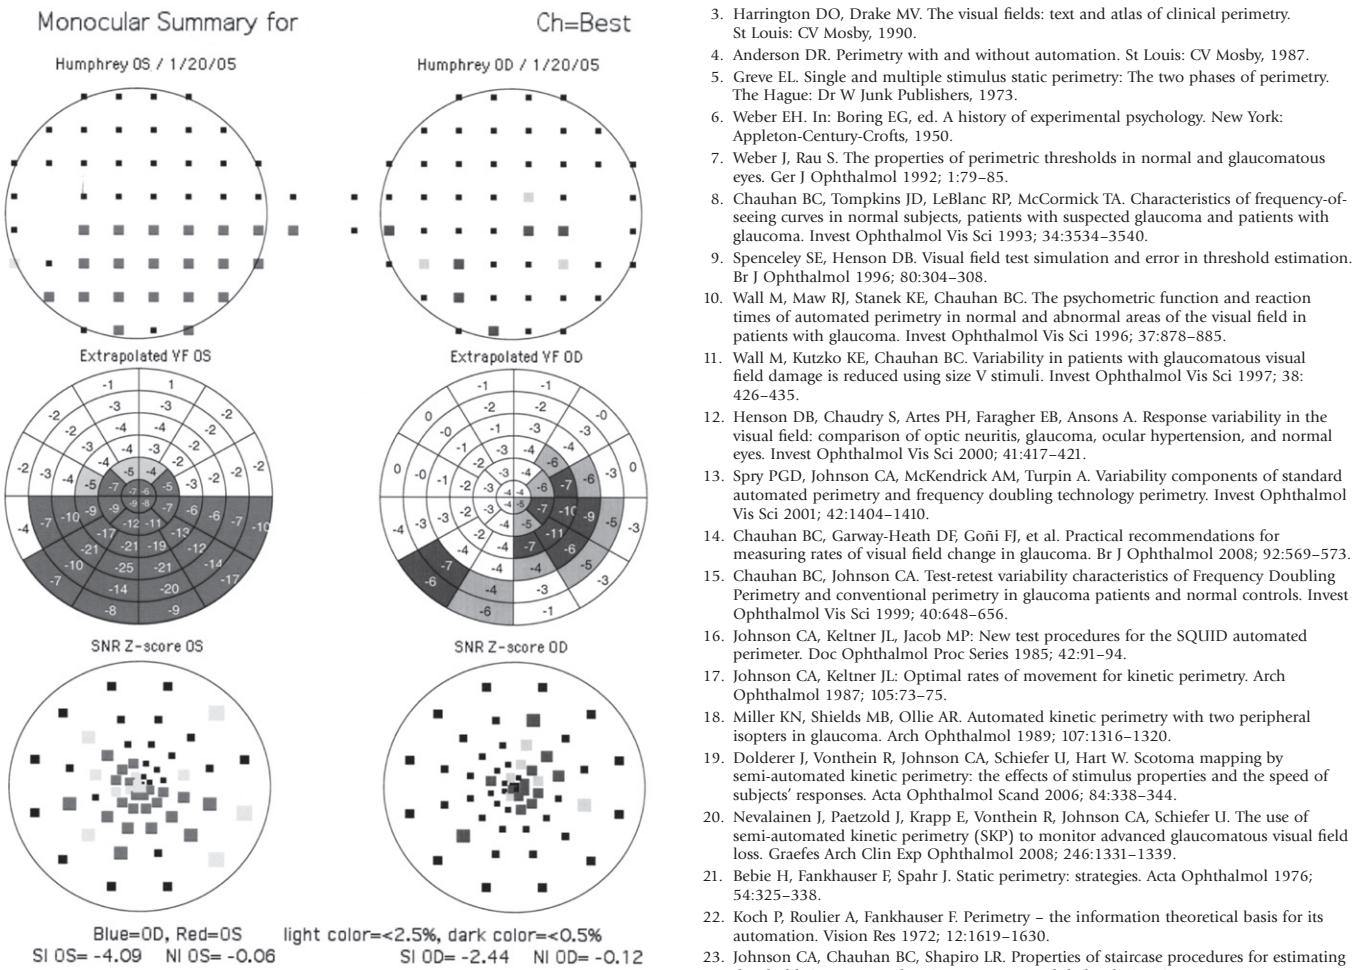

Figure 35.18 Multifocal visual evoked potential (mfVEP) results for the left and right eyes of a patient with primary open angle glaucoma resulting in an inferior arcuate to altitudinal visual field defect in the left eye (OS) and an inferior partial arcuate visual field defect in the right eye (OD).

status (although if this could be accomplished, clinical examinations could be performed much more rapidly). Therefore, it is helpful to keep in mind that visual field results should be interpreted within the context of information obtained from other portions of the eye examination, the patient's history (and family history), their primary complaints, and other pertinent information.

The intent of this chapter is to provide some guidelines for conducting and interpreting visual field information, and we hope that it has provided this service and will continue to be a resource for the future. However, as with most clinical ophthalmic procedures, there is no substitute for obtaining first-hand clinical experience with visual field testing. We hope that this chapter will provide you with the appropriate tools to achieve a high degree of expertise in the analysis and interpretation of perimetry.

Binocular Vision

Ronald S. Harwerth & Clifton M. Schor

Introduction

Humans and other animals with frontally located eyes attain binocular vision from the two retinal images through a series of sensory and motor processes that culminate in the perception of singleness and stereoscopic depth. Keen stereopsis is considered the paramount consequence of binocular vision because optimal performance depends on the normal functioning of all of the underlying vision processes, including central fixation with normal visual acuity in each eye, accurate oculomotor control to obtain bifoveal fixation, normal inter-retinal correspondence of visual directions, sensory mechanisms to produce haplopia (single vision), and neural mechanisms to extract selective depth signals from objects that are nearer or farther than the plane of fixation. Consequently, ordinary binocular vision represents a highly coordinated organization of motor and sensory processes and if any component in the organization fails, then binocular vision and stereopsis must be compromised to some extent. Clinically, the causes and significance of abnormal binocular vision are the primary emphasis, usually with a goal to alleviate any interference with clear, comfortable, single binocular vision. However, clinical applications must be established from an understanding of normal binocular vision. The topics included in this chapter were selected to provide the basic information on normal and abnormal binocular vision that forms the foundation for the clinical science of binocular vision.

Two eyes are better than one

It is obvious that an organism should gain an advantage by having two eyes rather than one. For example, it may be assumed that binocular vision is an important attribute because 75–80 percent of the neurons in primary visual cortex have inputs from both eyes.^{6,84} There are also several functional advantages to having two frontal eyes.

1. The binocular field of view is larger than either monocular field.⁶⁵ The normal visual field for each eye extends to approximately 60 deg superiorly, 60 deg nasally, 75 deg inferiorly, and 100 deg temporally from fixation. Thus, with binocular viewing, the horizontal extent of the visual field is increased from

160 deg to 200 deg, with a central 120 deg of overlap, or superimposition, of the monocular visual fields.

2. Any image distortion due to optical or pathological defects in one eye can be masked by a normal image in the other eye. In general, the degree of dysfunction from a unilateral disorder or bilateral eye disease can be predicted from the performance of the un- or less-impaired eye.^{33,110,111,108}
3. Pragmatically, having two eyes provides a resource to retain functional vision if an accident or disease causes the loss of sight of one eye.
4. Normal binocular vision improves functional vision by binocular summation and stereopsis. Binocular summation, which is the improvement in visual sensitivity with binocular viewing compared to monocular viewing,²⁶ provides only a small increase in sensitivity when measured by threshold responses,^{17,72} but may be a larger factor for performance measured with suprathreshold stimuli.⁷⁴ Stereopsis, on the other hand, is the quantitative and qualitative improvement in relative depth perception that occurs with binocular viewing. At its most elementary level, keen stereopsis benefits both the predator, at the point of attack, and the prey, by unmasking the camouflage of predators.¹⁴

Visual direction

Ordinarily, people are not aware that they are using two eyes, but rather, they have an impression of viewing with one eye located about midway between the two eyes (the egocenter, or cyclopean eye). Thus, the basic concept of visual space involves the relationship between the locations of objects in physical space and their perceived (subjective) spatial locations.¹¹³ These concepts are illustrated diagrammatically in Figure 36.1, which presents representations of physical space in panel A and subjective space in panel B. Perceived directions of objects are based on several factors, including the retinal locations of their images. Each retinal image location is associated with a specific visual direction, called its local sign or oculocentric direction.^{83,113} The primary visual direction is the oculocentric direction of an object that is fixated along the primary line of sight and is imaged on the center of the fovea (represented by the

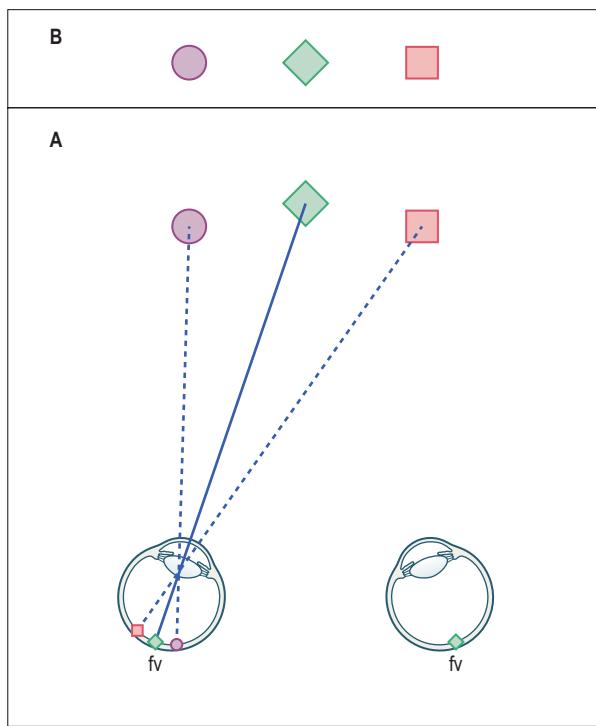

Figure 36.1 Perceived visual direction as a function of retinal image location. **(A)** The relationships between objects in physical space and their retinal images. The square represents a fixated object (primary line of sight) and the non-fixed objects (circle and square) are secondary lines of sight. **(B)** The relationships between retinal image locations and their visual directions (oculocentric directions). The perceived visual directions of the non-fixed objects (secondary visual directions of the circle and square) are relative to the primary visual direction of the fixated diamond.

diamond in Fig. 36.1). Secondary lines of sight are the oculocentric directions of other retinal image locations relative to the primary visual direction. As illustrated in Figure 36.1, the perceived visual directions of non-fixed objects (represented by the circle and square) are relative to the visual direction of a fixated object (represented by the diamond). In the example, an image located to the left side of the fovea is perceived to the right of the fixated object, e.g. the visual direction of the square. The normal ability to distinguish differences in oculocentric directions is extremely accurate, as demonstrated by Vernier alignment thresholds, which are on the order of 5 arcsec for foveal viewing.^{98,175}

In a natural, dynamic world, objects are localized with respect to the head and body rather than to the line of sight and, therefore, retinal image information is not sufficient to define valid relationships between the physical and perceived locations of real objects. The perceived direction of an object in space relative to the body, its egocentric direction, is derived from the combination of its oculocentric visual direction with information about eye orientation in the head and head position relative to the trunk of the body. Egocentric localization is referenced to an egocenter midway between the two eyes and the combined information allows an individual to distinguish between retinal image motion caused by eye movements and movement of the object.⁷³

From a clinical point, egocentric direction is an important concept for understanding the alterations of normal subjective visual space of patients with a misalignment of the two eyes from strabismus. The general principles of egocentric direction are illustrated in Figure 36.2. In the first examples (Fig. 36.2A&B), with normal binocular vision the retinal oculocentric directions from the two retinal images of an object at (panel A) or close to (panel B, circle) the plane of fixation are combined to produce a single direction

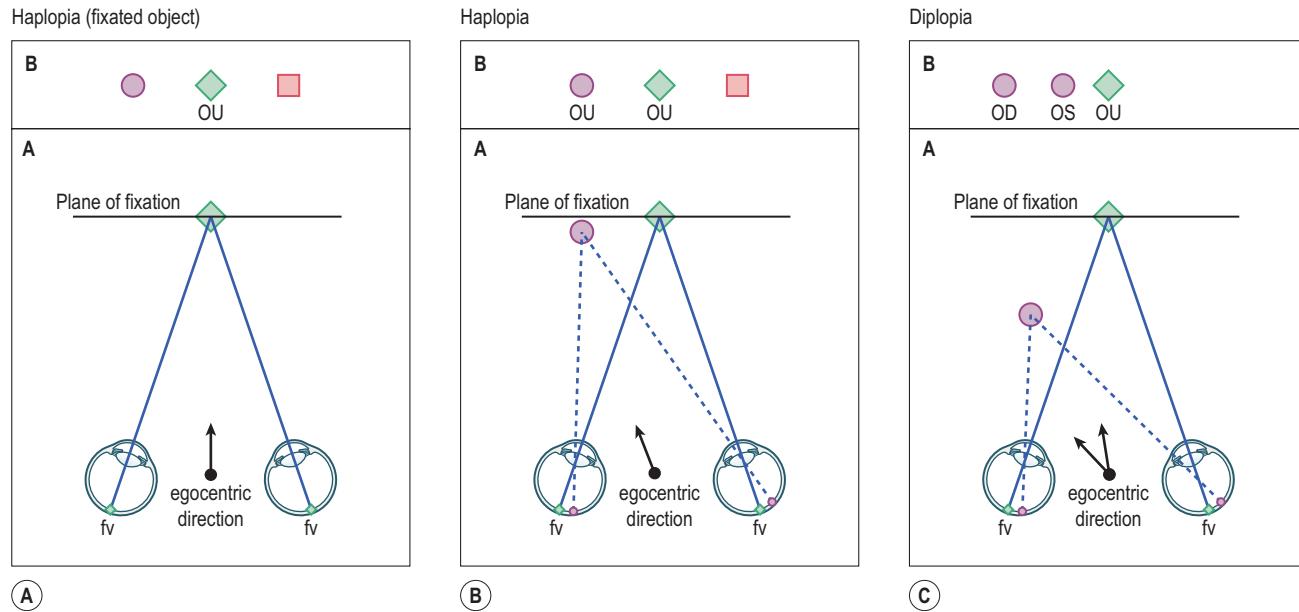

Figure 36.2 Egocentric directions for haplopia and diplopia. **(A)** The oculocentric directions of a fixated object are combined to produce a single egocentric direction. **(B)** The retinal images of non-fixed objects that are near the plane of fixation also will be combined to produce a single egocentric direction. **(C)** When the disparity of retinal images is larger than the normal fusion range (Panum's fusional area), the oculocentric directions are not combined and the object has two egocentric directions (physiological diplopia).

(haplopia) relative to the observer's egocenter. In contrast, for objects that are outside the range of single vision, either nearer or farther than the plane of fixation, a single object has two separate egocentric directions that correspond to the oculocentric direction of each of the retinal images relative to the perspective of the egocenter, i.e. diplopia, illustrated in [Figure 36.2C](#).

Binocular eye movements are defined by combinations of version and vergence ocular movements (see Chapter 9). Versions are yoked or conjugate changes in the visual axes of the two eyes in the same direction and amount; vergence movements involve rotations of the visual axes in opposite directions. Only the version component of binocular eye position influences the perception of egocentric direction, which is sensed as the average position of the two eyes. The vergence component is nullified because vergence movements of the two eyes have opposite signs and their correlates cancel one another in the computation of the average of right and left eye positions. Thus, when the two eyes fixate objects to the left or right of the midline in asymmetric convergence, only the version, or conjugate, component of eye position contributes to perceived direction.⁸²

In addition to averaged eye positions, the subjective computation of egocentric directions of non-fixedated objects involves a reconciliation of differences in oculocentric visual directions between the two eyes. For example, objects that are small distances in front or behind the plane of fixation are imaged at retinal locations with different angular distances from the visual axis and, therefore, have different oculocentric directions in each of the two eyes. When the retinal image disparity is small, the target still appears single, and the binocular egocentric direction is based upon the average oculocentric direction for the two eyes.¹⁵³ In other words, the binocular egocentric direction deviates from either of the monocularly perceived directions by one-half of the angular disparity ([Fig. 36.2B](#)). However when the retinal images have unequal contrast, the average is biased or weighted toward the direction of the higher-contrast image.⁷

As object distances from the plane of fixation increase, retinal image disparities become large, and an object appears diplopic with two separate egocentric directions. Egocentric directions of diplopic images are perceived as though both monocular components had paired images on corresponding points in the contralateral eye ([Fig. 36.2C](#)). The relative egocentric direction of each of the diplopic images depends on whether the object is nearer or farther than the plane of fixation. The example ([Fig. 36.2C](#)) illustrates that, for an object closer than the plane of fixation, the egocentric direction associated with the retinal image of the right eye is to the left of the egocentric direction produced by the image of the left eye. This form of diplopia, produced by near objects, is called "crossed" diplopia due to the right-left/left-right relationship between the eyes and perceived locations of the object. Conversely, objects farther than the plane of fixation will be perceived with uncrossed diplopia, where the right eye sees an object located on the right side and the left eye sees an object located on the left side.

In normal binocular vision, diplopia of non-fixedated objects, classified as physiological diplopia, occurs as a natural consequence of the lateral separation of frontally located eyes and the topographical organization of visual

directions across the retina. In contrast, patients with strabismus experience pathological diplopia, wherein objects in the plane of fixation are perceived as doubled.¹⁷⁰ In pathological diplopia, the retinal image location caused by misalignment of the visual axis of the deviating eye causes a fixated target to be seen in different egocentric directions during binocular viewing, and yet, under monocular conditions each eye veridically perceives its direction. Under binocular viewing conditions, only one of the two visual directions seen in pathological diplopia can be veridical at any given moment. In addition to diplopia, a form of visual confusion confounds the space perception of strabismic patients. An object imaged on the fovea of the deviating eye has the same egocentric direction as another object imaged on the fovea of the fixating eye, even though their physical locations are much different. Diplopia and visual confusion create an intolerable visual environment that is typically alleviated during binocular vision by the development of suppression, which is a suspension of the vision in the deviating eye. Another solution to diplopia is anomalous retinal correspondence, which is an alteration of the normal topography of oculocentric directions.^{18,171,172}

Normal retinal correspondence

The perceptions of haplopia and diplopia arise from the sense of oculocentric visual directions of corresponding or non-corresponding retinal areas that are stimulated during binocular vision. Binocular retinal correspondence is defined by the set of retinal image locations that produces perceptions of identical visual directions when viewing with one eye, or with the other, or with both eyes simultaneously.¹¹³ Identical visual directions associated with corresponding points depend primarily on retinal image locations and their associated oculocentric directions, rather than on eye position and egocentric directions. This fundamental principle was demonstrated by Hering's famous "window experiment"^{113,172} that illustrated the relationship between retinal image locations and perceived visual directions showed that objects imaged on the foveas have the same perceived visual direction regardless of their actual positions relative to the observer. Similarly, afterimages placed on the fovea of each eye always appear superimposed irrespective of the vergence or version positions of the two eyes.¹⁰ The identical visual directions of the afterimages show that normally corresponding retinal points are combined physiologically before eye position information is used to compute perceived egocentric direction.

These relationships for binocular visual directions are illustrated in [Figure 36.3](#), in which the two foveal images of a fixated object (diamond – panel A) share a common visual direction and are fused to produce the perception of a single haplopic object in subjective space (panel B). The specific pairs of retinal image locations in the two eyes that are perceived to have identical visual directions are called corresponding retinal points or areas.^{83,113,114} The foveas represent an important pair of corresponding retinal points, but there are many other pairs associated with secondary lines of sight and visual directions. For example, in [Figure 36.3](#) the square represents the location of an object in the right visual field that falls on paired retinal areas with a common

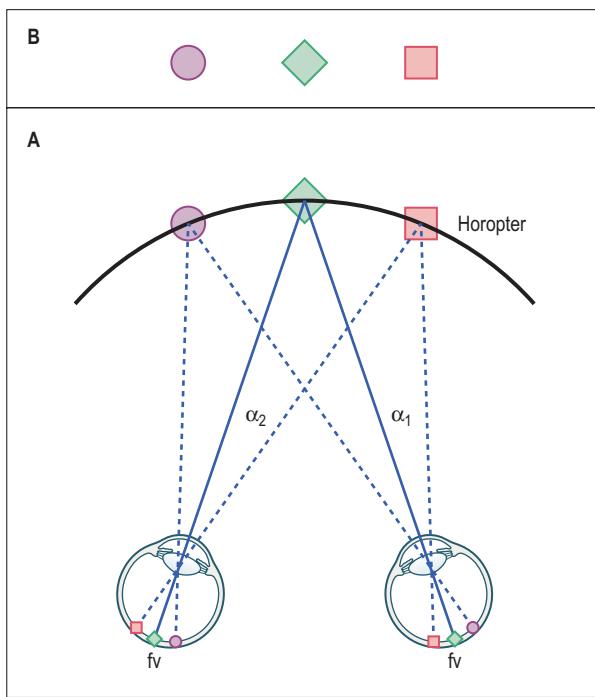

Figure 36.3 Corresponding retinal points. Retinal areas in the two eyes with identical oculocentric directions (panel B) are corresponding retinal points. The locations of objects along the horizontal meridian that are imaged on corresponding points (panel A) define the longitudinal horopter. The physical location of an object that is on the horopter is quantified by the longitudinal visual angles (α_1 & α_2).

visual direction for the two eyes, thus defining another set of corresponding retinal areas. Similarly, the circle in the left visual field represents a location of an object in the left visual field that is imaged on corresponding retinal points. For an infinite fixation distance, a large number of potential object locations are imaged on corresponding retinal points. These object locations in space that are imaged onto corresponding retinal points can be imagined to define a surface that resembles a cylinder with an infinite radius of curvature. This surface of points stimulates the perception of identical visual directions for the two eyes and is called the horopter.^{113,114,154} At finite viewing distances, the surface is reduced to a horizontal line and a vertical line that pass through the intersections of the lines of sight when the eyes fixate in symmetrical convergence.

Points in tertiary locations (elevated and displaced laterally from the lines of sight) are closer to one eye than to the other and subtend larger visual angles at the more proximal eye. As a result, all physical points in tertiary locations at finite viewing distances are imaged with vertical disparities and, by definition, their images do not fall on corresponding points.¹⁴⁹ At these finite viewing distances, only points imaged along the horizontal retinal meridian or along the vertical retinal meridian in the midsagittal plane can be formed on corresponding points without vertical disparities. The locations of object points that are imaged on corresponding points along horizontal meridians through the foveas define the longitudinal horopter,^{83,113} shown diagrammatically in Figure 36.3 by the arc passing through the fixated object and the two peripheral objects that stimulate

corresponding retinal points. A vertical horopter is defined by the location of object points in the midsagittal plane that are imaged on corresponding points along the vertical meridian.^{149,151,169}

The relationship between object and image space for the longitudinal horopter is quantified by longitudinal visual angles, defined as the horizontal visual angles subtended by the primary and secondary lines of sight for each eye. The longitudinal visual angles for an object in the right visual field are illustrated by angles α_1 and α_2 in Figure 36.3. Similarly, longitudinal visual angles can be defined for the object in the left visual field. The lateral separation of the eyes in the head results in each eye having a different perspective of objects not on the horopter, and these differences in perspective are used perceptually to reconstruct a three-dimensional space from the two-dimensional retinal images. The objects that are closer or farther than the horopter stimulate non-corresponding points, which is defined as a binocular disparity, retinal disparity, or simply, disparity¹⁷⁷ of the retinal images. The horizontal component of binocular disparity is the unique stimulus for stereoscopic depth perception and is quantified by the difference in the longitudinal visual angles, also called horizontal disparity angles.^{83,113,114,149} The horopter serves as a zero disparity reference from which the magnitudes of non-zero disparities are computed. In the absence of other depth cues, the curvature and slant of the horopter will influence the perceived shape and orientation of surfaces seen in depth. Optical devices such as spectacle lenses that magnify and distort one of the two eyes' retinal images will alter the horopter and produce predictable errors of space perception.¹¹⁴

The empirical longitudinal horopter illustrated in Figure 36.3 is a smooth surface that is symmetrical about the fixation point, but the actual shape and curvature of the empirical horopter will depend on physiological and optical factors that affect the retinal images and their cortical representations. If the locations of corresponding retinal areas simply were determined by equal angular distances from the primary line of sight, then the horopter would be a circle passing through the fixation point and the entrance pupil of each eye^{14,113} (geometric or theoretical horopter or Vieth-Muller circle) (Fig. 36.4). An analogy of "cover points" has been used to describe corresponding retinal locations determined by retinal distances.¹¹³ If the retina of one eye were to be translated and carefully aligned to cover the retina of the other eye, then a pin stuck into the retina would penetrate cover points, or corresponding retinal areas. Cover points, by simple geometry, would become corresponding points because the angles included by lines drawn from two points on the circumference of a circle to any other two points on the circle are equal. Consequently, the longitudinal visual angles will be equal ($\alpha_1 = \alpha_2$), and the theoretical horopter will be a section of a circle, specified as the Vieth-Muller circle (VMO), as illustrated in Figure 36.4.

Except for rare cases, the empirically defined horopter does not actually coincide with the Vieth-Muller circle, but the theoretical longitudinal horopter is an important reference for zero disparity; in fact, clinical tests of stereopsis use the Vieth-Muller circle as the zero disparity reference. Another important reference in physical space is the objective fronto-parallel plane (OFPP), which is the plane at the fixation distance that is parallel to a line passing through the entrance

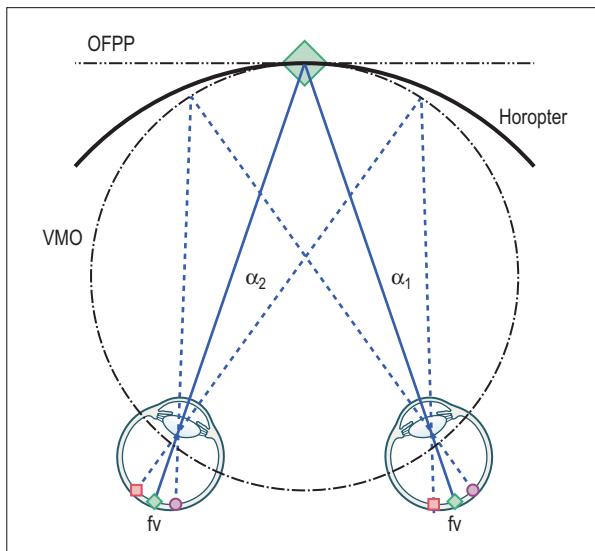

Figure 36.4 The empirical horopter (solid line) in relation to the Vieth-Muller circle (VMO; dot-dash line), defined by the locations of objects with equal longitudinal visual angles (α_1 & α_2), and the objective fronto-parallel plane (OFPP; dot-dot-dash line), defined by a plane at the fixation distance that is parallel to a line passing through the entrance pupils of the two eyes.

pupils of the two eyes (Fig. 36.4). Although, both the Vieth-Muller circle and the OFPP are used as reference surfaces to describe the empirical horopter, they are predicated on different perceptual correlates. The Vieth-Muller circle is based on a physical geometric assumption that identical visual directions are associated with retinal points that are equidistant from their respective foveas. The empirical longitudinal horopter, which is based primarily on identical visual directions, is the only pure measure of pairs of retinal corresponding points.¹⁵⁴ On the other hand, the OFPP, which is a measure of perceived surface shape and orientation, depends on egocentric directions derived by combining oculocentric directions and information about absolute distance and direction. The OFPP can be used as a frame of reference for adjusting the depth of objects at different retinal eccentricities so that the objects appear to lie in a flat plane parallel to the face (apparent fronto-parallel plane, or AFPP). The location, shape, and slant of the AFPP is based on disparity, azimuth cues, and absolute distance cues.³ The AFPP is used to evaluate how disparity is scaled by absolute distance and how slant is influenced by azimuth estimates to enable subjects to estimate the depth of surface shapes and orientations. Both the empirical longitudinal horopter and the AFPP are used to evaluate the influence of optical distortions, such as magnification, on perceived space, since they usually yield similar results.

The empirical longitudinal horopter and the AFPP can be measured in several ways, based on different properties of visual directions and stereoscopic depth.¹¹³ The empirical longitudinal horopter can be determined by identical visual directions for the two eyes; by the highest stereoacuity for points at various eccentricities from fixation; by the center of the sensory fusion range known as Panum's fusional area (see Fig. 36.7 below); and by object locations eccentric to fixation which result in a zero stimulus for disparity vergence. The vergence criterion assumes that horizontal version

movements guide the intersection of the visual axes along the empirical horopter, even if this surface is curved in depth. The AFPP horopter can be measured by positioning eccentric objects so that they all appear to lie in the same plane, or by positioning eccentric objects so that they appear to be equidistant from the observer (i.e. equidistant from the egocenter).

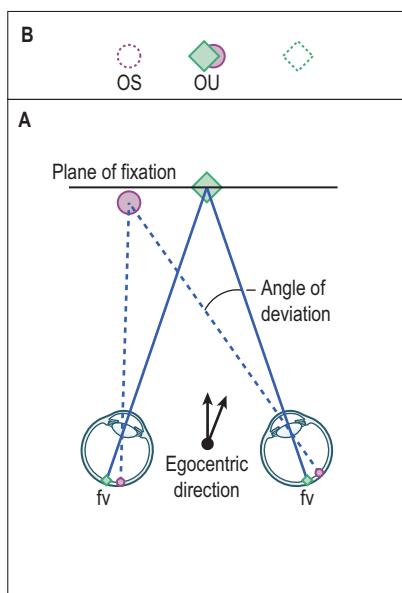

Abnormal retinal correspondence

The properties of corresponding retinal areas underlying normal binocular vision provide a stable sensory organization of the two eyes consistent with the functional properties of neurons in primary visual cortex^{123,157} that are present in infancy²⁷ (see Chapter 41). However, the normal sensory organization of binocular vision can be altered substantively in infantile strabismus by the development of anomalous retinal correspondence and/or suppression.¹⁷² Clinically, the type and extent of sensory adaptation is an important factor to be considered in treatments that are intended to reestablish functional binocular vision for a strabismic patient.^{87,122,166,172}

Sensory adaptations in strabismus are necessary to eliminate the constant diplopia (two egocentric directions for all objects) and common visual directions for fixated and non-fixated objects (visual confusion) that would otherwise prevail¹⁷² (Fig. 36.5A). Most strabismic patients do not experience diplopia and visual confusion, but their single vision is a result of suppression^{53,86} and/or anomalous retinal correspondence.^{2,4,18,25} Suppression causes the perception of objects normally visible to the deviating eye to be eliminated during simultaneous binocular viewing to provide single vision.¹⁷³ Suppression in some exotropes may involve an entire hemi-field,⁵⁸ but for esotropes the suppression is limited to a specific area (sometimes called a "suppression scotoma"), bounded by the fovea of the deviating eye and the area stimulated by the object that is fixated by the non-deviating eye⁸⁶ (the diplopia point; Fig. 36.5B).

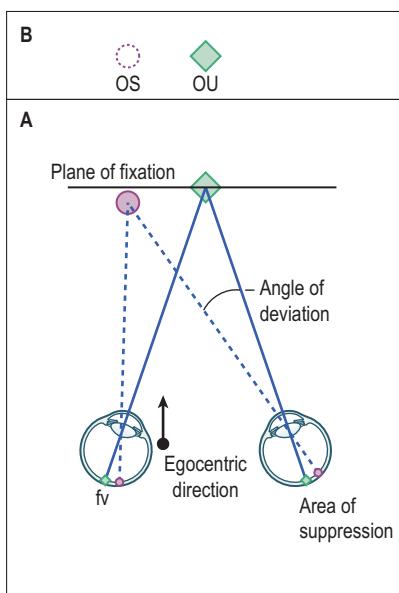

Anomalous retinal correspondence (Fig. 36.5C) is an adapted shift in the visual directions of the deviated eye relative to the normal visual directions of the fixating eye. The result is that, during binocular viewing, a peripheral retinal area of the deviating eye acquires a common visual direction to that of the fovea of the fixating eye.^{4,25,138,172} This shift in retinal correspondence produces a difference in the visual directions between the two eyes for foveally imaged objects, which can be sometimes demonstrated clinically with the Hering-Bielschowsky test for anomalous correspondence.¹⁷² For this test, after-images are formed on the foveas of both eyes. Even with an interocular deviation from strabismus, a patient with normal correspondence will perceive the after-images in a common direction, but a patient with deep anomalous retinal correspondence will perceive the after-images in different visual directions. The subjective separation of the monocular after-images is referred to as the angle of anomaly, which represents the magnitude of the perceptual shift from the normal corresponding relationship between the two foveas. When the magnitude of the angle of anomaly is equal to the magnitude of the oculomotor misalignment (harmonious anomalous retinal correspondence), then objects in space can appear single even though

Normal retinal correspondence

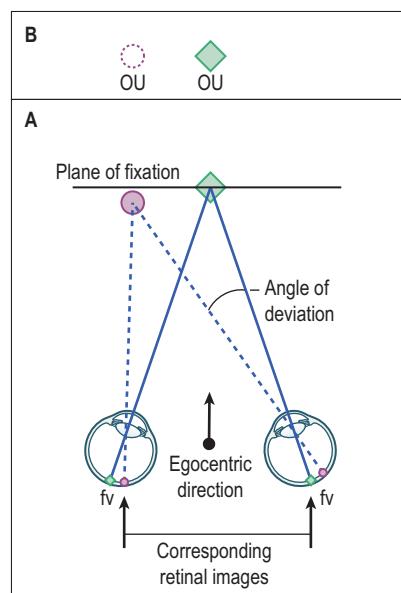

(A)

Suppression

(B)

Anomalous retinal correspondence

(C)

Figure 36.5 Retinal correspondence and suppression in strabismus. **(A)** A strabismic patient with normal retinal correspondence and without suppression would have diplopia, two egocentric directions of single objects (represented by solid and dashed images in panel B) and visual confusion, a common visual direction for two separate objects (represented by the superimposition of the images of the fixated diamond and the circle, which is imaged on the fovea of the deviating eye in panel B). **(B)** The elimination of diplopia and confusion by suppression of the retinal image of the deviating eye. **(C)** The elimination of diplopia and confusion by anomalous retinal correspondence, an adaptation of visual directions of the deviated eye.

one of the eyes is deviated. On the other hand, when the angle of anomaly is not equal to the angle of strabismic deviation (unharmonious anomalous retinal correspondence), the residual disparity will cause diplopia unless suppression is also present. The angular separation of the diplopic images is referred to as the subjective angle and in unharmonious anomalous retinal correspondence the subjective angle is usually smaller than the angle of strabismus (objective angle).

As illustrated by the data for a patient with infantile esotropia (Box 36.1) tests for the sensory adaptations of a strabismic patient are variable^{68,87,121,166,170} and generally the diagnosis of anomalous retinal correspondence for a given strabismic patient is test dependent.⁴⁸ Tests for anomalous retinal correspondence either locate the extra-foveal point in the deviating eye that has the same visual direction as fovea in the fixating eye, or quantify the angular separation of the visual directions of the foveas of the two eyes.¹⁷² Tests in the former category, e.g. Bagolini striated lenses or the Worth four-dot test, have a higher probability of being positive for anomalous retinal correspondence than tests in the latter category, such as the Hering-Beilschowsky after-image procedure.⁴⁸ The dependence of the state of a patient's retinal correspondence on the clinical procedure may be the result of variation in the angle of anomaly across the retina^{42,138} or some other property of the mechanisms underlying anomalous retinal correspondence.^{91,138,166,184} However, the practical consequence is illustrated by the patient with infantile esotropia (Box 36.1) who demonstrated harmonious anomalous retinal correspondence with the Bagolini striated lens test and normal retinal correspondence with the major amblyoscope and after-image tests.

Box 36.1 Infantile esotropia with anomalous retinal correspondence

- College student, 26 years old
- Infantile strabismus
- Prior treatment
Surgery at age 2 years
Patching ages 2–4 years
Surgery at age 8 years
- Cover test: Constant, unilateral, right eye esotropia
Distance: 20^A ET
Near: 18^A ET
- Refractive errors and BVAs
OD: +2.00 –2.00 × 180 20/20
OS: +1.00 –0.5 × 180 20/20
- Lateral heterophoria: constant suppression of OD
- Bagolini striated lens test: Lines intersect at the fixation point – harmonious anomalous retinal correspondence.
- Amblyoscope: Equal objective and subjective angles – normal retinal correspondence.
- Hering-Beilschowsky afterimage test: Images intersect at the fixation point – normal retinal correspondence.
- Stereopsis with two-pencil test: Better accuracy with both eyes viewing.

Comment: The patient has a constant, unilateral esotropia without amblyopia. He demonstrates harmonious anomalous retinal correspondence under the fovea-to-extrafovea testing conditions of the Bagolini test and normal retinal correspondence with the more dissociating tests (amblyoscope) or the test that evaluates fovea-to-fovea correspondence (after-image test).

Three main theories on anomalous retinal correspondence have been proposed.¹³⁸ The first theory states that, with anomalous correspondence the two eyes perceive space independently, much like the two hands explore space. Each eye computes egocentric visual direction from its own sense of eye position and oculocentric retinal image location. In effect, there is a lack of correspondence.^{23,168} The observation that the separation between foveal afterimages changes during spontaneous changes in the magnitude of the angle of strabismus supports this theory. This co-variation between the angle of anomaly and objective angle of strabismus results in a stable percept of space, even though the magnitude of the strabismus is unstable and varies in time.⁶⁶ The second theory proposes that there is a shift in retinal correspondence^{18,34,172} so that retinal points that are normally disparate are shifted to acquire an anomalous coupling in the striate cortex,^{91,184} e.g. the fovea of the fixating eye is anomalously coupled with a peripheral area of the deviating eye. Measures of the identical visual directions horopter in strabismics reveal that correspondence is mainly shifted in the periphery, and the angle of anomaly decreases near the fovea in the region of space that lies between the visual axes that is projected to opposite cortical hemispheres.^{20,47,68} The third theory proposes that strabismics who have no suppression are able to perceive space singly due to enlarged Panum's fusional areas.^{2,5,77} These three theories are not mutually exclusive and all of them can be expressed to some degree in the same strabismic patient, or different mechanisms may be present in different forms of strabismus, e.g. primary versus secondary microstrabismus.

Binocular (retinal) disparity

The empirical longitudinal horopter represents the specific locations of objects in physical space that have zero retinal image disparity. Objects not located on the horopter will have some amount of lateral binocular (retinal) disparity. With horizontal retinal disparity, an object is imaged on laterally separated non-corresponding retinal areas and, as the case for the empirical horopter, the longitudinal visual angles are not equal. Horizontal retinal disparity is a unique binocular stimulus for stereoscopic depth perception, horizontal disparity vergence eye movements, and diplopia, either physiological or pathological. In each case, the perceptual or motor response is a consequence of the relationship between the object's disparate images and the horopter.

The following relationships concerning binocular disparities are important to the understanding of binocular vision.

1. Binocular disparities are classified as uncrossed (distal) or crossed (proximal), based on the relationship between the disparate object and the horopter,^{83,177} as illustrated in Figure 36.6. For example, the square in the right visual field represents an object that is farther than the fixation point (represented by the diamond), and the secondary lines of sight for the square intersect behind the horopter. The binocular disparity produced by the square is classified as uncrossed and quantified by the difference between the longitudinal visual angles α_1 and α_2 . Perceptually, uncrossed disparities give rise to a sense of relative "far" stereoscopic depth or, if the disparity is large, to uncrossed diplopia (i.e. double vision with the right eye's image seen to the left side

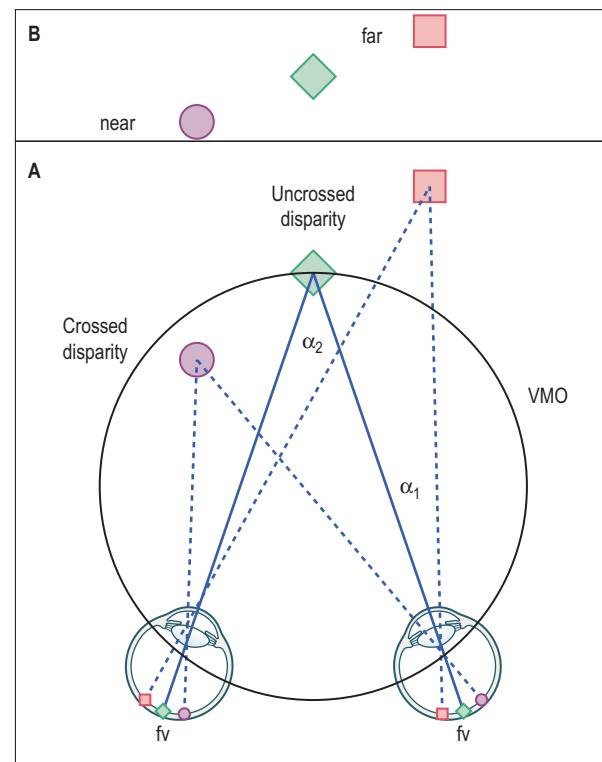

Figure 36.6 Binocular disparity and the perception of stereoscopic depth. Objects that are not located on the longitudinal horopter have binocular disparity, which may be crossed disparity (circle in panel A) and be perceived as nearer than the fixated object (the relative depth of the circle with respect to the diamond in panel B) or uncrossed disparity (square in panel A) and be perceived as farther than the fixated reference object (panel B).

of the left eye's image). As oculomotor stimuli, uncrossed disparities evoke divergence eye movements. By a parallel classification, crossed disparities (illustrated by the circle in the left field, Fig. 36.6) give rise to a perception of "near" stereoscopic depth or crossed diplopia and elicit convergence eye movements.

2. Binocular disparities are classified as either relative or absolute.^{31,177} The absolute disparity of a target is the difference between the angle subtended by the target at the two entrance pupils of the eyes and the angle of convergence. A relative disparity is defined as the difference between two absolute disparities. Stereoscopic depth normally arises from discriminating relative disparities, wherein judgments are based on the perception of the depth of one object relative to another (e.g. the relative depth of the square with respect to the diamond, Fig. 36.6). Stereopsis with relative disparities, as measured by clinical testing, is quite fine compared to the perception of depth based solely on absolute disparities.¹⁷² In contrast, an absolute disparity is the optimal stimulus for motor fusion, such as occurs with prism-induced disparity vergence or with changes in fixation distances, which change disparity of all objects in the visual field by a constant amount.⁸⁹

3. For a person with normal binocular vision, there is a finite range of binocular disparities that provides a clear perception of relative depth with normal fusion (haphlopa), and larger disparities produce diplopia.^{109,113} The disparity range for single vision, called Panum's fusional area (PFA),

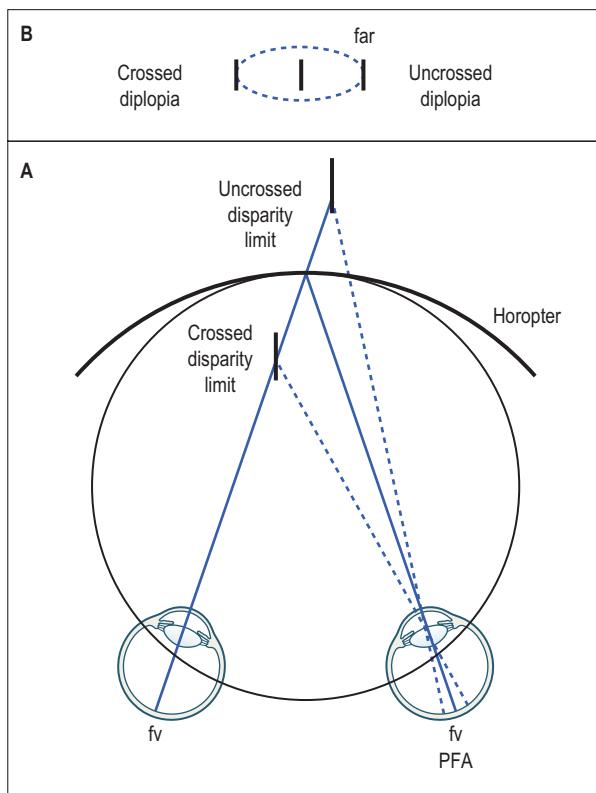

Figure 36.7 The binocular disparity range for single binocular vision (Panum's fusional area). With constant fixation, an object is moved along the primary line of sight of the left eye until the binocular disparity of the right eye's image exceeds the fusion limit, i.e. appears diplopic, first with crossed disparity and then with uncrossed disparity (A). The dimensions of Panum's fusional area (PFA) are illustrated in panel B.

is illustrated in [Figure 36.7](#). Panel A of the figure illustrates the measurement of Panum's area. A test object is moved along the primary line of sight of the left eye while the two eyes maintain binocular fixation at one point in space. The crossed disparity limit for fusion is the greatest distance that the test-object can be moved toward the subject before it appears diplopic. Similarly, the object can be moved away from the subject to establish an uncrossed disparity limit for fusion. Thus, in subjective space (panel B) Panum's fusional area (illustrated by the dashed oval) defines the disparity range for fused binocular vision, and objects subtending disparities outside this range will be diplopic unless one ocular image is suppressed. When the target is intersected by the primary line of sight of the left eye, the disparate image of the near target seen by the right eye is projected to the left visual field in crossed diplopia and the image of the far target is projected to the right visual field in uncrossed diplopia. In addition, there is also a vertical disparity range that is compatible with binocular sensory fusion, although it is generally smaller than the horizontal disparity range. Although the size and shape of PFAs depend on retinal eccentricity and spatio-temporal stimulus properties,^{146,165} the classical PFA for foveal vision is an oval with approximate horizontal and vertical dimensions of 15 × 6 arcmin.¹¹³

4. Most individuals with normal binocular vision will have small vergence errors known as fixation disparities.^{76,116,137} Because the retinal images only need to fall within Panum's fusional areas for single binocular vision to

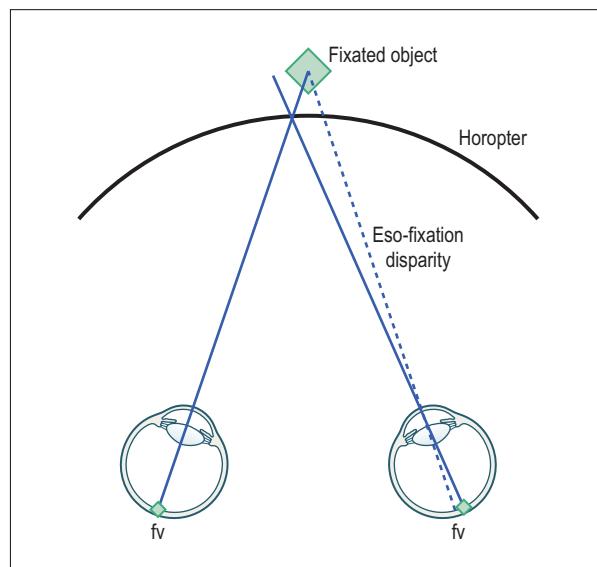

Figure 36.8 The displacement of the horopter with an eso-fixation disparity. Vergence errors cause a displacement of the horopter from the fixation point and retinal disparity of the fixated object. Single binocular vision will be maintained if the vergence error is smaller than Panum's fusional area (fixation disparity).

occur, a small residual misalignment of the visual axes (vergence error) can occur, resulting in a retinal disparity of a fixated object, i.e. a fixation disparity, without causing diplopia. This fixation disparity between the fixated object and the intersection of the primary lines of sight displaces the longitudinal horopter from the fixated object. An example illustrated in [Figure 36.8](#) shows a small convergence error (eso-fixation disparity) for the object of fixation (diamond). The convergence error causes an inward shift of the horopter, (the locations of normal corresponding points), i.e. in normal binocular vision, identical primary visual directions result from bifoveal stimulation and, therefore, the horopter always passes through the intersection of the visual axes. Consequently, the fixated object lies beyond the horopter and, by definition, has an uncrossed retinal disparity, described clinically as an eso-fixation disparity. Conversely, an exo-fixation disparity causes a displacement of the horopter beyond the fixation distance, and crossed disparity of the fixated object. In any case, the magnitude of a fixation disparity cannot be larger than the width of Panum's fusional area if the patient is to retain single binocular vision.

5. Clinically, fixation disparities have been considered a sign of stress on fusional vergence mechanisms.^{116,117,120} The clinical tests are based on the coincidence of the primary line of sight and the principal visual direction with normal retinal correspondence (see [Fig. 36.8](#)) and, therefore, the angular separation between dichoptic objects with a common visual direction is a measure of the convergence error (fixation disparity) at the given fixation distance. The assumption that clinically significant fixation disparity is caused by oculomotor stress is generally based on Ogle's extensive investigations of fixation disparity – forced vergence functions, which demonstrated systematic changes in the direction and magnitude of fixation disparity with variation in the magnitude of the stimulus for disparity vergence (see [Chapter 9](#)).^{116,117} Three examples of fixation disparity –

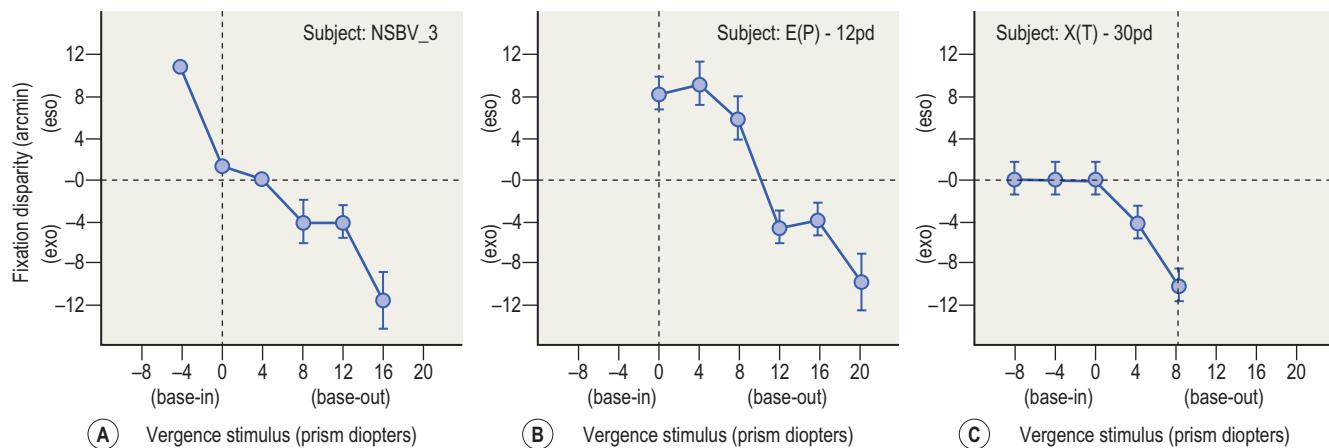

Figure 36.9 Fixation disparity as a function of prism-induced disparity vergence. The fixation disparity (defined in Fig. 36.8) changes systematically with the magnitude of the disparity vergence stimulus. The prismatic power that eliminates the fixation disparity, i.e. where the function crosses the abscissa, is defined as the associated phoria. The functions represent data for a patient with normal binocular vision (A), and patients with esophoria (B) or exophoria (C).

forced vergence functions are presented in Figure 36.9. These data were obtained using subjective alignment of dichoptic nonius lines, i.e., alignment of two stimuli, one seen by each eye, to define corresponding retinal locations while the subject viewed a binocular fusion stimulus. The separate functions represent data for a patient with clinically normal binocular vision (Fig. 36.9A), a patient with esophoria (Fig. 36.9B), and a patient with an intermittent exotropia (Fig. 36.9C). The functions show that fixation disparities occur when a large fusional vergence component is required to correct a vergence error such as a heterophoria. The amount of base-out prism needed to eliminate the vergence effort is determined from the prismatic power at which the fixation disparity was zero. This occurs when the forced vergence function crosses the abscissa (i.e. the “associated” phoria).^{116,120} An example of the clinical application of these concepts is illustrated by the patient with asthenopia and esophoria with a base-out associated phoria for near-vision tasks that is presented in Box 36.2. The fixation disparity can be a useful error with significant heterophorias because it provides a steady state stimulus to overcome the heterophoria and maintain ocular alignment with fusion.¹³⁷ When large vergence responses are needed to overcome phoria they may be associated with asthenopia.¹²⁰

In summary, broad ranges of binocular disparities are present under all conditions of normal seeing and the utilization of disparity information by the visual sensory and motor systems is the most fundamental process of normal binocular vision. The clinical evaluation of a patient’s binocular vision includes tests of several aspects of retinal disparity, including relative disparities by measures of stereoacluity, absolute retinal disparities by measures of disparity-induced vergence eye movements, and fixation disparities.^{137,123}

Stereopsis

Stereopsis is the perception of relative distance, or the depth separation, between objects that occurs as a result of neural

Comment: The patient’s asthenopia could be the result of astigmatism or oculomotor imbalance from an eso-fixation disparity caused by esophoria.

processing of the relative horizontal binocular disparities between the monocular retinal images. Binocular disparities are present because the lateral separation of the eyes in the head provides each eye with a slightly disparate view of a given object. Thus, as demonstrated by the seminal research of Wheatstone¹⁸⁰ and Julesz,⁹⁰ these horizontal (lateral) retinal image disparities produce stereoscopic depth. By themselves, vertical disparities do not result in depth perception; however, they are used to estimate azimuth and absolute distance in order to scale horizontal disparities into stereo-depth magnitudes.^{3,53,57,99,132,178}

Clinical measures of the smallest detectable stereoscopic depth (stereoacuties) are quantified by a stereo-angle (η) that is equal to the difference in the longitudinal visual angles (α_1 and α_2), or the parallax (convergence) angles (δ_1

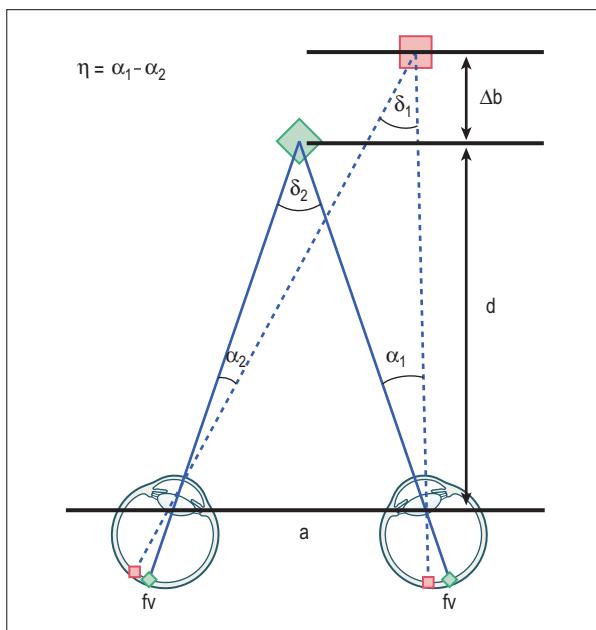

Figure 36.10 The quantification of binocular disparity. The binocular disparity (η) of an object (represented by the square), with respect to a fixated object (diamond) is equal to the difference in the longitudinal visual angles (α_1 & α_2) or the parallax angles (δ_1 & δ_2). The magnitude of binocular disparity is dependent on the fixation distance (d), the depth interval (Δb), and the interpupillary distance (a), see text for details.

and δ_2), as illustrated in Figure 36.10. For a conventional stereogram (see Fig. 36.14), η can be derived directly from the angular differences in positions of common objects in the two half-views of the stereogram. The retinal disparity associated with the physical depth of an object in normal vision (illustrated in Fig. 36.10) can be determined by the relationship:

$$\eta = [(a * \Delta b) / d^2] * c$$

where a is the interpupillary distance, Δb is the depth interval that is equal to the distance between the disparate object and the viewing distance, d is the viewing distance, and c is a constant to obtain the stereo-angle in dimensions of arcmin ($c = 3,438$) or arcsec ($c = 206,264$). The function shows that, for any given fixation distance, the relationship between depth interval and retinal disparity is linear, but the relationship varies across fixation distances by the square of the distance. For example, if an individual with a 60 mm PD can perceive stereoscopic depth from a retinal disparity of 10 arcsec, a depth difference of 0.12 mm can be discriminated at a 40 cm viewing distance. However, the same stereo-angle requires a 3 cm depth difference at 6 m, or an 800 m depth difference at a 1000 m viewing distance. The relationships between binocular disparities, linear depth, and observation distance for larger, suprathreshold disparities, are illustrated in Figure 36.11.

To maintain a valid perceptual constancy between depth and disparity, the relationship between stereo-angles and viewing distances requires an observer to scale the horizontal disparity with viewing distance. Perceptual information about viewing distance may be interpreted from the vertical disparity gradients that occur naturally in tertiary directions

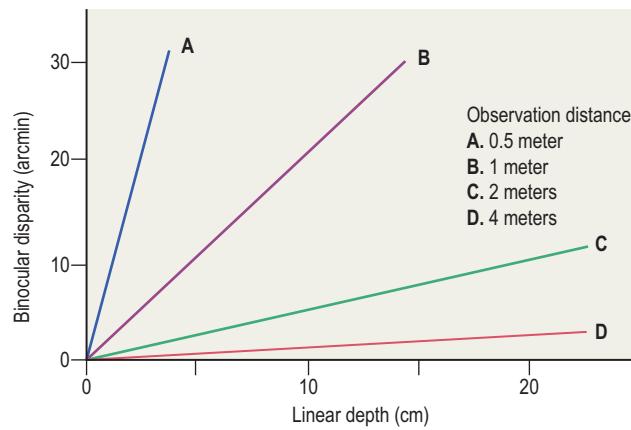

Figure 36.11 The relationship between binocular disparity and linear depth for four fixation distances. The disparity-depth relationship is linear for any constant fixation distance, but non-linear across fixation distances.

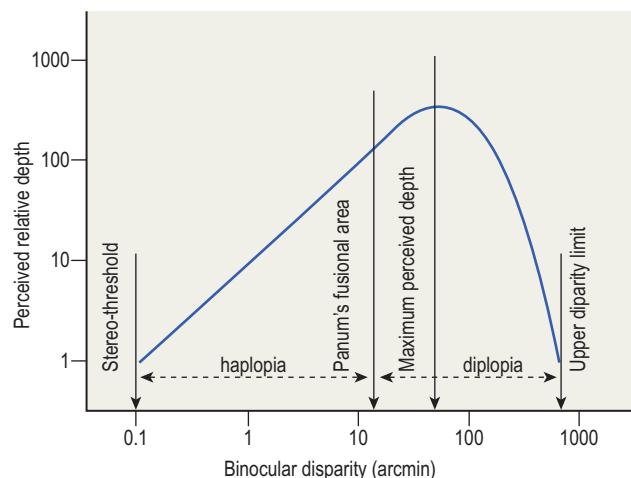

Figure 36.12 The relationship between perceived depth and binocular disparity for disparities from the lower to the upper limits of stereoscopic depth perception (modified from Tyler 1983¹⁶⁵).

of gaze, in which a nearby target subtends a larger visual angle vertically in one eye than in the other.^{53,57,99,132,149,178} If the target is elevated above the visual plane, it has a vertical disparity that increases with horizontal eccentricity and inversely with viewing distance. Other sources of perceptual information about viewing distance include the convergence angle,^{24,49} retinal cues, such as oblique disparities,¹⁷⁸ and non-stereoscopic or perspective cues.⁶⁰

Quantitative and qualitative stereopsis

The perception of stereoscopic depth at a constant viewing distance increases with disparity over a relatively large range.^{28,80,112,143,148,165} The relationship between perceived depth and disparity from the lower (D_{\min}) to upper (D_{\max}) limits of stereoscopic vision is illustrated by Figure 36.12. A perception of relative depth cannot be detected from disparities below the stereo-threshold (D_{\min}), but the relationship becomes proportional (quantitative stereopsis) for disparities larger than the stereo-threshold.^{28,165} Objects with larger disparities appear in increasing depth even beyond the limit of fusion (Panum's fusional limit), and the maximum

perceived stereoscopic depth occurs when the stimulus is clearly diplopic. With larger binocular disparities (qualitative stereopsis) the perception of depth decreases to the upper limit of stereopsis where the relative depth of diplopic objects can no longer be resolved. Qualitative depth has a direction, or sign, but a vague amplitude.¹¹²

The specific parameters of the depth-disparity relationship will depend on the spatial and temporal properties of the stimulus,²⁸ as well as on other non-stereoscopic factors. Binocular disparities above the stereothreshold produce a vivid quantitative sense of depth and a strong impression of solid three-dimensional structure, but the disparity threshold for the perception of depth is altered by various changes in stimulus parameters, such as contrast,^{67,96,142} spatial frequency,^{73,80,96,147,148} and viewing duration.^{71,118,150} For example, while depth in a stereogram may be perceived with just a spark of illumination,¹¹⁸ the stereo-depth detection threshold decreases with exposure duration for both line^{118,150} and random dot patterns.^{69,71} Quantitative stereopsis responds to stimuli that appear fused, the magnitude of perceived depth increases with disparity magnitude up to about 1 degree,²⁸ and the depth percept improves with exposure duration up to a critical duration where the stereo-threshold is independent of duration.^{50,69} A qualitative sense of stereo-depth can be seen with even larger disparities, but the magnitude of its range is difficult to specify, i.e. a range of qualitative stereopsis with disparities as large as 10 degrees.^{50,112}

In addition to the disparity range, qualitative stereopsis and quantitative stereopsis differ in two important ways. Quantitative depth perception improves with exposure duration,¹¹⁸ while qualitative depth perception is optimal with briefly presented stimuli and fades with exposures longer than 0.5 sec.⁹⁵ Thus, these two forms of stereopsis can also be classified as sustained-quantitative and transient-qualitative. Additionally, the two forms of stereopsis can be distinguished by the spatial aspects of their stimuli,^{39,140} especially by the similarity between the stimuli for both eyes that is required for quantitative, but not for qualitative, stereopsis.¹²⁴ Qualitative stereopsis arises from briefly presented stimuli even when a difference in size, shape, and/or contrast polarity exists between the two eyes.^{39,79,124,140} Transient-qualitative stereopsis is a useful alerting percept for the approximate location of objects that appear suddenly, and it is also a stimulus to initiate vergence alignment of the eyes to transient changes in both small and large retinal disparities.³⁹ Quantitative stereopsis, on the other hand, is keenly useful for judging the shape, depth, and orientation of continuously viewed features near the plane of fixation.

The stereoscopic appreciation of either quantitative or qualitative depth is not merely a function of relative retinal disparity. As indicated by the equation for computing retinal image disparity (η), the linear depth interval (Δb) depends on both disparity and viewing distance (d). The equation illustrates that retinal image disparity is scaled by absolute distance to yield stereo-depth magnitude in linear units. The magnitude of relative depth and the degree of surface curvature (depth ordering) stimulated by retinal disparity both depend on viewing distance and a zero disparity surface can have many different shapes. Because the empirical longitudinal horopter is flatter than the theoretical Vieth-Muller circle, its curvature decreases (becomes less concave or more

convex than the Vieth-Muller circle) with increasing viewing distance¹¹³ (Fig. 36.3). Even a horopter that follows the Vieth-Muller circle changes curvature with viewing distance and approaches a flat surface at an infinite viewing distance. Nevertheless, flat surfaces appear flat at all viewing distances and, thus, without viewing distance information, the pattern of retinal image disparities across the visual field is insufficient to sense either depth ordering (surface curvature) or depth magnitude.⁵³ Similarly, a given pattern of horizontal disparities can correspond to different slants about a vertical axis presented at various horizontal gaze eccentricities (i.e. azimuth).¹¹³ Convergence distance and direction of gaze are important pieces of information used to interpret slant from the disparity fields associated with slanting surfaces.³

Clinical anomalies of both quantitative and qualitative stereopsis have been identified. Patients with strabismus or binocular dysfunction demonstrate elevated thresholds for quantitative stereopsis, even when their eyes are aligned by optical or surgical procedures.^{12,13,121,166} However, if any residual stereopsis is present, once disparity exceeds the elevated threshold, it stimulates depth perception to the normal upper disparity limit for quantitative stereopsis^{139,174} with normal qualitative stereopsis at large disparities.³⁷ Interestingly, a normal range for sensory fusion, or Panum's fusional areas, can also accompany a total loss of stereopsis¹⁴⁶ but, for strabismic patients with a loss of binocular sensory fusion, stereopsis invariably is lost.¹⁷² For these individuals, binocular images appear to wash over one another, with no binocular binding of aligned images. Their vergence is unstable, and their eyes continually shift their fixation disparity.

Non-strabismic individuals may have sub-clinical anomalies of stereopsis, as demonstrated by directional biases in their ability to sense transient-qualitative depth from large (>1 deg) crossed and uncrossed disparities. Subjects with these sub-clinical anomalies generally discriminate the direction of depth better for flashed near objects than for flashed far objects. In subjects with severe stereoanomalies, transient-qualitative stereo-depth perception with one or both signs of disparity may be absent.^{128,129} Non-strabismic individuals who have a stereoanomaly can have normal quantitative stereopsis.^{28,88} The selective loss of transient disparity in one direction suggests that the disparity-detecting neurons are grouped into different pools tuned to broad ranges of crossed and uncrossed disparity, and sensitivity to one direction of disparity may be reduced or lost without affecting the other. A related motor anomaly of transient vergence has been found in patients with a stereoanomaly, who exhibit a marked reduction or absence of either convergence or divergence responses to large, briefly presented disparities.^{39,88}

Stereoacuity

Stereoacuity is one of the qualitative aspects of binocular vision commonly evaluated during clinical vision testing. It is the smallest relative binocular disparity stimulus for depth that can be detected (Fig. 36.13). The binocular disparity angles for depth detection normally are smaller than the resolution angles for visual acuity, even for unpracticed clinical patients, and are typically less than 30 arcsec. In practice, the terminology for visual acuity is maintained for

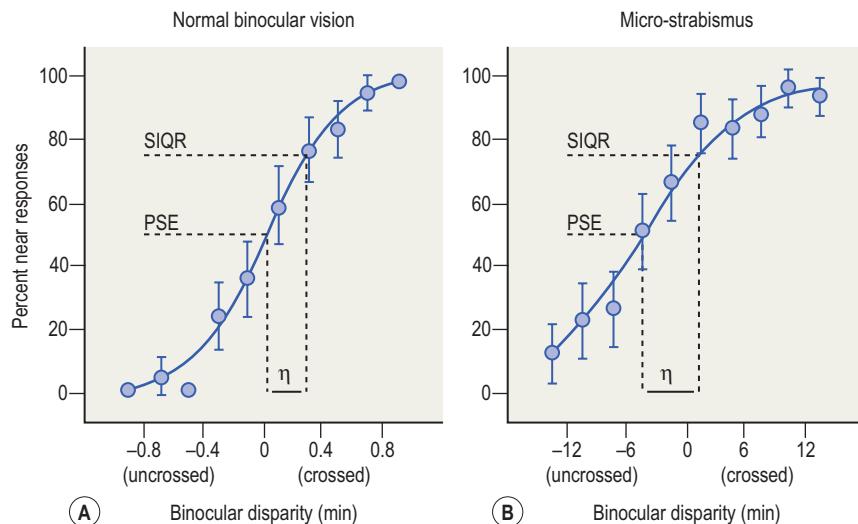

Figure 36.13 Psychometric functions for depth discrimination for: (A) an observer with normal binocular vision and (B) an observer with deficient stereopsis from micro-strabismus. The percentages of responses that a test stimulus appeared to be nearer than the reference stimulus are plotted as a function of the sign (negative values for uncrossed disparities and positive values for crossed disparities) and magnitude of disparity. The subjects' stereoacuities (η) are defined by the disparity range between the point of subject equality (PSE) and the semi-intraquartile range (SIQR) (adapted from Harwerth et al 2003⁶⁸).

stereopsis. A patient's stereo performance is specified as a stereoacuity (disparity sensitivity), rather than stereothreshold. While the true definition of stereoacuity is the reciprocal of the stereothreshold, stereoacuities are usually specified by arcsec of disparity at threshold and, by usage, the terms stereothreshold and stereoacuity have become clinically interchangeable.

Normal stereoscopic vision is experience-dependent and requires normal binocular visual experience over a period of early childhood (see Chapter 38). However, even after the early period of development, clinical testing of stereopsis is important to detect binocular abnormalities in children or adults, and most of the clinical tests are designed as screening tools for distinguishing normal from abnormal (e.g. stereoblindness, microstrabismus, or monofixation) binocular vision. The stereo threshold of a normal observer¹⁷⁷ is usually lower than the smallest disparity presented by most clinical tests, which employ a limited number of stimuli with relatively large disparity increments. Improving the accuracy of clinical stereopsis tests would require a greater number of stimuli with smaller disparity increments, without necessarily improving the detection rate for abnormal binocular vision. Nevertheless, it is an important concept that for any given patient, the relationship between stereoscopic depth perception and binocular disparity is probabilistic over a range of disparity values, as shown by the psychometric function (Fig. 36.13) for the detection or discrimination of stereoscopic depth.

Consider a stereopsis test in which a test stimulus, with variable disparity direction and magnitude, is located below a zero-disparity reference stimulus.⁷⁵ The test stimulus is presented to the observer many times, changing the direction and magnitude of the disparity between presentations, or trials. For each trial, the observer judges the relative direction of depth of the test stimulus with respect to the reference stimulus. When the trials are completed, the percentages of near responses are plotted as a function of disparity magnitude and sign (direction) of the test stimulus (Fig. 36.13). In the range of probabilistic performance, the discrimination of near stereoscopic depth with respect to a reference stimulus of zero disparity systematically improves as the sign of

the disparity becomes appropriate for near (i.e. crossed) and as the magnitude of the binocular disparity increases. The disparity between the test and reference stimuli for which the percent "near" responses equals 50 percent denotes the point of subjective equality (PSE) in the depth of the test and reference stimuli. The observer's PSE represents a disparity bias, or constant error, at the specific retinal eccentricity tested. Since this disparity (the PSE) is perceived as having zero depth difference from the reference stimulus, the PSE is, by definition, a point on the longitudinal horopter. The slope of the psychometric function represents the variability of the stereo depth percept and the corresponding stereothreshold. The binocular disparity required to achieve depth discrimination with a given level of accuracy (typically 75 percent) defines the observer's stereothreshold. Operationally, the stereothreshold (η) is quantified by the semi-intraquartile range (SIQR) of the psychometric function, i.e. by the range of disparities from the PSE to the disparity that gives a "near" response rate of 75 percent.

The fundamental differences between normal and reduced stereoacuities are illustrated in Figure 36.13 by comparison of the psychometric functions for a subject with normal binocular vision and a patient with primary microstrabismus.⁶⁸ The subject with normal binocular vision (Fig. 36.13A) had nearly perfect (100 percent) depth discrimination for binocular disparities of 0.6 arcmin, either uncrossed or crossed. Chance performance (PSE) occurred at zero disparity, indicating that the horopter was located at the fixation point, and the stereothreshold (η) determined from the SIQR was 12 arcsec. The performance of the microstrabismic subject, whose clinical data are presented in Box 36.3, is illustrated by Figure 36.13B. The psychometric function was similar in showing a systematic relationship between discrimination and disparity, although the range of binocular disparities required was fifteen times larger. The PSE for the microstrabismic subject was 4.5 arcmin of uncrossed disparity and the stereothreshold was greater than 320 arcsec. This example shows that accurate measurements of stereoacuities for patients with abnormal binocular vision, such as microstrabismus (Box 36.3) require the use of a different range and larger increments of binocular disparities than needed

Box 36.3 Reduced stereoacuity associated with primary microstrabismus

- College student, diagnosed at age 22 years of age
- No surgery or orthoptic treatment
- Cover test: Constant, esotropia with alternating fixation
Distance: 8^A ET
Near: 6^A ET
- Refractive errors and VAs:
OD: Non-significant 20/20
OS: Non-Significant 20/20
- Lateral heterophoria at distance with Maddox Rod – normal retinal correspondence.
- Bagolini striated lens test: at near. Lines intersect at the fixation point – harmonious anomalous retinal correspondence.
- No stereopsis with the StereoOptical circles test.
- Reduced stereoacuity (304 arcsec) with psychophysical testing (see Fig. 36.13B).

Comment: The patient has primary microstrabismus with central harmonious retinal correspondence and reduced stereoacuity, but with normal peripheral retinal correspondence and disparity vergence oculomotor responses (see Harwerth et al 2003⁶⁸ for details).

for normal stereoacuity, but otherwise the psychophysical data are similar. While most clinical tests cover a sufficient range of disparities for evaluating both normal and abnormal subjects, the disparity increments are too large for accurately measuring normal stereothresholds and, thus, an individual's clinical performance is compared to expected suprathreshold performance levels for patients with normal binocular vision. For the primary purpose of screening for abnormal binocular vision, determining that a patient's stereoacuity is at an expected level of performance is sufficient to demonstrate that their sensory and motor processes are compatible with normal binocular vision.

Stereopsis is not usually evaluated with real-depth stimuli, but rather most clinical tests of stereopsis utilize stereograms with either contour-defined or disparity-defined forms (examples of the two forms of stereograms are shown in Figure 36.14) and most individuals with normal binocular vision can observe the relative depth in the stereograms with "free fusion" either by over-convergence (crossed-eye viewing) or under-convergence (straight-eye viewing), but it should be noted that the two viewing strategies produce opposite directions of relative depth. These two configurations of stereograms are often distinguished as being tests of local vs. global stereopsis,¹⁶⁵ and each has some desirable attributes for clinical evaluations. For example, stereograms that test local stereopsis use high-contrast test figures having unambiguous relative disparities that can be detected by all patients with normal binocular vision, and even by some patients with micro-strabismus or monofixation.^{13,29,121,172} Thus, contour-defined stereograms provide valuable information for differentiating between normal and subnormal binocular vision. However, this form of stereogram unavoidably contains monocular cues that are discernable in targets having large disparities. These monocular cues could allow discrimination of disparate stimuli based on non-stereoscopic

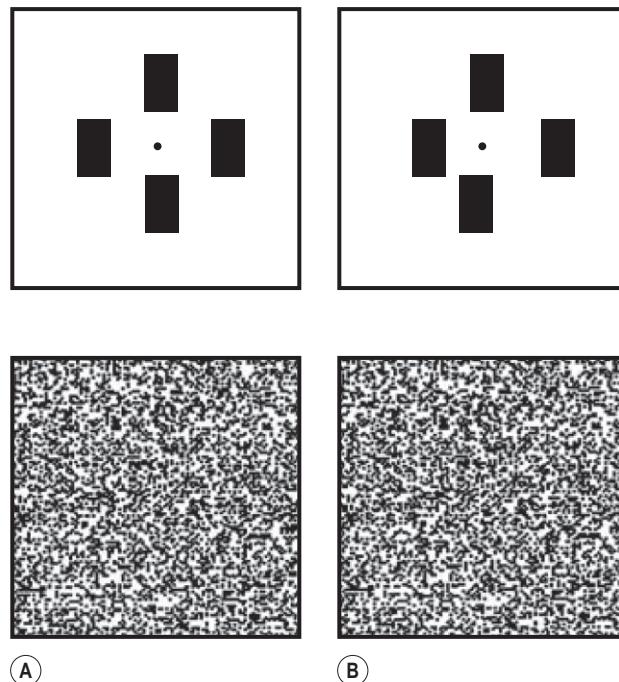

Figure 36.14 Examples of stereograms with contour-defined objects (local stereopsis) or disparity-defined objects (global stereopsis or cyclopean perception). The disparity patterns in the contour and random-dot stereograms are identical in size and disparity magnitude. Most individuals with normal binocular vision can learn to free-fuse the stereograms by either over-convergence or under-convergence and observe the stereoscopic depth in each example. However, it should be noted that the two viewing strategies produce opposite directions of relative depth.

information. Such non-stereoscopic cues are illustrated by the stereogram in Figure 36.14A. When properly fused, the contours in this stereogram provide clear stereoscopic depth appreciation from both crossed and uncrossed binocular disparities, but the relative differences in the positions of the stimuli are apparent without fusion or stereopsis.

The design of the random dot stereogram, which tests global stereopsis, or cyclopean perception,⁹⁰ eliminates almost all non-stereoscopic cues. Figure 36.14B is a random-dot stereogram of the same stimulus pattern as the contour stereogram in Figure 36.14A. Even though the locations, directions, and disparity magnitudes of the stimuli of the random-dot and contour stereograms are identical, the pattern is more difficult to see in the random-dot stereogram.²¹ Because of the inherent ambiguity of which element in one half-view is the correct "match" for a given element in the other half-view of random dot stereograms, global stereopsis is a more complex second-order process than local stereopsis.^{90,104}

The correct identification of a disparity-defined form embedded into the random-dot stereogram is definitive evidence that the patient's stereoacuity is higher than the disparity of the form and, therefore, clinical testing using random dot stereograms may be preferred. This property is especially useful for children because the identification of a familiar form is cognitively simpler than the discrimination of relative depth. However, clinical testing of global stereopsis requires a relatively long viewing duration to identify the stereoscopic form^{21,71,133} and the relative direction of stereoscopic depth in random-dot stereograms can be detected

with smaller disparities than needed for identification of the disparity-defined form.⁷⁰ In addition, an accurate registration of the random-dot patterns on corresponding retinal points is essential for form identification, for that reason, they may not be ideal for assessing the degree of binocularity in patients with subnormal binocular vision from microstrabismus or the monofixation syndrome,^{12,172} although patient's with primary microstrabismus can perceive the depth in some forms of random-dot stereograms.⁶⁸

Stereoacuity with refractive defocus

Occasionally a patient can be stereo-deficient or stereoblind even though they have normal eye alignment and visual acuity.⁵¹ More often, stereoacuities are reduced by some factor that has affected the retinal image quality of one or both eyes. For example, optical defocus of the retinal images, as occurs with uncorrected refractive errors, degrades stereoacuity in proportion to the magnitude of defocus.^{101,134,176} The effect of blurring the retinal images is greater for stereoacuity than for other resolution tasks, such as visual acuity or instantaneous displacement thresholds.¹⁷⁶

Unilateral optical defocus produces a greater reduction of stereoacuity than does symmetrical bilateral defocus,⁵⁴ which is consistent with other paradoxical effects on stereoacuity caused by interocular differences in stimulus parameters.^{32,67,96,142} For example, improving the focus in one eye will, paradoxically, degrade stereopsis more than equal defocus in both eyes. With unilateral defocus, stereoacuity decreases as the amount of defocus increases until stereopsis is suspended by interocular differences greater than about two diopters.^{54,119} The filtering of high spatial frequencies that occurs in defocused images cannot fully explain the resulting reduction in stereoacuity¹⁷⁹ and, hence, foveal suppression may also play a role.¹⁶³

Because of the effect of optical defocus on stereoacuity, usually a clinician's primary goal is to provide an accurate refractive correction for each eye in order to optimize binocular vision and stereoacuity. However, for one group of patients – presbyopes – interocular refractive error corrections are often purposely unbalanced to correct one eye for distance vision and the other eye for near vision.⁴² The scheme of providing an ocular correction for distance vision with one eye and a near vision correction for the other eye, either with single vision contact lenses,^{40,41,42,144} refractive surgery,^{22,85} or intraocular lens implants,^{59,61,62} is called monovision.^{41,145,161} The monovision procedure is successful for a majority of patients with normal binocular vision and usually the dominant (sighting) eye is corrected for distance vision because less disorientation is experienced during perceptual adaptation to the anisometropic refractive condition.^{40,107} After adaptation, most patients do not experience symptoms of asthenopia, nor are they aware of blurred vision at far or near viewing distances.¹⁴⁵ Although their binocular field of view and motor fusion ranges are generally normal, many monovision patients will experience diplopia at night or in dim illumination (when their pupils are dilated), or when they view bright targets of high contrast.¹⁴⁵ Some visual functions do not adapt to unilateral optical defocus, resulting in a loss of binocular summation for high spatial frequencies, reduced binocular visual acuity, and degraded stereoacuity with foveal suppression.^{38,40,45,107}

Spatial frequency and contrast effects on stereopsis

Stereoacuity is influenced both by spatial frequency and contrast. Studies of stereopsis, using narrowly tuned, spatially filtered stimuli, have provided evidence that retinal disparities are processed by independent channels that are tuned to different spatial frequencies and different types of disparity.^{46,67,80,93,96,142,147,148,185} Disparity can be described either as a positional offset of the two retinal images (measured in angular units) or a phase offset, where phase describes the disparity as a proportion of the luminance spatial period to which the disparity detector is tuned.^{73,147} The neural mechanisms tuned to high spatial frequencies (>2.5 c/deg) are sensitive to positional disparity and have higher sensitivities than the mechanisms tuned to lower spatial frequencies, which are sensitive to phase disparity.^{147,148,174}

Results from early experiments, using small, broadband stimuli, suggested that stereoacuity is relatively unaffected by lowering contrast and luminance unless the reduction diminishes the monocular visibility of the stereoscopic stimuli.¹¹⁵ However, more recent investigations, using narrowband stimuli that are more specific for the early spatial filters in the binocular vision pathway, have found that stereoacuity is reduced with decreased binocular contrast, and the reduction is greater for high than low spatial frequency stimuli.^{67,96,147} The effects of interocular differences are similar for contrast and optical defocus and stereoacuity is reduced more with unilateral or asymmetric reductions of contrast than with binocular or symmetric contrast reductions.^{67,96,147} Additionally, the relative effects of contrast asymmetries are greater for low than for high spatial frequencies.³² The improvement in stereoacuity with increasing bilateral contrast can be explained by an increased stimulus strength, which either intensifies signals from disparity-selective neurons or recruits signals from more disparity-selective neurons. However, the paradoxical decrease in stereoacuity with unilaterally increased contrast is not consistent with the improved signal strength explanation, but requires suppression, or masking, interactions.¹⁶³

For disparities above the stereothreshold, the contrast sensitivity function for depth perception has a unimodal peak when measured with a binocular phase disparity of approximately 90 deg.^{73,155,156} Using small or narrowband Gabor or Difference-of-Gaussian stimuli having low- or mid-range spatial frequencies, contrast sensitivity falls off as disparity increases, up to the upper disparity limit of stereopsis (D_{max}), but the upper limit of stereoscopic depth perception is also dependent on stimulus bandwidth (size).^{174,181}

Spatial distortions from aniseikonia

The two retinal images need to be similar in size and shape to support normal binocular vision; nonetheless, the visual system can tolerate small interocular differences without complete disruption of binocular fusion. An inequality in the size and/or shape of the two ocular images (aniseikonia) can occur from differences in the optics of the eyes, in the retinal receptor mosaics, or in cortical magnification.¹¹³ However, the most common cause of aniseikonia is a

Box 36.4 Spatial distortions caused by aniseikonia

- Electronics technician, 58 years old
- Cataract surgery for left eye with an IOL implant
- Refractive errors before surgery
OD: +3.25 –1.25 × 010
OS: +2.25 –0.50 × 180
- Refractive errors after surgery
OD: +3.25 –1.25 × 010
OS: +0.50 –2.75 × 005
- Symptoms after IOL surgery: Clear vision with each eye, but while reading a newspaper binocularly, the pages looked farther away on the left side and they appeared trapezoidal. He also complained of problems with depth perception, such as reaching and pressing the floor button in the elevator or soldering on a circuit board.

Comment: Using the rough rule-of-thumb of 1 percent magnification per diopter of anisometropia, the patient has an overall magnification of 2.75 percent with the right eye image larger, plus an additional 1.5 percent magnification in the vertical meridian of the right-eye image. Thus, the anisometropia following the cataract surgery has both an overall and meridional component, but the meridional component is the more likely cause of spatial distortions. The patient's complaints are consistent with an induced effect from the aniseikonia, and although a 1.5 percent image size difference may not cause symptoms in all patients, this electronics technician was quite disturbed by his altered perception.

difference in the refractive errors of the two eyes (anisometropia).^{1,14} In refractive anisometropia, the optical components of the two eyes differ in power. Spherical optical differences produce a relative overall size discrepancy in the two retinal images, and astigmatic optical differences produce a relative meridional size difference in the two retinal images. Anisometropia as a result of the natural development of refractive errors is a common cause of aniseikonia, although nowadays aniseikonia is more often associated with anisometropia as a result of intraocular lens implantation (Box 36.4), refractive surgery, or penetrating keratoplasty.^{11,55,59,81}

There are large individual differences in symptoms and toleration of aniseikonia. Aniseikonia is usually considered clinically significant when the image size difference is greater than 4 percent, but many patients experience distortions in spatial perception and/or uncomfortable binocular vision, headaches, and eyestrain with differences as small as 2 percent.^{19,113} The symptoms of eyestrain (asthenopia) are not specific^{1,19} and the diagnosis of aniseikonia in a patient with fusion and stereopsis must be made from measurements of retinal image size differences^{94,102,162} or from assessment of the aniseikonic spatial distortions.^{19,113} The size differences of the retinal images pose problems both for stereopsis and for control of eye alignment. The size discrepancy generated by an anisometric spectacle correction produces disparities that vary with eye position, causing a non-comitant variation of heterophoria (anisophoria).^{141,145} The oculomotor system can adapt tonic vergence to compensate for anisophoria. However, when a person is unable to adapt to the correction, the symptoms of eyestrain occur with attempts to adjust eye alignment as gaze shifts from one direction to another. These motor symptoms can be confused with

sensory disorders normally assumed to result from aniseikonia.⁵² Anisotropic contact lens corrections do not produce anisophoria because the optical center of the lens remains fixed with respect to the pupil center during eye movements.

The types of spatial distortions perceived from the relative magnification of one retinal image can be understood by the altered perception of the orientation of the fronto-parallel plane that is associated with aniseikonia.¹¹³ Unequal retinal image sizes cause the apparent fronto-parallel plane to be slanted around an axis at the fixation point by an amount and direction determined by three components of aniseikonia: the geometric effect, the induced effect, and declination errors. The three components of aniseikonic perceptual distortions are illustrated by stereograms in Figure 36.15, which were constructed for crossed-eye free fusion, and when viewed in a stereoscope or with straight-eye free fusion, the effects will be opposite to the descriptions in the text.

The geometric effect, simulated in Figure 36.15B, occurs with retinal image size differences in the horizontal meridian and is a consequence of the horizontal disparity caused by lateral magnification. The fronto-parallel plane appears slanted toward the eye with the larger horizontal magnification. The physiological basis for the apparent slant in the geometric effect is illustrated in Figure 36.16. To simulate the effect, an observer views an objectively flat plane (plane PFQ) through a ×090 size lens or afocal magnifier. A size lens is a small Galilean telescope without refractive power for objects at infinity. In this example, it produces magnification in the horizontal meridian of the right eye (×090). When viewed through the size lens, the plane does not appear parallel to the face, but rotated about the fixation point to the plane P'FQ'; i.e. such that point P is perceived as nearer and point Q as farther. The amount of perceived rotation is proportional to the magnification difference between the two retinal images produced by the size lens. The direction and magnitude of rotation result from the change in the horizontal disparity gradient produced by the unioocular horizontal magnification. The disparities across the gradient are in opposing directions in the left and right visual fields. In this example the gradient produces crossed disparities for objects in the left visual field and uncrossed disparities for objects in the right visual field. The perceptually slanted plane illustrated in panel B of Figure 36.15 incorporates a perceptual surface rotation and an apparent change in perceived size. Objects in the left visual field appear smaller than in the right. The size distortion is consistent with learned relationships between size and distance, e.g. if one object appears farther than another, but without a correlated difference in retinal image sizes, the cue conflict causes the farther object to be perceived as larger.

The second component of aniseikonia, the induced effect, is caused by a relative magnification difference in the vertical meridians of the two eyes, which can be simulated by a ×180 or vertical meridional magnifier. The induced effect is interesting because, as can be observed by the stereogram (Fig. 36.15C), vertical binocular disparities, by themselves, do not result in the perception of stereoscopic depth, but vertical meridional aniseikonia in a real-world visual environment causes a perceived rotation of the fronto-parallel plane. The induced effect is similar to the geometric effect in that it is perceived as a rotation of the fronto-parallel plane about a vertical axis, but the induced effect is in the opposite

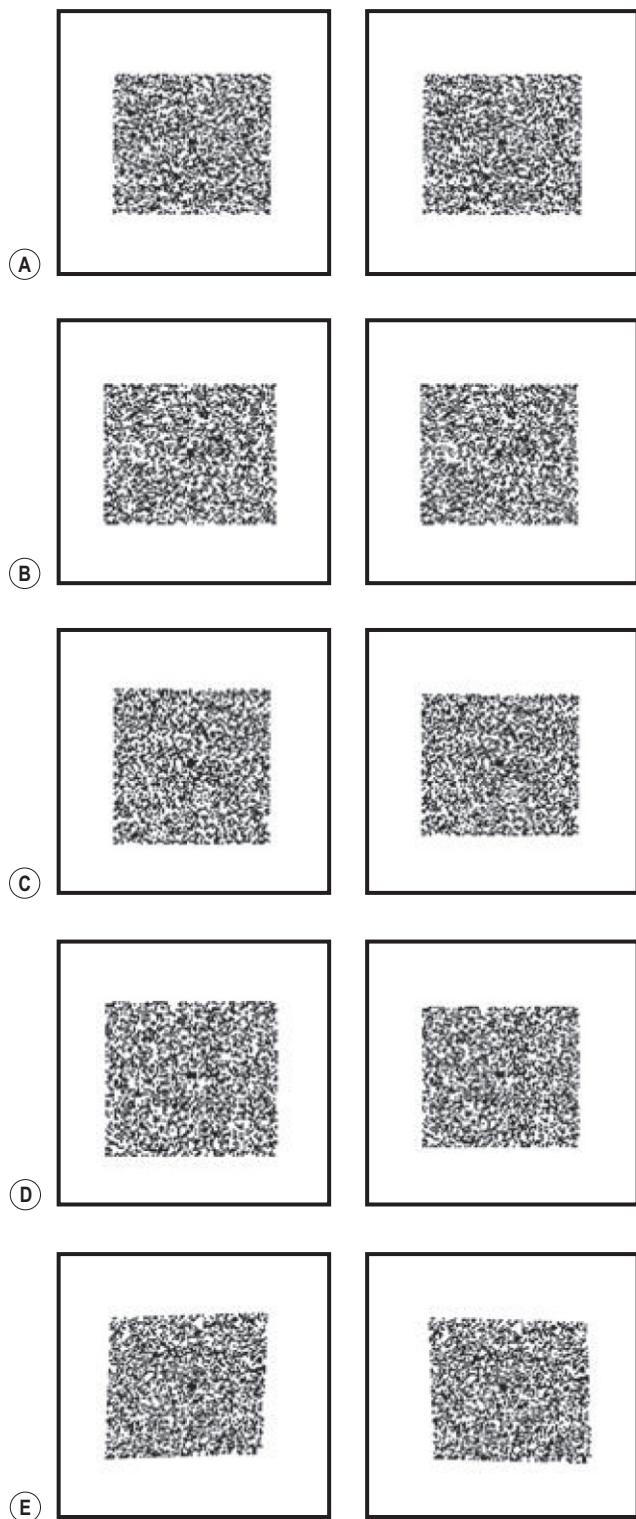

Figure 36.15 A series of stereograms to demonstrate the components of relative magnification from aniseikonia to illustrate subjective spatial distortions. The random-dot patterns represent fronto-parallel plane stereograms that have been constructed to simulate various components of aniseikonia during binocular fusion with crossed-eye viewing (other viewing strategies will produce perceptual effects that are opposite to those described). **(A)** Normal spatial perception with equal-sized images for each eye. For an observer without aniseikonia, the perceived fronto-parallel plane should not be distorted. **(B)** A stereogram with a relative magnification of 10 percent in the horizontal meridian to demonstrate the geometric ($\times 090$) effect. The observer should perceive a tilt of the fronto-parallel plane about a vertical axis with the right edge appearing more remote than the left edge of the plane. **(C)** A magnification of 10 percent in the vertical meridian to simulate the magnification of the induced ($\times 180$) effect. For most observers, vertical disparities in a stereogram will not produce the apparent distortion of the fronto-parallel plane that can be seen in a natural visual environment. **(D)** A combination of horizontal and vertical magnification to produce an overall magnification of 10 percent. **(E)** Relative magnification at oblique meridians (right eye: $\times 045$ and left eye: $\times 135$ for crossed-eye fusion) to simulate the declination effect. The fused perception should be a slanted surface with the upper edge appearing more remote than the lower edge.

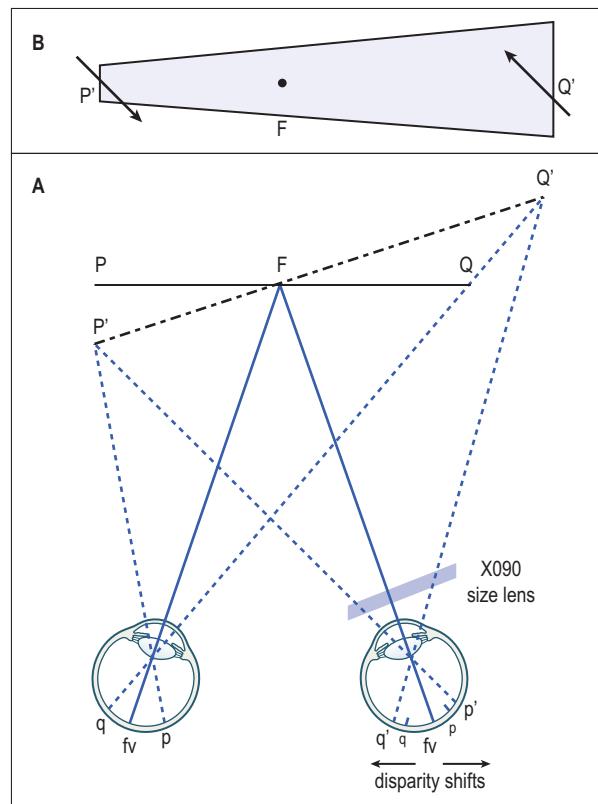

Figure 36.16 The physiological basis of spatial distortions caused by the aniseikonia from meridional magnification in the horizontal meridian of the right eye. The fronto-parallel plane PQF appears to be rotated to a plane $P'Q'F'$ as a result of the binocular disparity produced by meridional magnification. See the text for details (adapted from Ogle 1964¹¹³).

direction. The OFPP appears tilted away from the eye viewing through the vertical magnifier. Because the phenomenon is similar in form, but opposite in direction to the geometric effect, it is called the induced effect to convey the notion that the distortion is the same as if it was "induced" by a horizontal meridional magnifier over the fellow eye.

The induced effect results from the magnification of the vertical disparities, which are inherently present at relatively

near viewing distances due to differences in ocular perspective of the target. Naturally occurring vertical disparities increase as the eccentricity of the target increases and as the viewing distance decreases.¹⁶⁷ If the viewing distance is sensed from convergence, then target azimuth can be derived from the rate of increase of vertical disparity with eccentricity

(i.e. from the vertical disparity gradient). Vertical disparity gradients are used to scale disparity in order to quantify depth and to interpret slant information.^{3,56} Horizontal disparity alone is an ambiguous stimulus for slant perception. Identical horizontal disparity patterns can correspond to different slant patterns for surfaces seen in symmetrical and asymmetrical convergence. For example, while a zero disparity pattern describes the Vieth-Muller circle, this constant disparity pattern also describes a surface slant that increases with horizontal gaze eccentricity.¹¹⁴ In order to interpret slant from horizontal disparity correctly, knowledge of target distance and gaze eccentricity are needed. The combination of vertical disparity gradients and convergence provides this information. When vertical magnifiers distort vertical disparity gradients, the surface slant is changed to conform to the distorted vertical disparity gradient.⁸³ This induced effect is weak, or absent, for targets located at an infinite viewing distance because retinal images of remote targets lack a difference in perspective significant enough to produce a vertical disparity gradient. For most observers, induced and geometric effects are about equal in magnitude and opposite in direction¹¹³ thus, overall magnification differences, as opposed to meridional magnification differences, have little effect on the perception of space (see fronto-parallel plane stimulus D, Fig. 36.15).

The third component of aniseikonia is a declination error (perceived tilt about a horizontal axis) that arises from retinal image shear, or magnifications in oblique meridians (see stereogram E, Fig. 36.15). The direction of rotation (inclination or declination) of the oblique magnifier is predicted from the combined vertical and horizontal disparity components of the magnified retinal images. For example, the stereogram was constructed to simulate $\times 045$ magnification for the right eye and $\times 135$ magnification for the left eye with crossed-eye viewing, which creates a relative crossed disparity in the lower visual field compared to the upper (Fig. 36.15E). The resulting perception is a slanted surface with the bottom part of the surface closer. Oblique magnification can also cause horizontal tilt about a vertical axis if the horizontal and vertical components are unequal. Magnifiers at $\times 45$ and $\times 135$ degrees have equal horizontal and vertical magnification components, so that the resulting geometric and induced effects tend to cancel one another. However, oblique magnification along other meridians produces unequal amounts of geometric and induced distortion, and the stronger distortion usually dominates the horizontal tilt percept.

In the final analysis, the perceptual distortions from aniseikonia are a combination of the three components, geometric effect, induced effect, and declination error, with individual variability in the degree of tolerance and ability to adapt to stereoscopic misrepresentation of relative depth. These principles are illustrated by the case described in Box 36.4, where a relatively small induced effect caused disturbing spatial distortions for an electronics technician.

Motion-in-depth

The properties of visual direction and stereoscopic depth perception have been much more extensively studied with static stimuli at a constant fixation distance than under

dynamic stimulus conditions. However, providing valid judgments of the trajectories and distances of moving objects, to capture moving objects or avoid collision with them, is a vital function of binocular vision.⁶⁰ The mechanisms underlying perception of the distance and the direction of moving objects are not as well understood, but there are at least two possible mechanisms for the perception of motion-in-depth.^{36,126} First, the binocular disparity of an object moving in depth will change with time and, thus, the trajectory and distance could be interpolated from the responses of static disparity-sensitive mechanisms over time. The second type of mechanism for the perception of motion-in-depth is one that is sensitive to differential velocities of the retinal images. An object that is moving in depth will generate movements in the two retinal images that differ in speed and direction.

In natural scenes, as illustrated in Figure 36.7, changes in binocular disparity and differential interocular velocities are correlated. For this example, an object is moved along the visual axis of the left eye until the retinal image of the right eye is displaced outside the retinal region corresponding to Panum's fusional limit. During this measurement, if the test object had been moved from the uncrossed to the crossed disparity limits, it would have appeared to be moving in a depth trajectory toward the observer's left eye. The apparent trajectory is a property of the relative directions and velocities of the retinal images¹²⁵ and, if in another case, the two retinal images of an object move in the same direction and velocity, the object would not appear to move toward the head; rather, it would be perceived as moving in the fronto-parallel plane. If the retinal images move in opposite directions (i.e. temporal-ward), the object would appear to move towards the observer's head. In each example, the object's motion-in-depth may have been detected by mechanisms sensitive to the sign and magnitude of binocular disparity, which have changed with time. On the other hand, for any given time, the direction and velocity of movement of each of the object's retinal images are different; thus, the object's motion-in-depth could have been based on differential velocity information.

Some investigations of stereomotion have provided psychophysical and physiological evidence for velocity-dependent mechanisms,^{8,9,127} while other studies have shown comparable perception of motion-in-depth in the absence of coherent velocity information.^{36,126} Threshold and adaptation experiments have provided evidence for neural channels that are sensitive to the direction of motion in depth, with different channels selectively sensitive to approaching and receding motion. However, stereo-motion can also be detected in dynamic random-dot stereograms that produce changes in disparity over time without consistent signals for interocular velocity differences. Regardless of the mechanism, the normal sensitivity to stereomovement requires about 5–10 times greater disparity magnitudes than stereoacluity measures with static stimuli.^{36,177} Motion-in-depth may be present in patients with stereodeficiencies from early strabismus or amblyopia as a residual form of stereopsis.¹⁰³ But on the other hand, many individuals with normal visual acuity and stereopsis have areas of the binocular field that are insensitive, or even blind, to motion-in-depth.¹³⁰ Currently, clinical tests of stereomotion have not been developed.

Suppression in normal binocular vision

In complex three-dimensional scenes, there are several types of binocular information that must be combined to produce an integrated percept of depth and distance. First, some of the visual information is coherent and unambiguous, such as images formed within Panum's fusional areas and the coherent information contributes to normal fusion and stereoscopic depth perception. However, some forms of binocular information do not stimulate binocular fusion. For example, regions of space may be clearly visible to only one eye (i.e. partially occluded to other eye), and this fragmented binocular information also contributes to the perceptions of distance and depth. In addition, information from binocular images that are uncorrelated, either because the matches are ambiguous or would conflict with other cues, influences depth and distance perception. Visual confusion, in which there is superimposition of separate diplopic images arising from objects seen behind or in front of the plane of fixation, is an example of uncorrelation of binocular images that can be interpreted to suggest depth or distance. The binocular visual system attempts to preserve as much of the depth information as possible from all three sources to make inferences about objective space without introducing ambiguity or confusing space perception. At times, however, conflicts between the two eyes are so great that the conflicting information must be resolved by suppressing or suspending the perception arising from one of the retinal images.

Four classes of stimuli have been identified that appear to evoke different interocular suppression mechanisms in normal binocular vision.

1. *Interocular blur suppression* occurs when the retinal images have significant differences in defocus or contrast.¹⁵² A wide variety of natural conditions produce unequal contrast of the two ocular images, including naturally occurring anisometropia, unequal amplitudes of accommodation, and asymmetric convergence on targets that are closer to one eye than to the other. The relative differences in defocus can be partially eliminated by differential accommodation of the two eyes¹⁰⁵ and by interocular suppression of the blur.¹⁴⁵ The latter mechanism is requisite for adaptation to a monovision correction of presbyopia. Monovision suppression allows clear, non-blurred, binocular percepts and retention of stereopsis albeit with the stereo-threshold elevated by approximately two-fold.^{38,145}

2. *Suspension* is the mechanism that eliminates one of the two ocular percepts that arise during physiological diplopia, in which targets lying in front of or behind the singleness horopter would be seen as doubled.³⁰ Binocular eye alignment optimizes depth information from binocular disparities near the horopter, but at the same time it produces large disparities for the objects that are at some distance in front of or behind the plane of fixation. Even with binocular disparities that are well outside the limits of Panum's fusional areas, the perception of diplopia under normal casual viewing conditions is rare because of the suppression of one image. The suppression of physiological diplopia is called suspension because this form of suppression does not alternate between the two images. Instead, only one image is continually suppressed, favoring visibility

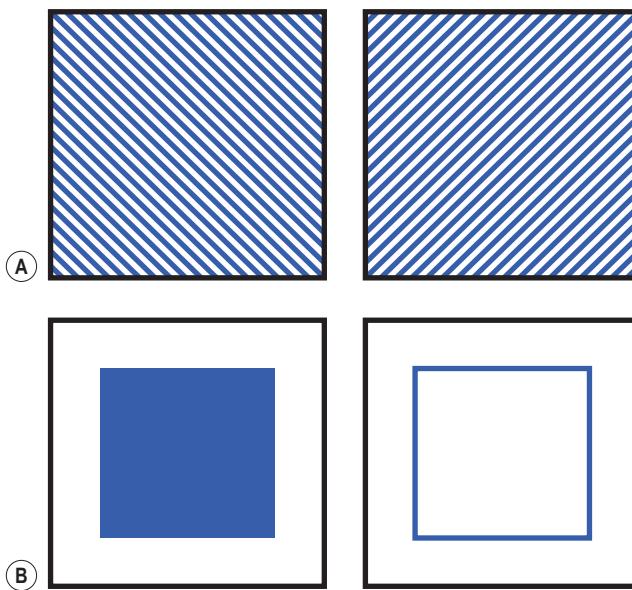

Figure 36.17 Stereograms to demonstrate the perceptual consequences of binocular viewing of non-fusible objects or surfaces. (A) Binocular rivalry. (B) Binocular luster.

of the target imaged on the nasal hemi-retina.^{35,43,92} However, suspension is not obligatory, and calling attention to the disparate target can evoke physiological diplopia. It has also been suggested that suspension may be involved in the permanent suppression of pathological diplopia associated with strabismus.^{44,63,135,136}

3. *Binocular (retinal) rivalry suppression* is a rhythmic alternating perception of each of the retinal images when substantial differences in their sizes and/or shapes preclude their fusion.¹⁵ The classic demonstration of binocular rivalry arising from non-fusible images formed on or near corresponding retinal points is shown in Figure 36.17A, which presents orthogonal-oriented gratings to the two eyes. In this example, rivalry suppression can take the form of either exclusive domination or mosaic domination. During exclusive or wholesale domination, each of the two images alternates between dominance and suppression: one set of lines will be seen and, after several seconds, the image of the other set of lines appears to wash over the first. In mosaic domination, the two monocular images become fragmented, and small interwoven retinal patches from each eye alternate independently of one another. In this case, piecemeal suppression is regional, localized to the vicinity of the contour intersections.

The perceived rivalrous patches alternate between the two ocular images approximately once every 4 seconds, but the rate of oscillation and its duty cycle vary with the degree of difference between the two ocular images and with the stimulus strength. The rate of rivalry increases as the orientation difference between the targets increases beyond 22 degrees,^{43,135} indicating that rivalry is not likely to occur within the tuned range for cortical orientation columns. Levelt⁹⁷ formulated a series of rules describing how the dominance and suppression phases of binocular rivalry vary with the strength of stimulus variables such as brightness, contrast, and motion. He concluded that the duration of the

suppression phase of one of the retinal images decreases when its stimulus visibility or strength is increased relative to the retinal image of the fellow eye. If the strengths of the stimuli for both eyes are increased, then the suppression phase for each eye decreases, and the oscillation rate of rivalry increases. Reducing the stimulus contrast of both eyes also reduces the oscillation rate, until at a very low level of contrast, rivalry is replaced with a binocular summation of non-fusible targets.¹⁰⁰

The perception of rivalry has a latency of approximately 200 msec so that briefly presented non-fusible patterns appear superimposed.⁷⁸ However, rivalry occurs between dichoptic patterns that are alternated rapidly at 7 Hz or faster, indicating an integration time of at least 150 msec.¹⁸³ When rivalrous and fusible stimuli are presented simultaneously, fusion takes precedence over rivalry,¹⁵ and the onset of a fusible target can terminate suppression, although the fusion mechanism takes time (150–200 msec) to become fully operational.^{64,184} Suppression and stereo-fusion appear to be mutually exclusive outcomes of binocular rivalry stimuli presented at a given retinal location,^{16,164} but stereoscopic depth and rivalry can be observed simultaneously when fusible contours are superimposed on rivalrous backgrounds.

Because both binocular rivalry suppression and strabismic suppression result in a functional loss of visual information from one eye during binocular viewing, binocular rivalry suppression and strabismic suppression have been hypothesized to be related phenomena.¹⁷² However, the patterns of suppression¹⁵⁹ are different for normal and for esotropic subjects suggesting that strabismic observers do not demonstrate normal binocular rivalry and that strabismic suppression and normal binocular rivalry suppression are mediated by different neural mechanisms.^{158,160}

Another form of binocular rivalry occurs when un-fusible surface brightnesses (e.g. black and white) or surface colors (e.g. red and green) are dichoptically superimposed. In this form, the phenomenon is known as binocular luster or as luminance or color rivalry.^{83,114} Figure 36.17B presents a stereogram that evokes binocular luster, which is usually described as a shimmering, unstable surface percept, as though one surface is being seen through another. The perception of luster requires a certain level of binocular vision, but does not require fusion ability and, therefore, testing for binocular luster has been advocated for evaluating binocularity and anomalous retinal correspondence in strabismic patients.

4. *Permanent-occlusion suppression* is a more stable form of suppression that occurs when one eye views a contoured stimulus while the other eye views a spatially homogeneous field.¹⁰⁶ Under these conditions, the image of the eye viewing the contoured field dominates, while the image of the eye viewing the homogeneous field is almost continually suppressed. Because of the stability of the dominance/suppression percept under these viewing conditions, the term “permanent suppression” is used to distinguish this type of suppression from binocular rivalry suppression.

There are many occasions in which the two eyes see dissimilar forms as a result of partial occlusion in the near visual field. Natural partial occlusion occurs when one eye’s view of a distal target is partially obstructed by a nearby object, such as the nose, or when distal objects are viewed

through a narrow aperture. Under these conditions, the occluding object is normally suppressed to retain a constant view of the background. This phenomenon can be demonstrated by holding a cylindrical tube in front of one’s right eye and placing the palm of one’s left hand in front of the left eye near the distal end of the tube. The combined stable percept is that of a hole in the left hand. The hand is seen as the region surrounding the aperture through which the background is viewed. This ecologically valid example of occlusion gives priority to the background seen through the aperture. The mechanisms underlying stable, permanent suppression are unlike those underlying rivalry suppression because different changes in the increment-threshold spectral sensitivity function are produced by these two phenomena.¹³¹

Summary

Binocular vision is an intricate organization of biological and psychological components to provide haplopia and an accurate subjective representation of the depth and distance of every object in the environment. The present chapter has presented some of the basic principles of the normal and clinically abnormal sensory processes, but they are just one part of the system. Equally important are the oculomotor components (Chapter 9), which in normal binocular vision interact with sensory mechanisms to place the ocular images on appropriate retinal areas to support fusion and stereopsis, or with abnormal oculomotor control as in strabismus, to enlist adaptive sensory mechanisms of suppression and anomalous retinal correspondence. Further, whether an individual has normal or abnormal binocular vision is a product of environmental influences in infancy (Chapters 38 & 40). During an early sensitive period, normal visual experience is required to develop the full capacity of the visual system, otherwise, abnormal visual experience will produce abnormal monocular and/or binocular visual processes. Clinical application of the science of binocular vision involves all of these components with the goal to alleviate any interference with clear, single binocular vision.

Temporal Properties of Vision

Allison M. McKendrick & Chris A. Johnson

Our visual perception arises from the interpretation of light information, which varies in space, wavelength, and time. It is the latter of these attributes that is explored in this chapter. Subjectively, the world appears to be stable despite continuous changes in the visual scene. How does the visual system respond to and interpret light variations that occur as a function of time?

The duration of a light affects both the ease with which we can see it, as well as its subjective appearance. This chapter emphasizes the first of these issues, that is, how sensitive we are to temporal variations in light and which factors influence our sensitivity. Temporal sensitivity cannot be studied in isolation because other stimulus attributes, such as spatial properties, chromaticity, background features and surround characteristics, all influence our ability to detect temporal variations. In the natural world, most temporal variation occurs through image motion. This may arise from motion of the observer, the eyes, or the object itself. Motion is a special form of temporal variation in which the change with time is associated with a change in spatial position.

This chapter summarizes a number of basic phenomena that describe the sensitivity of our visual system to temporal information. The application of these phenomena to the clinical study of abnormalities of visual processing, such as in disease, is also discussed.

Temporal summation and the critical duration

To detect the presence of something in the visual world, it must be present for a finite period of time. Although a single quantum of light may be sufficient to generate a neural response, multiple quanta are generally required during a short period before the light is reliably seen, a property known as *temporal summation*. In the human visual system, temporal summation occurs for durations of approximately 40 to 100 milliseconds, depending on the spatial and temporal properties of the object and its background, the adaptation level, and the eccentricity of the stimulus.^{1–5} The maximum time over which temporal summation can occur is the *critical duration*.

Let's say we wish to determine how long a light needs to be presented on a dark background to be visible. In general

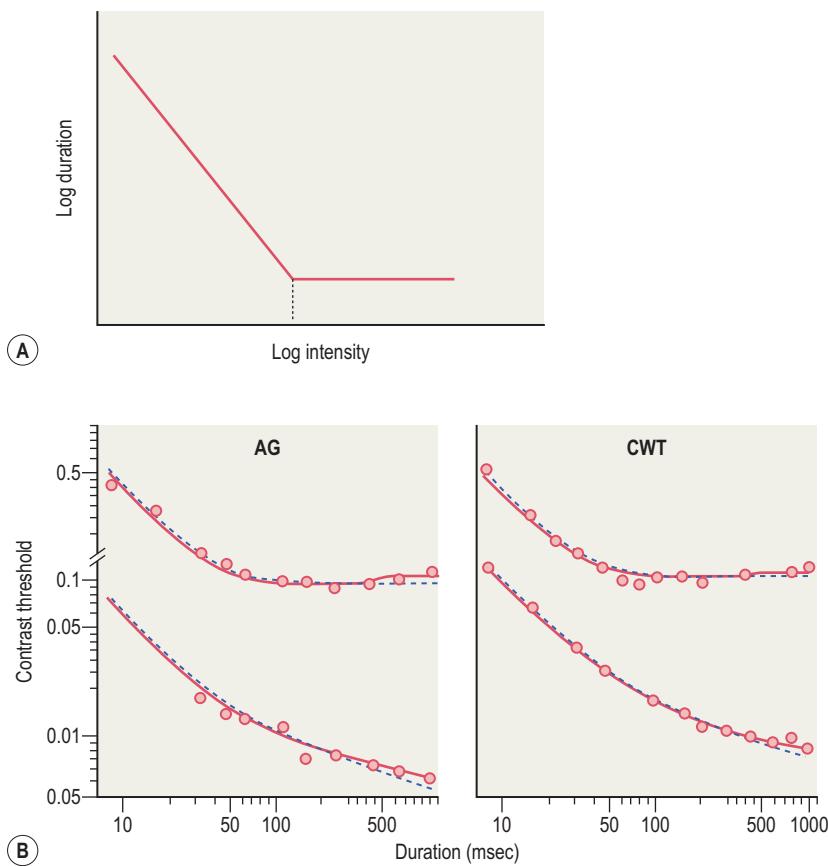

terms, a more intense light does not need to be presented for as long as a less intense one to reach threshold visibility. The relationship between the luminance of the light and the duration of its exposure to reach visibility is linear over a limited range. Provided that the light pulse is shorter than the critical duration, it will be at threshold when the product of its duration and its intensity equals a constant. The formula that describes this time-intensity reciprocity is *Bloch's law*:⁶

$$Bt = K$$

where: B = Luminance of the light, t = Duration, K = A constant value.

Bloch's law is shown schematically in [Figure 37.1A](#). When stimulus intensity and duration are plotted on log-log coordinates, as in [Figure 37.1A](#), *Bloch's law* describes a line with a slope of -1 . When the critical duration is reached, the threshold intensity versus duration function is described by a horizontal line; that is, a constant intensity is required to reach threshold. *Bloch's law* has been shown to be generally valid for a wide range of stimulus and background conditions, including both foveal and peripheral viewing. Once the duration of the stimulus exceeds the critical duration, the luminance required for it to reach visibility is classically considered to be constant.

The preceding discussion assumes that whenever the observer's threshold is exceeded, he or she will respond accurately to the stimulus. This predicts an abrupt and idealized transition between the two curves, as depicted in [Figure 37.1A](#). In the real world, both visual stimuli and the physiologic mechanisms that we use to detect them are subject to random fluctuations in response. We may consider the length of the stimulus presentation to be divided into a number of discrete time intervals. The signal is detected when the response exceeds threshold in at least one interval and the probability of detection in each interval is considered independent. This description of the probabilistic nature of visual detection is known as *probability summation over time*.⁷ The concept of probability summation is included in many models of temporal visual processing and is thought to be at least partly responsible for the less-than-abrupt transition between the region of temporal summation and constant intensity that occurs under some experimental conditions.³ One experimental situation in which this arises is

when threshold contrast is measured as a function of signal duration for sinusoidal grating stimuli. This is illustrated in Figure 37.1B.³ In Figure 37.1B the upper curve shows threshold duration data for a 0.8 cycle per degree grating, and the lower curve shows those for an 8 cycle per degree grating. The upper curve conforms well to the schematic diagram that is illustrated in Figure 37.1A. For the lower curve depicting results for the 8 cycle per degree grating, however, a gradual transition is observed. In this latter case the actual critical duration (traditionally the point of intercept of the two slopes in Fig. 37.1A) is somewhat difficult to define. Data similar to those shown in Figure 37.1B, have been interpreted to indicate that the critical duration increases with increasing spatial frequency.^{1,4} Gorea & Tyler³ use an alternative form of analysis that includes the effects of probability summation; they conclude that the critical duration is minimally affected by spatial frequency.

Factors affecting the critical duration

The time interval defined by the critical duration depends on properties of both the stimulus and the background. The critical duration has been shown to vary with light adaptation level; that is, with brighter backgrounds, the critical duration decreases.^{8–12} Conversely, with dark adaptation, the critical duration increases.^{13,14} Unless dark adapted, the size of the stimulus also affects the critical duration, with larger stimuli having a decreased critical duration.^{9,12,15} Retinal eccentricity also influences the critical duration, as does the visual task.^{16,17} Temporal summation is also affected by the

Figure 37.1 (A) Schematic of the idealized relationship between threshold light intensity and the duration for it to reach visibility. For durations less than the critical duration, the threshold intensity is linearly related to duration, as described by Bloch's law. (B) The relationship between threshold light intensity and duration for flickering grating stimuli for two observers as measured by Gorea & Tyler. (Reproduced with permission from Gorea & Tyler 1986.³) Upper curves represent data from 0.8 cycle per degree gratings, whereas lower curves show data for an 8 degree per cycle grating stimulus. Note that for the higher spatial frequency (lower curve), there is a more gradual transition between the two curves depicted schematically in (A).

spectral composition (wavelength or color) of the light stimuli, with isolated chromatic stimuli having longer temporal integration than achromatic (luminance) stimuli.^{18–20} For colored lights, the critical duration decreases with increased chromatic saturation of the background, similar to the decrease in critical duration with increased luminance for achromatic stimuli.²¹ Figure 37.2 demonstrates how chromaticity and retinal eccentricity markedly alter the sensitivity to temporal pulses and the critical duration.²⁰

Temporal sensitivity to periodic stimuli

The preceding section has considered how the human visual system responds to aperiodic stimuli (for example, a single pulse of light). We will now consider how the visual system responds to periodic stimuli (repeatedly flickering stimuli). Most research in this area has been directed to explore the following questions: (1) what is the fastest flicker rate that can be detected by the human visual system (the critical flicker fusion frequency); and (2) what factors influence sensitivity to flicker slower than this critical rate?

Critical flicker fusion frequency

When a light is turned on and off repeatedly in rapid succession, the light appears to flicker, provided the on and off intervals are greater than some finite time interval. If the lights are flickered fast enough, we perceive the flashes as a

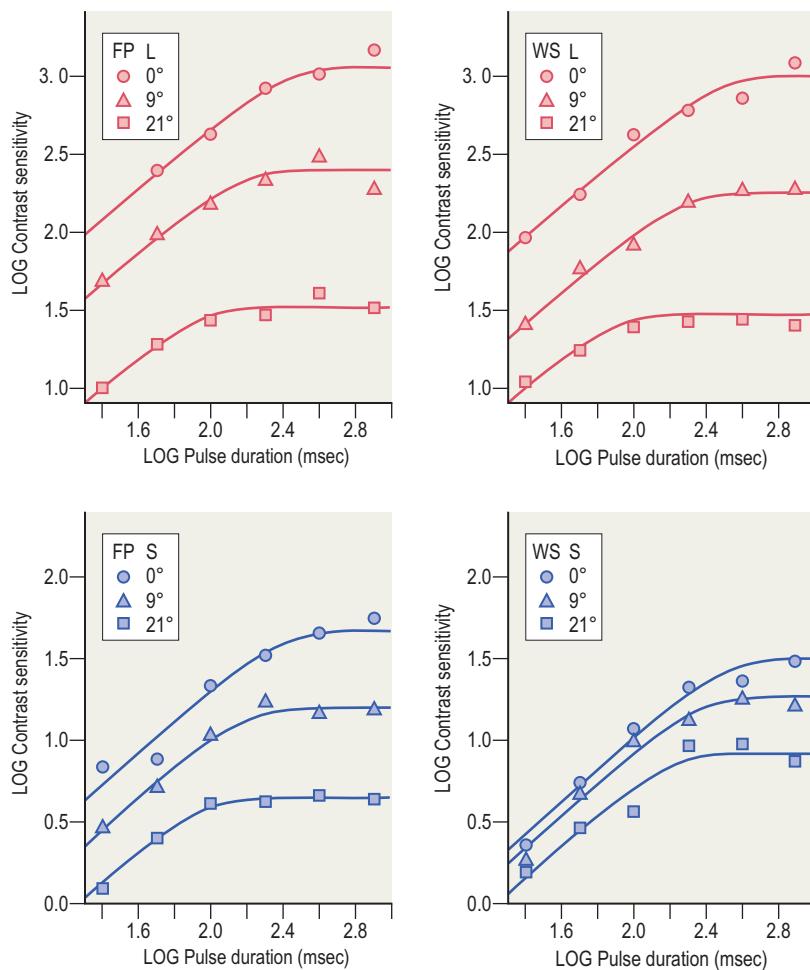

Figure 37.2 Log contrast sensitivity versus pulse duration for equiluminant chromatic pulses. Data are shown for two observers (left and right panels). The upper panels show performance for “red-green” modulation (long-wavelength sensitive [L] and middle-wavelength sensitive [M] cone modulation); whereas the lower panels show data for short wavelength modulation. (Reproduced with permission from Swanson et al 2008.²⁰)

single fused light rather than a series of flashes. In simple terms, when the perception of fusion occurs, we have reached the limit of the temporal-resolving ability of our visual system. The transition from the perception of flicker to that of fusion occurs over a range of temporal frequencies; the boundary between the two is called the *critical flicker fusion (CFF) frequency*. The value of the CFF varies, depending on a large number of both stimulus and observer characteristics. Some of the important factors that influence the CFF (Box 37.1) are discussed in the following sections.

Effect of stimulus luminance on CFF

In general, the CFF increases as the luminance of the flashing stimulus increases. This relationship is known as the *Ferry–Porter law*, which states that CFF increases as a linear function of log luminance.^{22,23} The Ferry–Porter law is valid for a wide range of stimulus conditions and is illustrated in Figure 37.3.²⁴ The lower curves (*solid lines and symbols*) show data collected in the fovea, and the upper curves show data collected at 35 degrees eccentricity. For both locations the upper curves are for smaller targets (0.05 degree foveally and 0.5 degree eccentrically), and the lower curves are for larger targets (0.5 degree foveally and 5.7 degrees eccentrically). Figure 37.3 demonstrates several interesting observations about the relationship between CFF and luminance. First, the Ferry–Porter law is upheld despite changes in stimulus size. Second, the linear relationship between log luminance

Box 37.1 Critical flicker frequency (CFF)

- The critical flicker frequency (CFF) describes the fastest rate that a stimulus can flicker and just be perceived as a flickering rather than stable.
- While the CFF is dependent on the temporal resolution of visual neurons, it is also considered to be a measure of conscious visual awareness because, at CFF threshold, an identical flickering stimulus varies in percept from flickering to stable. Functional magnetic resonance imaging demonstrates involvement of the frontal and parietal cortex in the conscious perception of flicker.¹⁷³
- CFF has been utilized as a measure of conscious visual awareness in a wide range of pharmacological and psychological research studies.
- Perimetric tests of CFF have also been developed with most research directed towards visual field assessment in glaucoma.

and CFF is present for both central and peripheral viewing, although the slope of this relationship increases in the periphery, implying faster processing.²⁴ The Ferry–Porter law holds not only for spot targets but also for grating stimuli.²⁴ For scotopic luminance levels, at which rods mediate detection, CFF decreases substantially to approximately 20 Hz and no longer obeys the Ferry–Porter law.^{23,25,26}

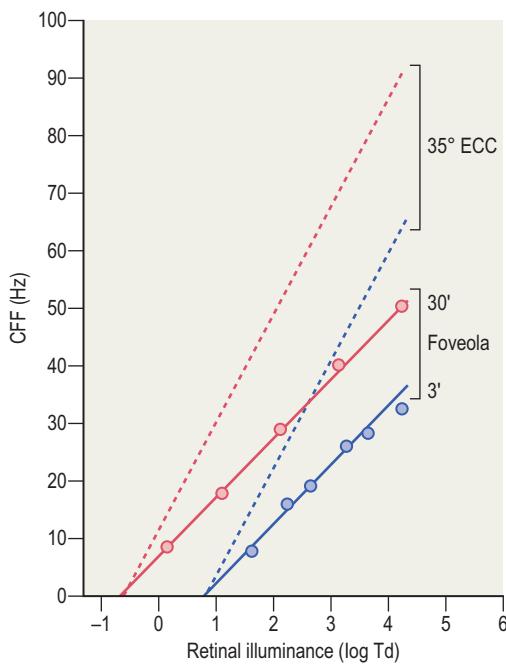

Figure 37.3 Photopic critical flicker fusion (CFF) versus intensity functions measured in the fovea (solid symbols and lines) and at 35 degrees eccentricity (dotted and dashed lines) from Tyler & Hamer. (Reproduced with permission from Tyler & Hamer 1990.²⁴) The test stimulus was 660 nm presented on a equiluminant white surround. Foveal test stimuli were 0.5 degree (large filled circles) and 0.05 degree (small filled circles). Eccentric stimuli were 5.7 degrees (dashed lines) and 0.5 degree (dotted lines). Note the adherence to the Ferry-Porter law for all eccentricities tested. ECC, Eccentricity.

Effect of stimulus chromaticity on CFF

The linear relationship between CFF and log luminance, as described by the Ferry-Porter law, is also valid for purely chromatic stimuli.^{27–30} However, the slope of the relationship has been shown to vary with stimulus wavelength.²⁸ This relationship is demonstrated in Figure 37.4, which shows CFF versus illuminance functions derived from four separate studies.^{27–30} In all four studies the foveal CFF illuminance functions are well fit by Ferry-Porter lines, and in all cases the functions for green (middle wavelength) lights were found to be steeper than those for red (long wavelength) lights. The steeper slope for green stimuli has been interpreted as evidence supporting the green cone pathways being inherently faster than the red cone pathways for the transmission of information near the CFF.²⁸ The CFF is lowest for blue stimuli detected by the short-wavelength pathways.^{31,32}

Effect of eccentricity on CFF

The CFF varies as a function of eccentricity in the visual field. If the stimulus size and luminance are kept constant, the CFF increases with eccentricity over the central 50 degrees or so of the visual field and then decreases with further increases in eccentricity.^{33,34} This is illustrated in Figure 37.5, which plots the CFF as a function of eccentricity in the temporal visual field.

Effect of stimulus size on CFF: the Granit-Harper law

As shown in Figure 37.3, the CFF increases with stimulus size. For a wide range of luminances, CFF increases linearly with the logarithm of the stimulus area. This relationship is known as the *Granit-Harper law*, named after the

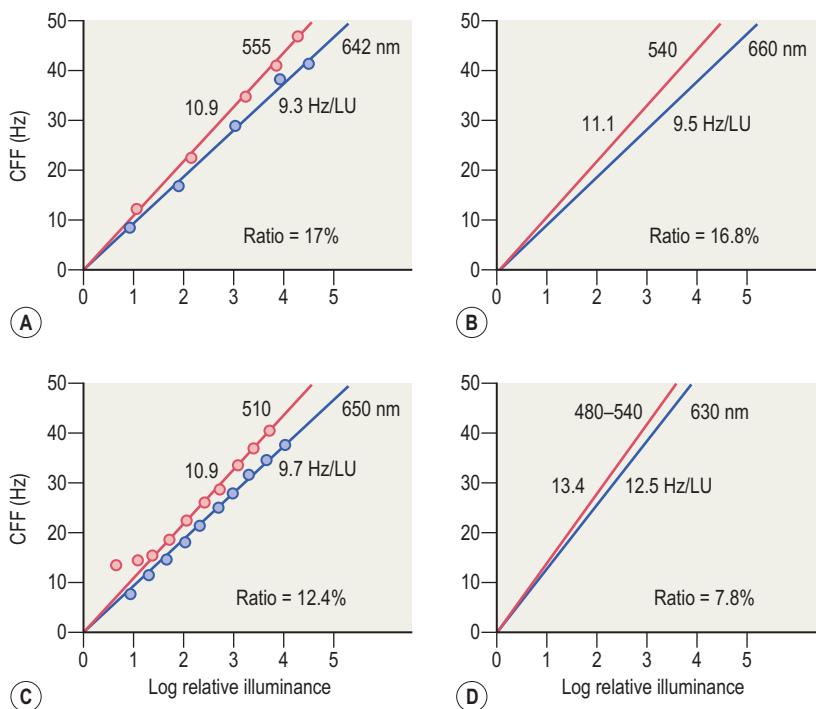

Figure 37.4 Critical flicker fusion (CFF) versus illuminance functions for red and green flicker measured by Hamer & Tyler. (Reproduced with permission from Hamer & Tyler 1992.²⁸) Note that all data are well fit by the Ferry-Porter law, with green lights having a steeper slope than red. **(A)** Data for one subject from Hamer & Tyler.²⁸ The green light function is steeper by 17 percent. **(B)** CFF data from Ives²⁹ for red (650 nm) and green (510 nm) flicker stimuli viewed foveally. The green light function is steeper by 12.4 percent. **(C)** CFF data for red (660 nm) and green (540 nm) flickering stimuli for a single observer tested by Pokorny & Smith.³⁰ The green light function is steeper by 16.8 percent. **(D)** CFF data for green light (mean of 480 and 540 nm data) and red light (630 nm) flicker from Giorgi.²⁷ The green light function is steeper than the red by 7.8 percent.

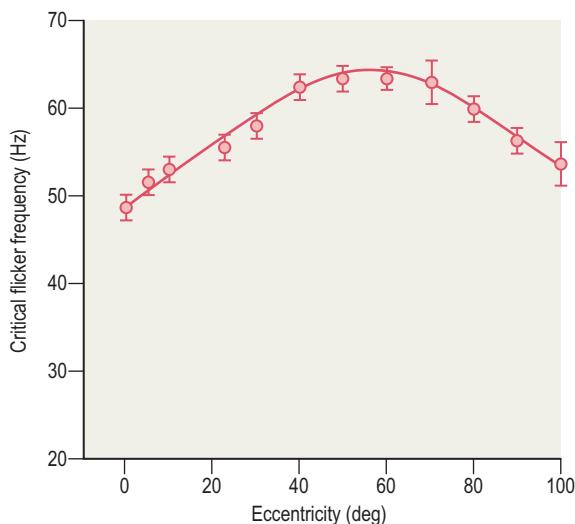

Figure 37.5 Critical flicker frequency (mean \pm standard deviation) as a function of eccentricity in the temporal visual field of the right eye of one observer. (Reproduced with permission from Rovamo & Raninen 1984.³⁴) Stimulus area was 88.4 degrees², pupil diameter was 8 mm, and retinal illuminance was 2510 photopic trolands.

investigators who first reported it.³⁵ The Granit–Harper law holds for a wide range of luminances, retinal eccentricities out to 10 degrees, and stimuli as large as almost 50 degrees. However, subsequent investigators have determined that it is not the overall area of the stimulus that is critical, but rather the local retinal area with the best temporal resolution. This was demonstrated by Roehrig,^{36,37} who measured the same value for the CFF for a complete 49.6-degree field in comparison to an annulus of the same diameter, with its central 66 percent not illuminated. Because the midperiphery has better temporal resolution than central vision, an eccentric annulus produced the same CFF as the full 49.6-degree stimulus. The Granit–Harper law does not hold under dim light conditions in which rods mediate performance.

Beyond the fovea, a revised form of the Granit–Harper law is required to fit the changes in CFF with stimulus area. Rovamo & Raninen³⁸ have shown that the Granit–Harper law can be generalized across the visual field by replacing the retinal stimulus area with the number of ganglion cells stimulated. In this more general case, the CFF increases linearly with the logarithm of the number of ganglion cells stimulated. This is illustrated in Figure 37.6. Figure 37.6A plots CFF against eccentricity for three different stimulus areas. The CFF decreases with increasing eccentricity irrespective of the stimulus area. Figure 37.6B plots the same CFF data as a function of the number of retinal ganglion cells stimulated at each eccentricity and results in a linear relationship between these two parameters.

Temporal contrast sensitivity

The CFF defines an upper limit for temporal sensitivity (Box 37.2), beyond which we can no longer detect that a light is flickering. How sensitive are we to flicker below the CFF, and how does the visual system respond to more complex temporal variations of light than simple flashes or trains of flashes? Classical work on human temporal contrast sensitivity was performed by De Lange in the 1950s.^{39–41} De Lange

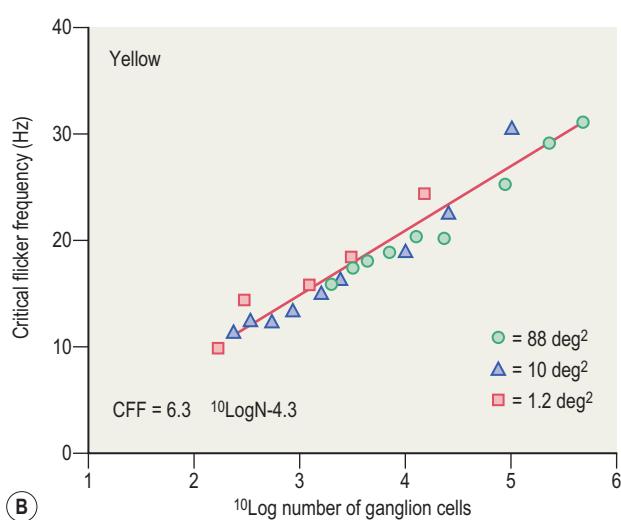

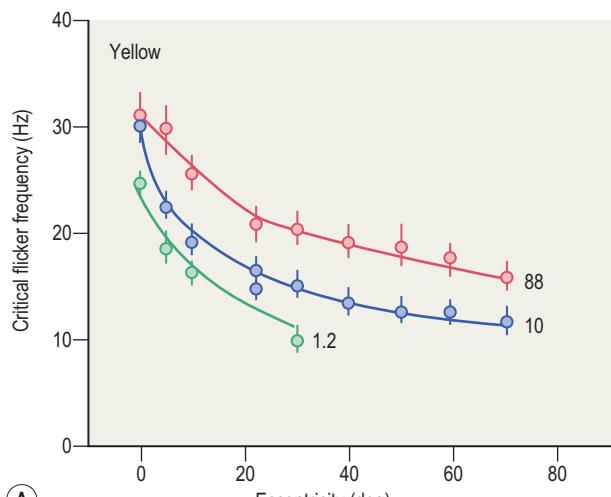

Figure 37.6 (A) Critical flicker frequency (mean \pm standard deviation) for targets viewed eccentrically for one observer reported by Rovamo & Raninen. (Reproduced with permission from Rovamo & Raninen 1988.³⁸) Similar target sizes were used at all eccentricities, but retinal illuminance was F scaled by reducing the average stimulus luminance in inverse proportion to photopic Ricco's area.¹⁴⁴ The numbers on the right of the curves refer to the stimulus area in degrees². When eccentricity increased from 0 to 70 degrees, the stimulus luminance nominally decreased from 50 to 0.80 photopic cd/m². Note that critical flicker frequency (CFF) decreases with increasing eccentricity irrespective of stimulus area. (B) CFF data from (A) plotted as a function of the number of retinal ganglion cells stimulated.

Box 37.2 Temporal contrast sensitivity

There are several versions of clinical perimetry that measure variants of temporal contrast sensitivity. These include:

- flicker on a pedestal temporal modulation perimetry, such as in the Medmont perimeter
- mean modulated contrast sensitivity perimetry
 - both of these display small spot targets that vary in contrast either about the mean luminance of the perimeter background or above and below a luminance pedestal
- spatio-temporal contrast sensitivity is measured in Frequency Doubling Technology Perimetry.

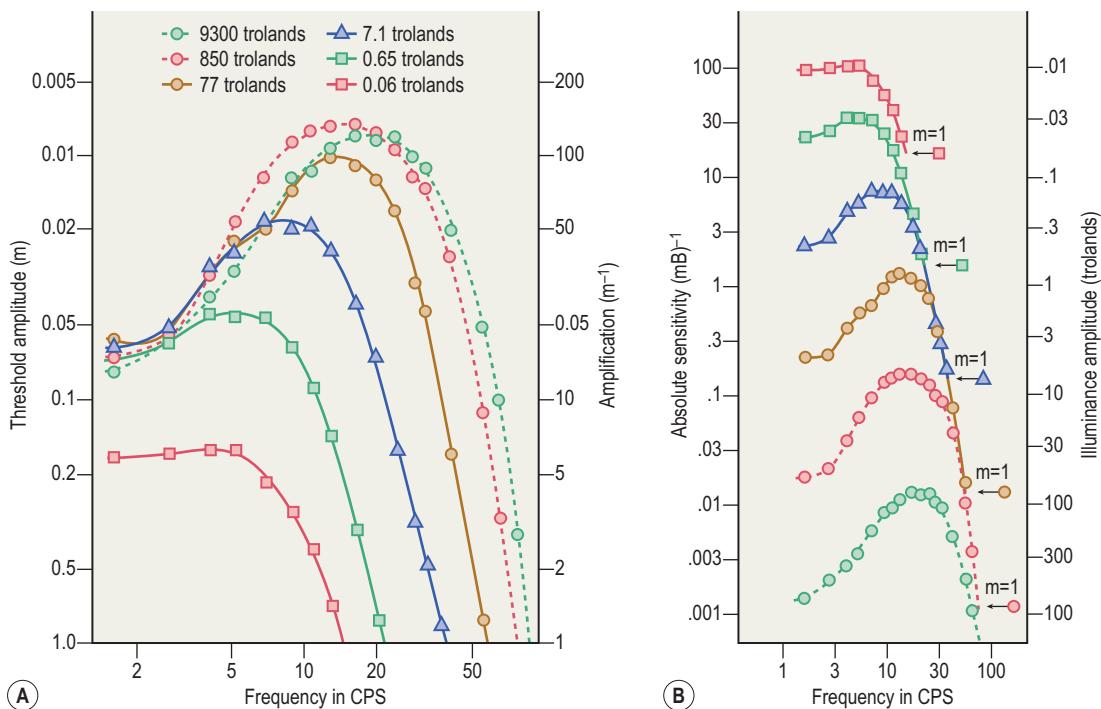

Figure 37.7 Temporal sensitivity data collected by Kelly. (Reproduced with permission from Kelly 1961.⁴²) Visual attenuation characteristics, as measured with sinusoidal variation about different levels of retinal illuminance, are shown. **(A)** Threshold modulation ratios for just detectable flicker plotted as a function of temporal frequency. **(B)** Absolute amplitudes of retinal illuminance variation for just noticeable flicker plotted as a function of temporal frequency. Absolute sensitivity is the reciprocal of threshold absolute amplitude at each frequency.

evaluated temporal sensitivity to flicker using mathematical analysis of temporal waveforms and linear filter theory.

Figure 37.7 shows the results from flicker-sensitivity experiments by Kelly.⁴² The vertical axis plots flicker sensitivity, which is the reciprocal of the flicker threshold, measured as a “threshold modulation ratio,” which is the extent that the sinusoidally modulated light deviates from its average direct current (DC) component. The modulation ratio is calculated as a fraction of its DC value because the amplitude cannot be greater than the DC component (negative values of luminance are not physically possible). The modulation ratio expresses the amplitude as a percentage deviation of the stimulus from its average value.

The left panel of Figure 37.7 plots the modulation ratio as a function of flicker frequency. A series of curves are shown, each obtained at a different average retinal illumination or adaptation level. The curves define the flicker detection boundary for the particular level of adaptation. For a given level of adaptation, any combination of frequency and modulation amplitude below the curve is seen as flickering, whereas any combination above the curve is perceived as a steady light. The point at which the curve intersects the abscissa (x-axis) corresponds to the CFF. Note that at low adaptation levels, the shape of the curve is low-pass, meaning that modulation sensitivity is similar for low temporal frequencies and then falls off systematically for higher temporal frequencies. At high adaptation levels, the shape of the curve is band-pass, meaning that modulation sensitivity is greatest for a band of intermediate temporal frequencies and systematically falls off for lower and higher temporal frequencies.

With increasing retinal illuminance, more conditions are seen as flickering, consistent with the simpler Ferry–Porter law. At low frequencies the curves are similar, indicating that low-frequency flicker reaches threshold at a similar value of modulation ratio for all levels of photopic adaptation. This is not the case for high frequencies, at which the threshold is determined by both adaptation level and frequency. At higher luminance levels the sensitivity for flicker detection peaks at frequencies of approximately 15 to 20 Hz. This is similar to the Brücke brightness enhancement effect, which is discussed later.

The right panel of Figure 37.7 replots the data of Figure 37.7A as a function of the absolute amplitude of the high-frequency flicker. This has the effect of reversing the curves so that the amplitude sensitivity is greatest at the lowest adaptation level. It can be seen that the curves of Figure 37.7B approach a common asymptote at high frequencies. This convergence of curves measured at many different luminance levels implies that at high temporal frequencies, sensitivity is predicted by the absolute amplitude of the signal, independent of adaptation level. This behavior is not apparent at the low temporal frequency range.

Chromatic temporal sensitivity

Chromatic temporal contrast sensitivity measured with sinusoidal grating stimuli also varies with retinal illuminance,⁴³ however there are two key differences when compared to performance measured with achromatic stimuli. Firstly, chromatic functions are generally low-pass, that is, sensitivity is similar for a range of low temporal frequencies before falling off at higher temporal frequencies. Secondly, the

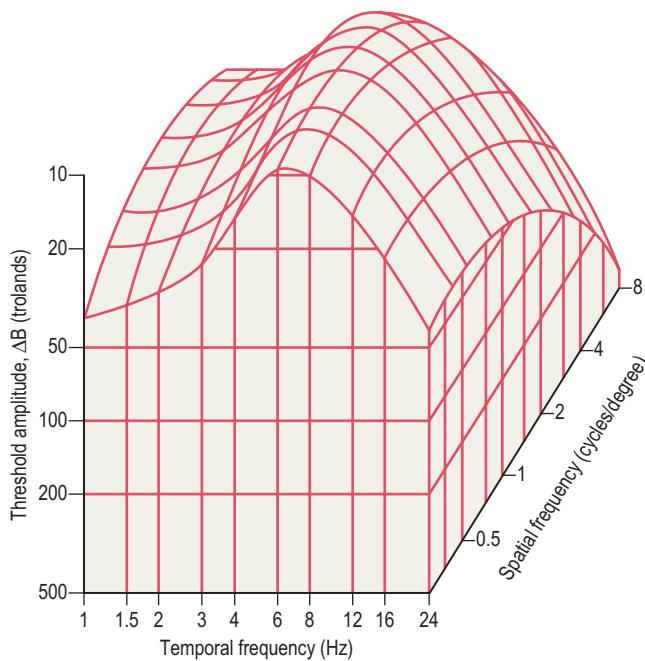

Figure 37.8 Human spatiotemporal amplitude threshold surface obtained with circular gratings of 16 degrees viewed binocularly with natural pupils. (Reproduced with permission from Kelly 1972.⁴⁶)

high-frequency cut-off is at lower temporal frequencies, that is, a lower CFF is found for chromatic in comparison to achromatic stimuli for a given retinal illuminance.⁴³

Spatial effects on temporal sensitivity

The work of De Lange⁴⁰ and Kelly⁴² describes our temporal contrast sensitivity characteristics, that is, how sensitive we are to temporal sinusoidal variations in stimulus contrast. This does not consider the effect that the spatial characteristics of the light source have on sensitivity. Human contrast sensitivity depends on both the spatial and temporal properties of the stimulus.^{44,45} Figure 37.8 shows a surface plot of the human *spatiotemporal contrast sensitivity* function, as derived by Kelly, from a large number of psychophysical measurements.^{44,46,47} One axis of the graph shows the temporal frequency of the stimulus; the other shows the spatial frequency. The height represents the observer's contrast sensitivity for the particular spatial and temporal conditions.^{44,47,48} Paths running through the curve parallel to the temporal frequency axis represent the temporal contrast sensitivity functions, and those running parallel to the spatial frequency axis represent the spatial contrast sensitivity functions. The temporal contrast sensitivity function is band-pass at low spatial frequencies, becoming low-pass at high spatial frequencies.

Mechanisms underlying temporal sensitivity

The shape of the human spatial contrast sensitivity function has been explained in terms of a multiple-channel model in which the total curve is the window of a number of channels, each tuned to a different peak spatial frequency.^{49–51} Similar to spatial processing, there is evidence for a discrete number of channels for temporal processing, each tuned to a different peak temporal frequency.^{52–55} There appear to be fewer

independent temporal frequency filters than there are filters conveying spatial frequency information. The number of temporal mechanisms identified has been shown to be dependent on the spatial frequency of the stimulus, in addition to the retinal location.

How can we determine whether different mechanisms are governing performance? One method relies on the assumption that different mechanisms result in different subjective representations of the stimulus; that is, when separate mechanisms are governing detection, the stimulus looks different. Kelly⁴⁴ and Kulikowski⁵⁶ report that flickering gratings at threshold produce one of three percepts depending on the spatiotemporal parameters of the grating: slow flicker, apparent motion, or frequency doubling (i.e. the perceived spatial frequency is twice the actual spatial frequency). This is consistent with three mechanisms underlying temporal processing. Watson & Robson⁵⁴ measured temporal discrimination, that is, the ability to determine that stimuli are flickering at different rates. For grating patches of 0.25 cycle per degree, there were three temporal frequencies that were uniquely discriminable, which Watson & Robson⁵⁴ interpreted as evidence for three unique filters mediating temporal processing. Mandler & Makous⁵³ modeled temporal discrimination performance and also found evidence for three mechanisms underlying temporal processing.

An alternative method for identifying mechanisms underlying visual processing is that of *selective adaptation*. If a stimulus that activates one mechanism to a greater extent than another mechanism is presented, the sensitivity of the activated mechanism will be selectively depressed if the stimulus is viewed for a prolonged period. This should allow other, less sensitive mechanisms to detect the stimulus and hence allow their profile to be explored. Selective adaptation has been widely used to isolate the mechanisms underlying color vision processing.⁵⁷ Hess & Snowden⁵² used selective adaptation with temporal stimuli to uncover temporal mechanisms; an example of their data is displayed in Figure 37.9. The first stage of these experiments (not shown in the figure) involved measuring foveal contrast detection thresholds for a wide range of spatial and temporal conditions. These measures were used to set the contrast of the *probe* stimulus, which was set to be just detectable (4 dB above threshold). The detectability of this probe stimulus was then measured in the presence of masking stimuli of the same spatial frequency but different temporal frequency. The contrast of the masking stimulus was varied until the probe was just visible.

Figure 37.9A presents data for three probes presented foveally with no spatial content (0 cycles per degree) but flickering at either 1, 8, or 32 Hz. The figure shows the contrast sensitivity of the mask plotted against the mask temporal frequency. Three mechanisms are revealed: one low-pass (red circles) and two band-pass (blue circles, green triangles). Figure 37.9B shows data for a probe of 3 cycles per degree, and only two mechanisms are revealed. The band-pass mechanism, centered on higher temporal frequencies in Figure 37.9A disappears when the spatial frequency content of the stimulus increases. Using a similar method, Snowden & Hess⁵⁸ have shown that for retinal eccentricities of 10 degrees, only two mechanisms are found, reducing to a single mechanism at eccentricities of greater than 30 degrees.

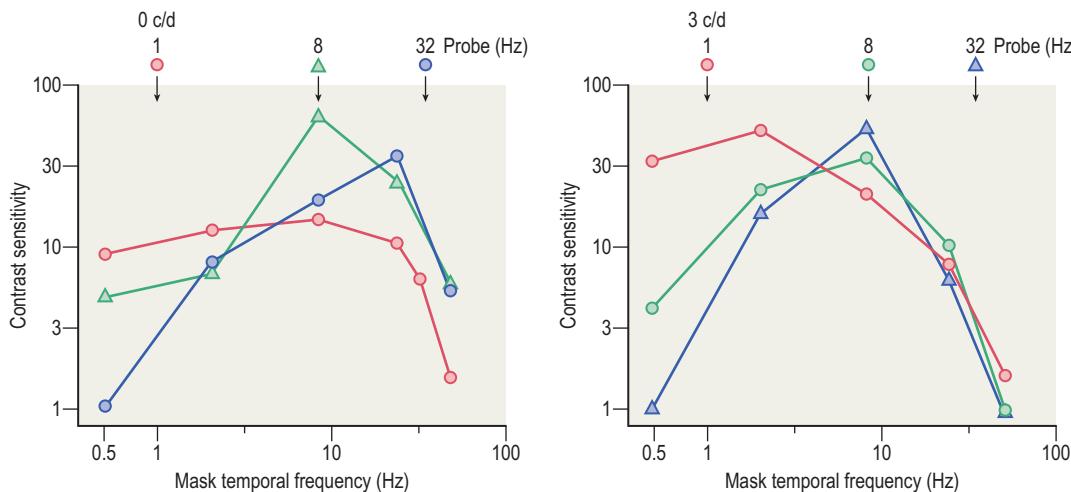

Figure 37.9 Properties of temporal mechanisms identified using a selective adaptation method. (Reproduced with permission from Hess & Snowden 1992.⁵²) Mask contrast sensitivity is plotted against mask temporal frequency for detection of a just suprathreshold probe. Data are for probes of 1, 8, and 32 Hz. The left panel shows data for a probe of 0 cycles per degree, for which three mechanisms are revealed: one low-pass and two band-pass. The right panel shows data for a 3 cycle per degree probe, and only two mechanisms are revealed.

More recent evidence suggests that these channels are not as independent as initially thought. Using a masking paradigm, Cass & Alais⁵⁹ demonstrated two channels underlying human temporal vision. High-frequency masks were able to suppress low-frequency targets suggesting interaction between temporal channels. The high-frequency channel was orientation invariant, which suggests a precortical origin (as significant orientation selectivity of visual neurons is not apparent until V1). In contrast, the low-frequency filter demonstrated orientation dependence, suggesting a cortical origin.

So what is the neural basis of these psychophysically measured temporal channels? Visual information from the retina is carried to the visual cortex, via the lateral geniculate nucleus, by several major neural pathways (magnocellular, parvocellular, and koniocellular). These pathways have been shown to carry largely independent, but sometimes overlapping, visual information. Magnocellular neurons are capable of processing achromatic fast flicker.^{60,61} Parvocellular retinal ganglion cells are well established to be the physiological substrate for red-green chromatic modulation.⁶¹ It is important to note, however, that retinal ganglion cell responses persist at considerably higher temporal frequencies than the human psychophysical CFF.⁶² This is particularly the case for chromatic modulation where the human psychophysical function limit is approximately 10–15 Hz, yet parvocellular retinal ganglion cells will respond up to 30–40 Hz. These differences are explained by models where responses from multiple single retinal cells converge on cortical detection mechanisms. The exact manner in which this convergence occurs and how the site of convergence is represented in the visual cortex is an active area of current research.^{20,63,64}

Surround effects on temporal sensitivity

Our sensitivity to temporal variations depends not only on the properties of the flickering light but also on those of the background surrounding the light. In the dark (scotopic conditions), detection of light increments is mediated by rods, and in the light (photopic conditions), detection is mediated by cones. For flicker sensitivity, it has been shown

that when photopic flickering lights are presented on dark backgrounds, interactions between rods and cones (rod-cone interactions) act to decrease sensitivity.^{65–70} The effects of rod-cone interactions on flicker sensitivity are most significant at high temporal frequencies (Fig. 37.10) and in the retinal periphery. Suppressive effects between cone mechanisms of flicker thresholds (e.g. long-wavelength-sensitive cones and medium-wavelength-sensitive cones) have also been demonstrated.^{71,72}

Within the photopic range, luminance differences between a flickering target and its surround are particularly important in determining temporal contrast sensitivity for low temporal frequencies.^{73–76} This is illustrated in Figure 37.11. The crosses represent the temporal contrast sensitivity for a surround equal to the average luminance of the flickering light (25 cd/m^2), and sensitivity at low temporal frequencies is constant under this condition. For either a dark surround (0 cd/m^2 , squares) or a light surround (50 cd/m^2 , circles), the sensitivity drops off at low temporal frequencies.

The presence of a surround differing in luminance from that of the flickering target creates a contrast border at the edge of the target. Spehar & Zaidi⁷⁶ have demonstrated that the presence of such a border decreases temporal contrast sensitivity. Whether the background is brighter or dimmer is not important; rather the decrease in temporal contrast sensitivity depends on the magnitude of the contrast at the border, with larger border contrasts resulting in larger decreases in temporal contrast sensitivity at low temporal frequencies. In short, we are most sensitive to temporal changes when the luminance of the background is matched to the average of the flickering target. One experimental paradigm in which such surround effects become important is the case of luminance-pedestal flicker, which is discussed in the following section.

Differences between mean-modulated and luminance-pedestal flicker

Historically, studies of temporal sensitivity have generated flicker using one of two methodologies, which are illustrated

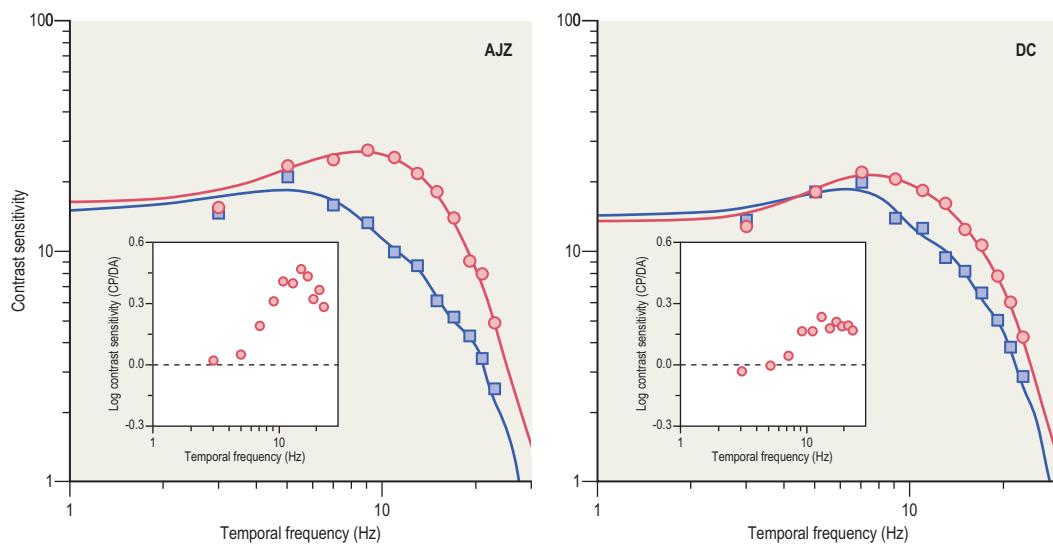

Figure 37.10 The effect of rod–cone interactions on temporal contrast sensitivity. Temporal contrast sensitivity to a 80 photopic troland sinusoidal stimulus measured after (1) 30 minutes of dark adaptation (closed squares) where the rods are fully sensitive; and (2) during the first 5 minutes following the termination of a 2-minute exposure to a 10,000 troland broad band light (partial rod bleach). After dark adaptation, temporal contrast sensitivity is attenuated for temporal frequencies above 6–8 Hz. Panel insets show the difference in log contrast sensitivity between the two conditions for each observer. (Reproduced with permission from Zele et al 2008.⁶⁵)

schematically in Figure 37.12.⁷⁷ The upper panel of Figure 37.12 illustrates mean-modulated flicker, in which flicker is modulated about a mean luminance. Flicker generated in this fashion results in no change in the time-averaged luminance (examples of studies using mean-modulated flicker include those by De Lange⁴⁰ and Roufs⁷⁵). The lower panel of Figure 37.12 illustrates luminance-pedestal flicker, in which flicker is generated by modulating a luminance increment over time. This results in both a flickering component and an increase in time-averaged luminance above the background level (examples of studies using luminance-pedestal flicker include those of Alexander & Fishman;⁶⁹ Eisner,⁷⁸ Eisner, Shapiro & Middleton;⁷⁹ and Anderson & Vingrys⁷⁷). Because both of these methods have been used to assess temporal sensitivity, it is important to understand whether they yield equivalent or differing results.

Luminance-pedestal flicker yields equivalent results to mean-modulated flicker only if the luminance pedestal has no effect on thresholds, which seems unlikely. In the previous section, we discussed how flicker sensitivity changes with light adaptation (see Fig. 37.10); as such, it may be expected that the local increase in luminance created by the luminance pedestal may act to increase thresholds. This is the case and has been reported by Anderson & Vingrys.⁷⁷

Furthermore, the presence of the pedestal causes a difference between the surround and the flickering target. The surround affects temporal sensitivity (see Fig. 37.11), so it is likely that the presence of a non-luminance-matched surround, created by the very nature of the luminance-pedestal flicker stimulus, will result in interactions that alter our sensitivity to this type of target.⁷⁶ It has been shown that both local adaptation mechanisms and surround interactions are important to explaining the differences in thresholds between mean-modulated and luminance-pedestal flicker thresholds.^{80,81}

The effects of flicker on perception

The presence of flicker can alter both the apparent color and brightness of a light.^{82–88} When a light is flickered, its apparent brightness varies depending on the frequency of the flicker, with maximum apparent brightness occurring between 5 and 20 Hz. This phenomenon is known as the *Brücke brightness enhancement effect*.⁸⁹ Such brightness enhancement can be demonstrated experimentally by matching the brightness of a flickering light to that of a non-flickering standard.⁸⁵ When the light is flickered at rates faster than those that result in brightness enhancement, the apparent brightness of the flickering light decreases. Eventually, the apparent brightness plateaus, and at rates beyond the CFF, the apparent brightness is the same as the apparent brightness of a steady light equal to the time-averaged luminance of the flickering light. This observation was made by Talbot⁹⁰ and Plateau⁹¹ and is known as the *Talbot–Plateau law*. Lights flickering above the CFF, at which point flicker is invisible, appear identical to steady lights of the same chromaticity and time-averaged luminance. Under most conditions of adaptation, the Talbot–Plateau law appears to hold. One exception is the case of blue targets presented on bright yellow backgrounds, in which case the target appears more yellow than a steady light, even when it is not visibly flickering.⁸⁸

Temporal phase segmentation

An important task of the visual system is to distinguish objects from their background, a task known as *image segmentation* (see Chapter 32). Useful information for the process of image segmentation includes differences in luminance and color between the image and its background. Differences in temporal phase are also sufficient for image segmentation.^{92–95} For example, if a field of identical dot elements is rapidly flickered from black to white in phase

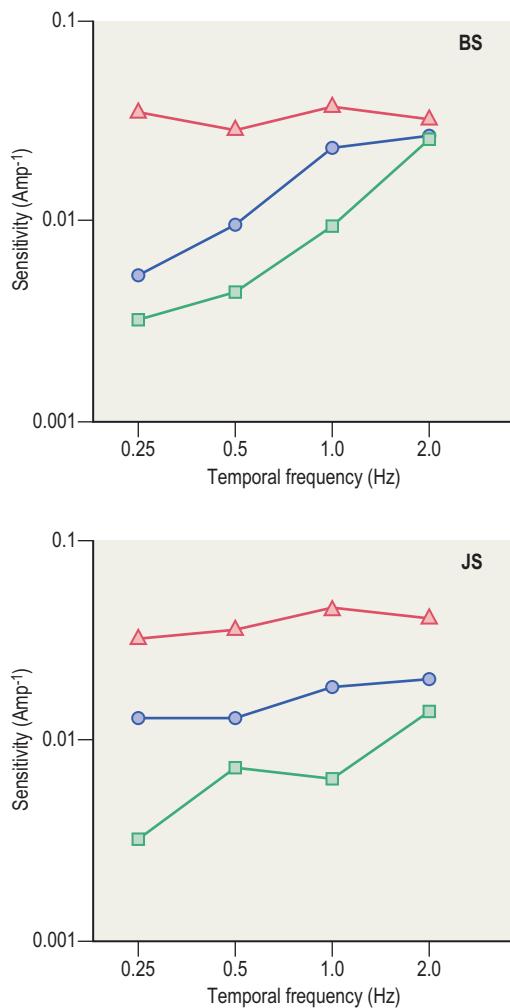

Figure 37.11 Surround effects on temporal sensitivity. (Reproduced with permission from Spehar & Zaidi 1977.⁷⁶) Amplitude sensitivity is plotted as a function of temporal frequency for different surround conditions: squares, 0 cd/m² (dark surround); triangles, 25.0 cd/m² (equiluminant surround); and circles, 50 cd/m² (light surround).

(i.e. all dots appear white simultaneously, then black simultaneously), the field appears to be uniformly flickering. If, however, elements in a subregion flicker in counterphase to the rest (i.e. within the subregion the dots are white when those outside are black), a contour between the subregion and the rest of the display is observed. At high temporal frequencies (greater than approximately 10 Hz), the difference in phase of individual elements cannot be detected; however, the contour between regions is easily visualized provided the gap between regions is less than about 0.4 degree.^{93,95} Temporal image segmentation is possible only at low temporal frequencies for chromatic stimuli.⁹⁵

Clinical applications of temporal sensitivity measurements

Measurements of temporal processing have been used extensively for clinical testing. Both measures of CFF and temporal contrast sensitivity have been used to explore visual function in disease. Often, these measures are performed across the visual field, with use of perimetric strategies (see

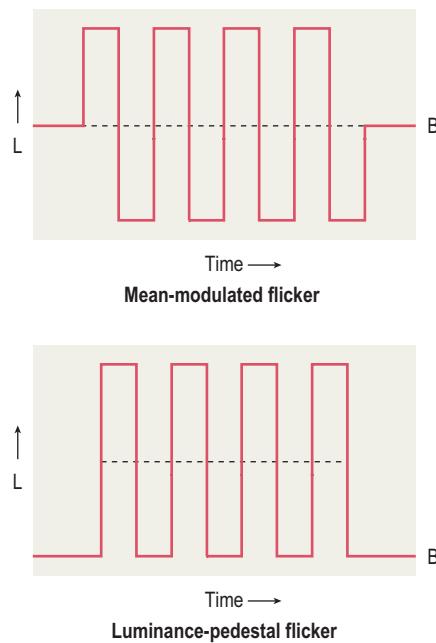

Figure 37.12 Schematic of mean-modulated (upper panel) and luminance-pedestal (lower panel) flicker from Anderson & Vingrys. (Reproduced with permissions from Anderson & Vingrys 2000.⁷⁷) The time-averaged luminance during the presentation of flicker is represented by the dashed lines, and B represents the background luminance. Note that for luminance-pedestal flicker, the time-averaged luminance is greater than the background by an amount that is the luminance pedestal.

Chapter 35). There are a number of different perimetric techniques for exploring temporal sensitivity across the visual field: CFF perimetry (which measures the CFF for small spot targets at various field locations), temporal modulation perimetry (which measures temporal contrast sensitivity for small spot targets either about a mean luminance or displayed on a luminance pedestal), and frequency doubling perimetry. Frequency doubling perimetry measures contrast sensitivity for patches of sinusoidal grating of low spatial and high temporal frequency, parameters that result in the grating appearing to have twice its actual spatial frequency.

The development of perimetric methods for measuring temporal sensitivity has been largely directed to the detection of glaucoma or identification of glaucomatous visual field progression.^{96–103} Abnormalities in temporal processing have also been identified in a range of other diseases, using perimetric and other strategies, including: Parkinson's disease, dyslexia, age-related macular degeneration, multiple sclerosis, optic neuritis, high-risk drusen, central serous chorioretinopathy, and migraine.^{104–115}

Temporal segmentation stimuli have also been used in a clinical setting to assess the patency of the magnocellular system. Letters created from small rapidly flickering dots are presented, and the subject must then identify the letters. The dots within the letters flicker in opposite phase to the dots external to the letter. Temporal segmentation stimuli have been used to identify abnormalities in temporal sensitivity in dyslexia and glaucoma.^{116–119} A new commercially available perimeter (the Heidelberg Edge Perimeter) utilizes the principle of temporal segmentation.

Motion processing

The detection of motion is an extension of temporal processing that forms a far-reaching separate area of study. *Motion* is a change in spatial position over time. Indeed, practically everything of visual interest in the world is moving, if not as a result of movement of the object itself, then by movement of the observer's head or eyes, causing the image on the retina to move. As we have already discussed, the ability of the visual system to detect temporal changes in luminance is exquisite. The visual system is also extremely sensitive to changes in spatial position. Hence, it may seem that to extract motion information, all that is needed is a comparison of separate measurements of an object's location at various times. Nevertheless, special visual mechanisms are specifically used for the processing of the linked spatiotemporal information that constitutes motion. This section briefly describes some perceptual and psychophysical data on human motion perception. A brief description of the neurophysiologic substrates underlying motion perception is included because this provides a basis for understanding the applications of motion tasks to the study of functional visual loss in disease. There are a number of detailed reviews of motion processing elsewhere (for example: Derrington et al.,¹²⁰ Vaina & Soloviev¹²¹).

Psychophysical and perceptual evidence for unique motion processing

A number of perceptual phenomena provide evidence for the existence of mechanisms designed specifically to process motion information. One of these is known as the *motion aftereffect*, which occurs after prolonged viewing of a moving stimulus (this is also known as *motion adaptation*).^{122–125} After prolonged staring at a moving stimulus, stationary objects appear to move in the opposite direction and the apparent speed of moving objects is distorted. Importantly, the apparent position of such stationary objects does not change, suggesting that motion and position are encoded separately.

Another example demonstrating that the perception of motion is not merely a simple representation of physical motion is that of *apparent motion*. Apparent motion occurs when spatially separate lights are flashed in sequence, giving the perception of movement despite each light remaining

stationary. This phenomenon is sometimes used in shop fronts, where the motion induced by sequential flashing of lights is designed to draw attention. Apparent motion can be induced by a single pair of lights flashed in succession. This movement is also known as *phi* and was first described in detail by Wertheimer.¹²⁶

The neural encoding of motion

Further evidence for motion as a primary sensory dimension arises from the existence of distinct neuronal architecture capable of supporting the encoding of motion information. Hubel & Wiesel¹²⁷ observed that some neurons in cortical area V1 have directionally selective receptive fields. Cells with this property respond well when a stimulus moves in one direction, but they respond in a limited fashion, or not at all, when the stimulus moves in the opposite direction. Direction-selective neurons are not evenly distributed throughout area V1; they are predominantly located in layers 4A, 4B, 4C α , and 6.¹²⁸ Layer 4C α receives its main input from magnocellular pathways,¹²⁹ suggesting that the magnocellular pathway is part of a functional specialization designed to carry information about motion. As discussed earlier, magnocellular neurons are preferentially involved in the visual processing of flicker.^{60,130–132} Signals from the magnocellular pathway are passed from 4C α to layer 4B, from which neurons connect to cortical area MT (medial temporal, otherwise known as area V5).^{133–136} In area MT a high proportion of directionally selective cells are present (approximately 80 percent).^{137,138} It should be noted that not all magnocellular neurons follow the path to V5/MT; a number of neurons converge with the parvocellular neurons in area V1.^{139,140}

The importance of area V5/MT to motion perception has been demonstrated by behavioral studies of primates with selective V5/MT lesions. A V5/MT lesion causes performance deficits in motion tasks, without corresponding losses to visual acuity or color perception.^{141,142} Using a dynamic random-dot motion task, Newsome & Pare¹⁴¹ investigated motion perception in the presence of MT lesions in rhesus monkeys. This task requires the observer to identify the predominant direction of motion within a field of randomly moving dots (Fig. 37.13). The proportion of dots moving in a common direction (coherence ratio) is varied to determine the direction identification threshold. Key to this task is that the moving dots be selected randomly for each frame of

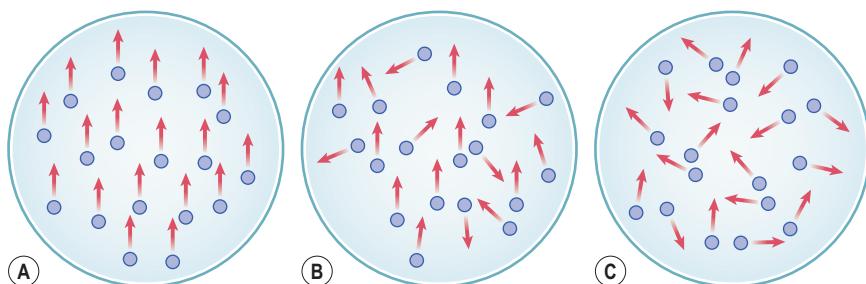

Figure 37.13 Representation of a global-dot motion stimulus. (Reproduced with permission from Edwards & Badcock 1994.¹⁴⁴) The subject is required to identify the global direction of motion of the dots (up/down). The signal strength is varied by changing the number of signal dots moving in that direction in successive frames. The remaining dots, the noise dots, moved in random directions. The dots that comprise the signal dots are chosen at the start of each frame. **(A)** One hundred percent signal strength condition. **(B)** Fifty percent signal strength condition. **(C)** Zero percent signal strength condition; there is no global motion of the dots, only random local motion.

Box 37.3 Motion perception

- Normal motion perception is a precursor for many tasks of daily living such as driving, avoiding obstacles, and navigating through the environment.
- Motion perception is tested widely throughout the clinical and behavioral sciences.
- Deficits in the ability to detect the direction of motion are considered cortical as the earliest stage of the visual processing hierarchy capable of discriminating direction of motion is V1.
- Deficits in the ability to integrate local motion signals into coherent global percepts imply extrastriate dysfunction.

presentation so that the direction of motion cannot be determined by tracking the location of a single dot. Rather, the local motion signals must be combined over a large area of the visual field to determine the global motion percept. Newsome & Paré¹⁴¹ found striking elevations in such motion thresholds to be present when selective lesions to area MT were made. Newsome et al¹⁴³ further demonstrated that the activity in a single MT cell correlated directly with the monkey's trial by trial performance in a motion discrimination task. They also demonstrated that microstimulation of tiny regions of MT can bias a monkey's motion perception in a manner predictable from the response characteristics of cells adjacent to the stimulating electrode.

Zihl et al,¹⁴⁵ Hess et al,¹⁴⁶ and Baker et al¹⁴⁷ provide a series of reports investigating the motion perception of a human patient with a bilateral loss of the superior temporal cortical region. This patient was found to have a specific deficit to motion processing while other measured forms of visual processing were normal or relatively intact. In particular, the patient performed poorly on a random-dot motion task similar to that used by Newsome & Paré.¹⁴¹ This pattern of deficit is consistent with that found when area V5/MT is lesioned in primates, providing evidence for a similar specialized area for motion processing in humans.

In summary, motion perception (Box 37.3) appears to be performed largely by the visual pathway leading from the magnocellular layers of the lateral geniculate nucleus through area V1 to area MT. This pathway is not the only carrier of motion information in humans, however; area MT also receives input from the superior colliculus via the pulvinar.¹⁴⁸ In addition, Nawrot & Rizzo¹⁴⁹ have also demonstrated that the cerebellum may also play an important role in human motion processing. In their study, motion direction discrimination deficits were found in a group of patients with acute midline cerebellar lesions. These patients were unable to discern the direction of motion in a global motion task, similar to the deficit reported following MT lesions in primates.^{141,142} Area V3 also appears important to human motion perception, particularly when spatial judgments are required. Brain imaging studies support the importance of areas V5/MT and V3 to human visual motion perception.^{150,151}

While the magnocellular pathways possess the temporal resolution capacity to subserve motion perception there is clear evidence for additional input of information from orientation and form processing to motion perception. In 1999 Geisler¹⁵² proposed a new model for motion perception that

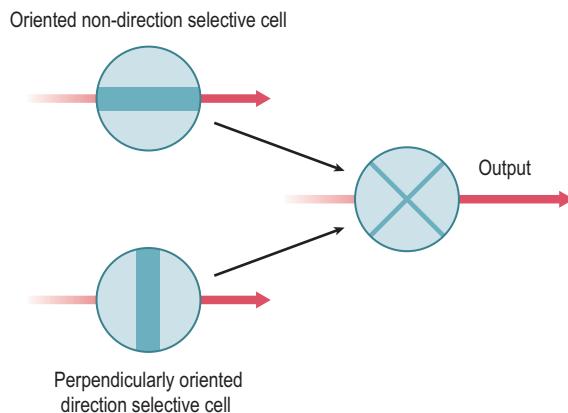

Figure 37.14 Schematic of the motion streak model of motion processing described by Geisler.¹⁵⁰ The output of a direction selective neuron is combined with that of a neuron, or population of neurons, with oriented receptive fields but no directional selectivity that respond to the motion streak created during the temporal integration period. This combination of outputs significantly enhances the selectivity of the motion detection unit.

involves the combination of responses from detectors oriented orthogonal to the direction of motion and those oriented along the direction of motion (Fig. 37.14). The premise for this model was the observation that the visual system integrates information over time, hence that moving objects should leave behind 'motion streaks' along the direction of motion. Such streaks potentially provide information about the direction of image motion that is available to orientation selective neurons of the primary visual cortex. There is psychophysical evidence^{152–154} for visual motion perception being influenced by motion streaks as well as neurophysiological evidence for responsivity to motion streak signals in primary visual cortex.¹⁵⁵ It has therefore become apparent that motion and form processing are far more interlinked than previously thought. Such interlinking needs to be considered in the interpretation of clinical deficits of motion perception.

Clinical applications of motion processing

Motion perception has been explored extensively in a range of clinical conditions because motion is a unique sensory dimension, processed by a relatively well-understood neural pathway. As discussed in the preceding section, the detection of stimulus motion occurs early in the motion pathway (retina to V1), the ability to discriminate the direction of motion is first present in cortical neurons within V1, and the ability to extract global motion information occurs in the extrastriate visual areas (MT or higher). The clinical study of motion processing often uses tasks chosen to localize deficits of motion processing to these sequential stages. For example, if the ability to detect stimulus motion and discriminate its direction is intact yet global motion perception impaired, this suggests damage at extrastriate areas.

The ability to both detect motion and discriminate its direction declines with age.^{156,157} Motion processing abnormalities have been documented in Parkinson's disease.^{158,159} Global motion processing, as measured using random-dot global motion stimuli (similar to that illustrated in Fig. 37.12), has been shown to be affected in people with migraines¹⁶⁰ and Alzheimer's disease.¹⁶¹

Visual motion processing has also been extensively studied in individuals with glaucoma. Perimetric approaches to testing motion processing have been developed because the visual dysfunction associated with glaucoma is more readily measured in the peripheral visual field (see Chapter 35). For example, random-dot motion perimetry assesses global motion perception at discrete locations across the visual field. A number of studies have found random dot motion perimetric deficits in glaucoma.^{162–169} The magnitude of such motion deficits in glaucoma has been shown to be correlated with the extent of loss for contrast discrimination tasks designed to assess magnocellular processing, consistent with the source of the motion perception loss arising prior to cortical processing.¹⁶⁵ Peripheral motion displacement thresholds (the minimum distance for which a line or random-dot pattern that is laterally displaced appears to move) are also elevated in glaucoma.^{167,170–172}

The temporal properties of vision are critical to the detection and perception of visual stimuli. The visual processing of motion, flicker, and other temporal characteristics is vital for us to effectively interact with and navigate through our environment. Because these visual functions are highly susceptible to pathophysiologic insults to the visual pathways, tests of motion sensitivity, flicker sensitivity, and other temporal visual functions are extensively used as sensitive clinical diagnostic procedures.

Development of Vision in Infancy

Anthony M. Norcia

The limited behavioral repertoire of the infant and the impossibility of instructing the test subject have made it necessary for vision scientists interested in human visual development to adapt the classical methods of psychophysics and electrophysiology for use with infants and pre-verbal children. First these methodological adaptations and their interpretation in the context of a hierarchical model of visual processing are considered. Within this framework, the criteria for selecting material for review are discussed.

Methodologies for assessing infant vision and their interpretation

Preferential looking

Infants' spontaneous visual fixation is attracted to certain stimuli more readily than to others.^{1,2} In particular, infants prefer to look at patterned stimuli rather than regions of uniform brightness. This spontaneous behavior has served as the basis for a quantitative measure of stimulus visibility known as *forced-choice preferential looking* (FPL).³ In the FPL task, the infant is confronted with a randomized series of patterns of varying visibility, presented either on the left or the right of a test screen. An observer judges whether the infant's fixation behavior is biased to the left or the right on a trial-by-trial basis. If the observer's judgments agree (or disagree) systematically with the actual position of the stimulus, it can be said that the infant's behavior is under the control of the stimulus. Distributions of the observer's judgments for a series of stimulus values are used to plot a psychometric function that relates the observer's percent correct to the stimulus values presented to the infant. Thresholds are estimated by curve fitting and interpolation to a criterion value of percent correct.

Visual evoked potentials

Visual evoked potentials (VEPs) are electrical brain responses that are triggered by the presentation of a visual stimulus. VEPs are distinguished from the spontaneous electroencephalogram (EEG) due to their consistent time of occurrence after the presentation of the stimulus (time-locking).

For example, the abrupt contrast reversal of a checkerboard pattern consistently produces a positive potential at the surface of the scalp at a latency of approximately 100 msec in adults.⁴ Time-locked responses to abrupt presentations are referred to as *transient VEPs*. A second method of recording VEPs, the steady-state method, uses temporally periodic stimuli. For commonly used pattern reversal stimuli, the frequency of the repetition is often specified as the pattern reversal rate in reversals per sec. This rate is twice the stimulus fundamental frequency (in Hz), which is more commonly used to describe the temporal frequency of pattern onset–offset stimuli. As the stimulus repetition rate increases, the responses to successive stimuli begin to overlap. At high stimulation rates, the response is comprised of only a small number of components that occur at exact integer multiples of the stimulus frequency. Activity at each of the frequency components of the steady-state response is characterized by its amplitude and phase, where phase represents the temporal delay between the stimulus and the evoked response.

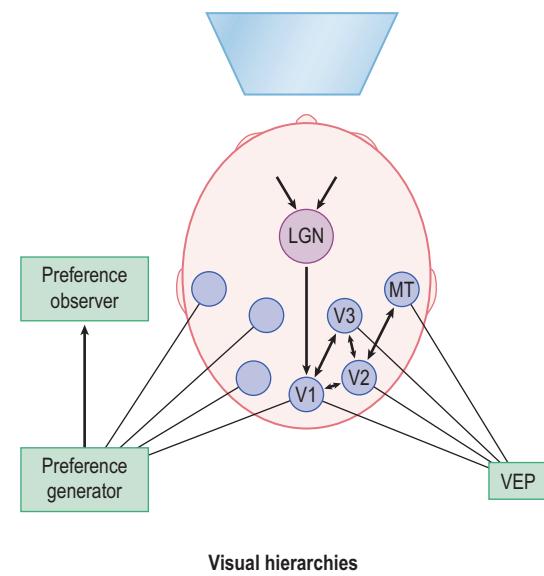

The surface-recorded VEP reflects the activity of cortical visual areas, with contributions from subcortical generators being apparent only under highly specialized recording conditions.^{5–7} The primary adaptations of adult VEP recording techniques for infants involve the control of fixation through the use of fixation toys or super-imposed video images and the rejection of trials when the infant's fixation was not centered on the stimulus.

Ocular following movements

Both infants and adults make reflexive eye movements following the presentation of a moving target. Optokinetic nystagmus (OKN) is characterized by a repetitive saw-tooth waveform. Rapid displacement of large fields also elicits short latency ocular following movements.⁸ Ocular following can also take the form of slower, pursuit-like movements.⁹ Reflexive eye movements are controlled by a combination of cortical and subcortical mechanisms.¹⁰ Infrared tracking, electro-oculography, and naked-eye observation of the preponderant direction of eye motion (DEM) are the primary assays used in infants and pre-verbal children.^{9,11}

Hierarchy of visual processing

Figure 38.1 presents the schematic framework of visual processing that is used to focus the discussion of empirical studies of visual function in infants and young children. The visual processing hierarchy is divided into three stages: early, middle, and late. The progression from early to late correlates roughly with an ascent from the retina to the cortex and with a functional hierarchy corresponding to the complexity of the information extracted at each level. In this view, early vision begins in the retina and continues through the lateral geniculate and on into primary visual cortex. By the level of primary visual cortex, stimulus attributes such as orientation, direction of motion, and disparity have been extracted from the retinal images.^{12–14} Middle vision – the process by which local measurements of image features such as line orientation are integrated across space – begins no sooner than primary visual cortex and no doubt extends through a number of first- and second-tier extrastriate visual areas. The content of the representation at the level of middle vision

	Early	Middle	Late
Attributes	Contrast Color Disparity Direction Speed Orientation	Collinearity Symmetry Figure/ground Occlusion Texture Depth Shape	Object categories recognition
Where	Retina, LGN, and V1	V1-Vn	Face area, Place area Temporal lobe
When	Up to 100 msec Sensation	100 to 200 msec Perception	After 200 msec Cognition

Figure 38.1 Visual processing hierarchy. Top panel: schematic diagram of early visual pathways. VEP method records activity directly from several early visual areas. Preference-based behavioral measures require an additional “stage” at which preference and spontaneous fixation behavior is generated as well as a behavioral observation stage.

includes information regarding the shape of extended contours, figure/ground relationships, the symmetry of objects, surface depths, but not the identity of the objects in the scene. The identification of objects (object recognition), which involves not only visual perception, but memory, is conceptualized as occurring in higher-order visual and visual association areas functionally associated with “late vision”.

Each of the different methods for assessing visual function in the pre-verbal child has a different relationship to the visual processing hierarchy. The FPL technique depends on the integrity of the early visual system as well as additional mechanisms responsible for the spontaneous preference for pattern (labeled “preference generator” in Figure 38.1). Whether or not middle or late mechanisms are invoked may depend on the discrimination the infant is called on to perform. Orienting behaviors could be driven from many levels of the cortical hierarchy or from subcortical structures. In any case, the output of the preference generator must produce robust fixation behavior that can be detected reliably by the FPL observer. Information regarding the location of the stimulus can be lost at the level of early vision, or at the level of the preference generator or by the observer of the infant’s behavior. Given the additional sites for potential information loss after early vision, FPL is a conservative estimator of the function of the early part of the visual pathway.

Like FPL, the VEP depends on the integrity of the retina and an unknown amount of cortical processing. Fixation, in the sense that the stimulus must fall on central retina is required, but spontaneous orientation to a preferred stimulus is not. Electrical activity in the visual pathway is obscured by non-stimulus-related electrical activity associated with the EEG and muscle activity, as well as electrode-motion artifacts. The obscuring experimental noise can be reduced effectively, either through time-locked averaging or spectral analysis. At this point relatively little is known about the contribution of extrastriate cortical areas to the VEP. Given this, the VEP is quite likely to reflect the capabilities of early vision, but caution must be used in inferring the integrity of later stages of processing – especially if simple stimuli are used.

Ocular following movements require the integrity of the retina, certainly, but given the substantial role of subcortical mechanisms in the control of eye movements,¹⁰ it is difficult to specifically relate eye movement data to the hierarchy of cortical mechanisms in Figure 38.1.

This review emphasizes developmental studies that have used the VEP. The rationale for this choice is several-fold. First, there is now sufficient evidence to indicate that the infant VEP is generated distal to the site of orientation selectivity,^{15,16} direction selectivity,^{17–19} Vernier offset detection,²⁰ and binocular correlation detection.^{21,22} All these features are considered to be the outputs of early vision. In adults, it has been found that the VEP reflects both rivalry and suppression^{23–27} as well as several aspects of middle vision, including figure-ground segmentation based on either texture or motion.²⁸ Second, the VEP does not require visual preference or transfer of information through the observation of spontaneous behavior and is thus less likely to underestimate the capabilities of early vision. Third, the VEP provides a rich source of information regarding the temporal dynamics of the visual response. Finally, there are already

excellent reviews that have emphasized FPL and OKN measures of developing visual function.^{9,29–31} In deciding which studies to include, emphasis has been placed on those results that have been replicated by more than one research group, wherever possible. Data from the other methods are selectively discussed when these data can help to fill in gaps or when they illustrate particularly sharp contrasts.

Spatio-temporal vision

The retinal images contain a precise spatio-temporal mapping of the visual scene onto two-dimensional surfaces. At the most basic level of processing, the visual system must extract the contrast of the retinal images as a function of time and spatial scale. Visual sensitivity is limited by both spatial and temporal factors. Infant developmental studies have tended to focus on sensitivity along one dimension at a time – by measuring contrast sensitivity as a function of spatial frequencies for a fixed temporal frequency or vice versa. Sensitivity depends strongly on both parameters. While the FPL technique can be used at any combination of spatio-temporal frequencies, the eye movement and VEP measures each require temporally modulated stimuli. Given the fundamental importance of contrast sensitivity for subsequent visual processing, contrast sensitivity and the related function, grating acuity are among the few visual functions to have been studied extensively with each of the major methods discussed above.

Figure 38.2 plots peak contrast sensitivity as a function of age as determined by the steady-state VEP,³² directional eye

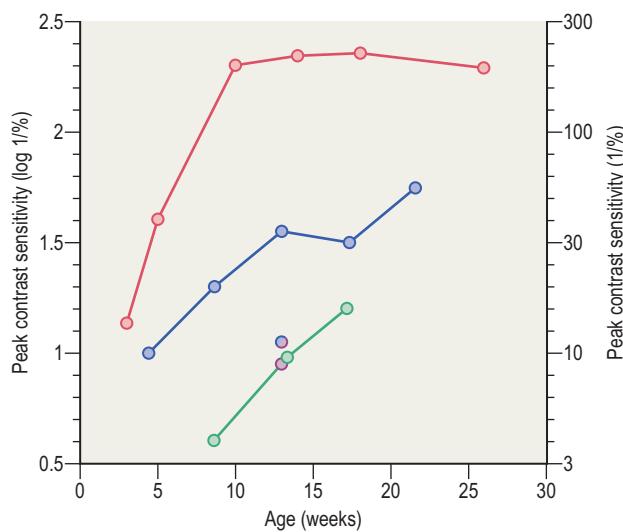

Figure 38.2 Peak contrast sensitivity measured with the steady-state (VEP), directional eye movement (DEM), and FPL methods. The VEP study³² (red circles) used grating patterns that were reversed in contrast at 6 Hz (mean luminance of 220 cd/m^2). Peak sensitivity was derived from recordings over the 0.25 to 1 cpd range. The DEM studies (blue circles,³³ half-filled circle³⁴) used 0.07 to 2.4 cpd gratings drifting at a constant velocity of 7 deg/sec or 0.25 cpd gratings drifting at 6 Hz. Dobkins & Teller³⁴ measured FPL thresholds for 0.25 cpd/6Hz, as well (purple circle). Rasengane et al³⁶ measured contrast sensitivity for 10 deg luminance fields over the 1 to 25 Hz range (green circles). Peak sensitivity at any temporal frequency is plotted. Contrast sensitivity improves rapidly within each method.

movements,^{33–35} and FPL^{34,36} methods. Each of these studies obtained peak sensitivity measures at a mid-range of temporal frequencies (around 5–10 Hz). There is considerable development of contrast sensitivity in each of the techniques, but the absolute contrast sensitivity is higher with the VEP. By 10 weeks of age, infant peak contrast sensitivity over the 0.25–1 cycle per degree (cpd) range is within about a factor of 2–4 of adult levels measured on the same apparatus.^{32,37} Skoczenski & Norcia³⁸ found a factor of 4 difference between infant and adult sensitivities at 1 cpd. Shannon and co-workers³⁹ found sensitivities at 1.2 cpd that were a factor of 11 lower than adults at 2 months, with the difference decreasing to a factor of 4 at 3 months. Contrast sensitivity measured with the steady-state reversal VEP develops over progressively longer intervals as spatial frequency increases³² (Fig. 38.3).

In contrast to the VEP, several behavioral measurements of contrast sensitivity in this age range are much lower than adult levels. Rasengane and colleagues³⁶ reported that low spatial frequency flicker sensitivity of 2-month-olds was a factor of 45 lower than adults, with 3- and 4-month-olds being a little less than 20 times less sensitive with FPL. Brown and colleagues³⁵ used a directional eye movement measure (0.31 cpd/ 15.5 deg/sec drift) and found that 3-month-olds were a factor of 100 less sensitive than adults on the same measure. Dobkins & Teller³⁴ measured both FPL and directional eye movement thresholds in 3-month-olds. They found that infants were almost 30 times less sensitive on the directional eye movement measure and about 60 times less sensitive when FPL and adults' forced choice thresholds were compared. FPL and directional eye movement thresholds were within 20% of each other in the infants. In adults DEM thresholds were higher than psychophysical thresholds by a factor of 2–3, depending on whether

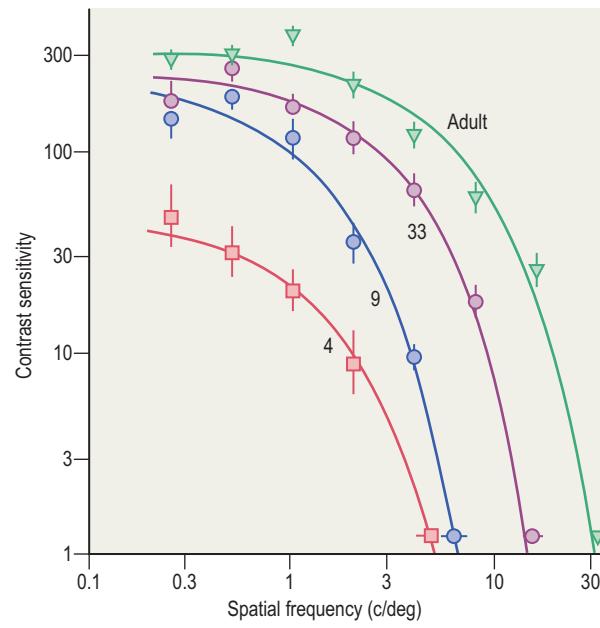

Figure 38.3 VEP contrast sensitivity is re-plotted from Norcia et al³² as a function of spatial frequency and age for 6 Hz pattern reversal. Sensitivity development is progressively delayed at higher spatial frequencies.

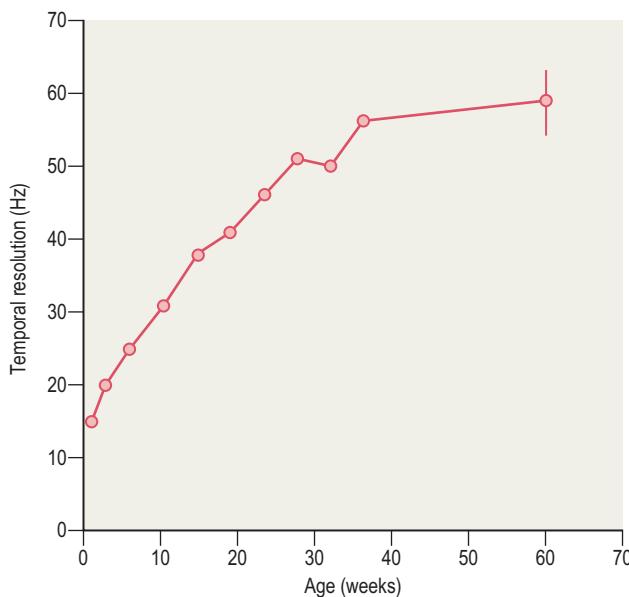

Figure 38.4 Flicker resolution frequency, measured with the steady-state VEP.¹⁵² Resolution frequency increased linearly up to age 40 weeks. Adult values are plotted at 60 weeks. Infants in the 20–30-week age range have resolution acuities that are nearly adult.

the subject's task was detection of the direction of motion or simple contrast detection.

Hainline & Abramov³³ used directional eye movements recorded by an infrared eye tracker to measure contrast sensitivity. The observer made a forced choice judgment on the output of the tracker (noise level 0.5 deg) rather than on naked eye observation. Contrast sensitivity with this method develops to adult levels by 5 months of age (see Fig. 38.2). Absolute thresholds are lower than those measured with the VEP by a factor of about 4. Hainline & Abramov's contrast sensitivities are higher than those observed by Dobkins & Teller³⁴ or Brown and colleagues³⁵ who used naked eye observation at substantially higher luminances. The difference in sensitivities obtained with naked eye and instrumented observation of eye movements suggests that at least some of the lower sensitivity seen in previous behavioral studies may have been due to information loss in the observer who is judging the infants' behavioral output.

Temporal resolution

Temporal resolution is highest for coarse stimuli. The highest temporal frequency to which the visual system responds undergoes a somewhat different developmental progression than that for spatial resolution at low temporal frequencies. Figure 38.4 shows the development of temporal resolution measured with luminance flicker (a low spatial frequency target) in a large group of 130 infants and 6 adults. Temporal resolution was determined from the highest flicker rate from a large series that produced a measurable response. Adult temporal resolutions are approached by 20–30 weeks of age, a time at which grating acuity is still significantly lower than in adults (see Figs 38.3 & 38.5). A psychophysical study in children 4–7 years of age found temporal resolution to be fully adult at age 4, but that grating acuity continued to improve until about 6 years of age.⁴⁰

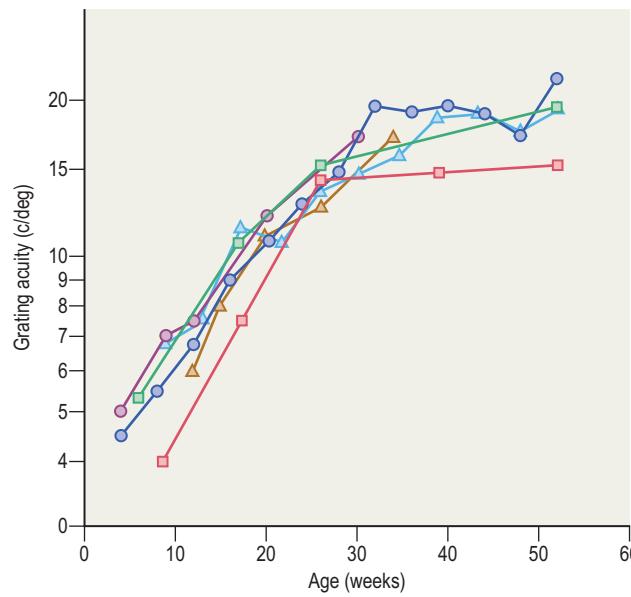

Figure 38.5 Grating acuity as a function of age for 5–10 Hz pattern reversal stimuli. Each study employed the swept spatial frequency technique. Acuity growth functions are similar across studies, with acuity increasing from 4–6 cpd in one month olds to around 15–20 cpd around 8 months of age. Data are re-plotted as follows: blue circles,¹⁵³ purple circles,³² tan triangles,¹⁵⁴ blue triangles,¹⁵⁵ red squares,¹⁵⁶ green squares.⁸⁹

Grating acuity

At the limit of the high spatial frequency limb of the contrast sensitivity function lies the observer's grating acuity. Grating acuity is limited by the optical quality of the eye, the spacing of the photoreceptors and the spatial pooling properties of the ganglion cells and subsequent receptive field mechanisms.^{41–44} Grating acuity is also limited by temporal factors, being maximal at low temporal frequencies.

VEP grating acuity has been measured most commonly using steady-state, pattern reversal targets in the frequency range of 5–10 Hz (10–20 contrast reversals per sec). The acuity measurement is extrapolated from the high spatial frequency portion of the amplitude versus spatial frequency function, an example of which is illustrated in Figure 38.5 for the spatial frequency sweep technique. In this method, originally developed by Regan,⁴⁵ the spatial frequency of a temporally modulated pattern is systematically changed (swept) over a large range of spatial frequencies that span the expected acuity limit of the observer. Figure 38.5 plots grating acuity as a function of age for such pattern reversal stimuli. Each study employed the swept spatial frequency technique. Acuity growth functions are similar across studies, with acuity increasing from 4–6 cpd in 1-month-olds to around 15–20 cpd around 8 months of age.

VEP acuity has also been measured with pattern onset-offset stimuli, in both transient and steady-state paradigms. Two studies of the transient on-off acuity growth function found that acuity improved from approximately 2 cpd at 1 month to 30 cpd by 5 months.^{46,47} A third study which used checks rather than gratings⁴⁸ found an acuity of 2.3 cpd (corrected for Fourier fundamental spatial frequency of the checks) at 8 weeks, with an increase to 8 cpd at 24 weeks.

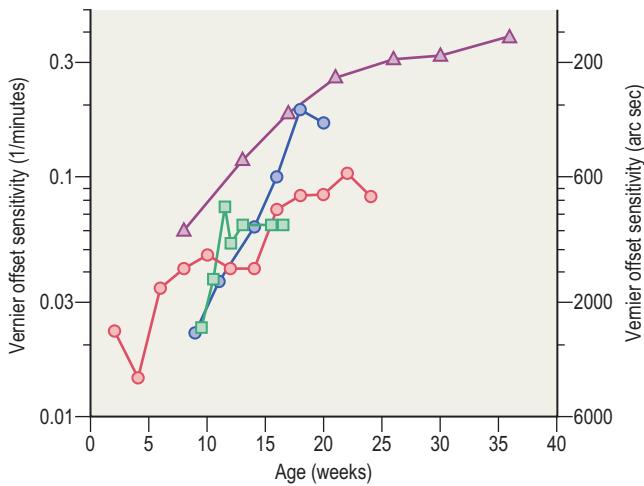

Figure 38.6 Behaviorally determined Vernier sensitivity from: triangles,⁵⁵ blue circles,⁵⁷ red circles,⁵⁹ squares.⁵⁰

When both transient onset–offset and 6 Hz contrast reversal stimuli were used to measure acuity in the same infants, two different rates of growth were found: transient onset–offset acuity increased 0.63 octaves per month versus 0.28 octaves per month with 6 Hz pattern reversal.⁴⁶ These observations suggest that the rate at which acuity increases depends on the response component being measured suggest that different post-receptor visual mechanisms have different rates of development.

Vernier acuity

Vernier acuity refers to a collection of spatial localization tasks requiring the detection of a misalignment relative to a reference. Adult Vernier thresholds are significantly better than would be predicted based on either the optical or anatomical properties of the eye. Therefore, Vernier acuity is considered one of the hyperacuities.^{49–51} Since cortical processing is believed to be a critical factor limiting the hyperacuities,^{52–54} the time course for the development of Vernier acuity has been investigated with great interest.

Most investigations of Vernier acuity during the first year of life have been cross-sectional, employing behavioral responses to moving stimuli.^{55–58} However, two studies used stationary stimuli.^{59,60} The results of several of these behavioral studies, plotted over the first 6 months of life, are summarized in Figure 38.6. On average, Vernier acuity improves by about a factor of 6–8 over the first 6 months of life, with the best thresholds recorded to be around 200 seconds, 1.3 to 1.8 log units poorer than adults.

While one group reported that by 5 years of age performance on their Vernier acuity task became comparable to that of adults,⁵⁸ others report that Vernier development is incomplete at age 5.^{61–63} Based on data from preschool children, Vernier acuity is 2 times the adult threshold at 5.6 years of age (confidence interval 3.5–6.5 years).⁶² Thus, there is some agreement in the literature that the development of Vernier acuity is incomplete during the early school years. However it is not clear if development is complete before 18 to 20 years of age.^{64–69} Typical adult thresholds are in the 3–8 second of arc range.^{69–71}

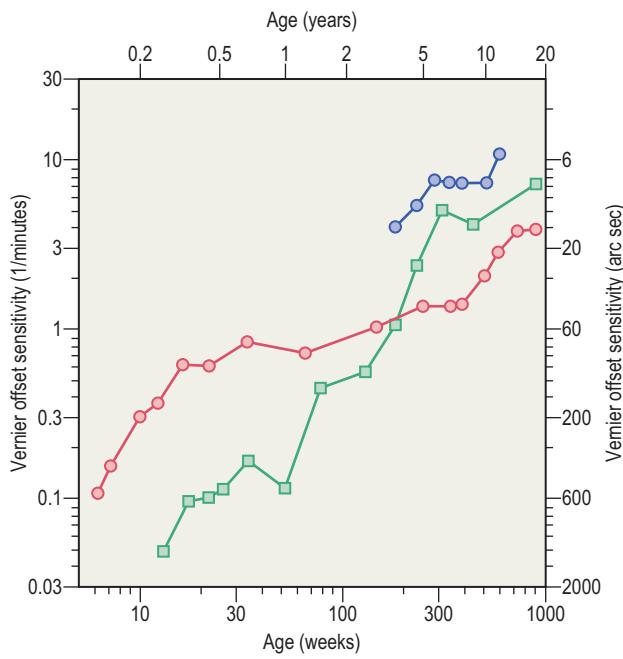

Figure 38.7 Vernier acuity determined by the visually evoked potential (red circles).⁷⁴ Shown for comparison are behavioral data from Carkeet and co-workers⁶² (blue circles) and from Zanker and colleagues (squares).⁵⁸

As noted above, the majority of the behavioral paradigms used to investigate the development of Vernier acuity contained motion. Skoczenski & Aslin⁷² have demonstrated that temporally modulated stimuli improve the Vernier thresholds of 3-month-old infants and suggest that Vernier thresholds obtained with moving stimuli may be governed by a local motion mechanism rather than a position-sensitive mechanism. Therefore, our understanding of the developmental time course of Vernier acuity and its relationship to the development of other visual functions is potentially confounded by some of the stimuli that have been used in behavioral paradigms to gain the infant's attention and interest in the task.

The visual evoked potential (VEP) offers a unique solution to this problem. Norcia and colleagues⁷³ have suggested that by analyzing the separate Fourier components in the steady state visually evoked potential, Vernier response components may be isolated from those arising from stimulus motion. The VEP response to the introduction of a Vernier offset (alignment/misalignment) differs from the response to the return to alignment (misalignment/alignment). This asymmetric response to the introduction and then removal of a Vernier offset is reflected in the odd harmonics of the response to the stimulus modulation. The even harmonics in the evoked potential are produced in response to the symmetrical spatial aspects of the stimulus modulation (e.g. local motion of the offset grating) and may be used to examine motion acuity. The results obtained with a sweep VEP technique⁷⁴ are shown in Figure 38.7. There is a rapid improvement in Vernier acuity over the first 4 months of life. By 6 months of age, Vernier acuity has improved by about a factor of 7 reaching a threshold of nearly 70 seconds, approximately one log unit poorer than the normal adult values obtained psychophysically. Between 6 months of age

Box 38.1 Developmental abnormalities of VEP grating and Vernier acuity

Abnormalities of VEP grating acuity have been found in amblyopia,^{81,82} cortical visual impairment,^{83,84} Down syndrome,⁸⁵ spastic cerebral palsy,⁸⁶ and albinism.⁸⁷ Exposure to environmental toxins during development (organic solvents⁸⁸), or nutritional status during infancy⁸⁹ also affect VEP grating acuity.

Vernier acuity measured psychophysically is often more affected than grating acuity^{90–93} and is better correlated with letter acuity than is grating acuity.^{90,93} Consistent with this VEP, Vernier acuity is more affected than grating acuity in children with cortical visual impairment.⁸⁴ VEP Vernier acuity is correlated with psychophysical Vernier acuity and with letter acuity in adults with amblyopia.⁹⁴

and 7.5 years, improvement occurs at a slower rate reaching about 40 seconds, a 1.75 times improvement over the course of about 7 years. After the age of 7.5 years there is another more rapid improvement in Vernier acuity. Although quantitatively better thresholds were obtained psychophysically by Carkeet and colleagues with stationary stimuli, there is a similar period during the early school years where no significant change in threshold was found.

The developmental time course for Vernier acuity appears to occur in at least 3 phases. There is a rapid development over the first 4–6 months of life, then a more gradual improvement up to about 7–10 years of age, followed by a more rapid improvement to reach adult levels no later than 18–20 years of age. Box 38.1 describes clinical applications of acuity measures and their interpretation.

Optotype acuity

Optotype recognition acuity as measured with standard eye charts shows a similar prolonged developmental time course. Improvement has been reported to continue until 25⁷⁵ to 29⁷⁶ years of age, reaching 0.56 MAR (minimum angle of resolution expressed in minutes of arc⁷⁵) to 0.67–0.69 MAR.^{76–78} At age 3–5 years, chart acuity is 1.25 MAR,^{79,80} about a factor of 1.8 poorer than the most conservative estimate of the adult acuity noted above. At 6.8 years of age, chart acuity has improved to 1.09 MAR,⁸⁰ a factor of 1.6 poorer than the most conservative estimate of normal adult recognition acuity.

Motion

The detection of motion involves the determination of speed and direction. The presence of direction-selective mechanisms early in development has been demonstrated using each of the three major methods, FPL, VEP and OKN. Directionally appropriate eye movements can be seen at term or even before.⁹⁵ Uncertainty remains as to whether these early ocular following responses are controlled by cortical or subcortical pathways. Direction selectivity has been demonstrated behaviorally using FPL and looking time-habituation methods by 6–8 weeks.^{96,97} VEP responses associated with changes of direction have been recorded by 10 weeks of age.^{17,19}

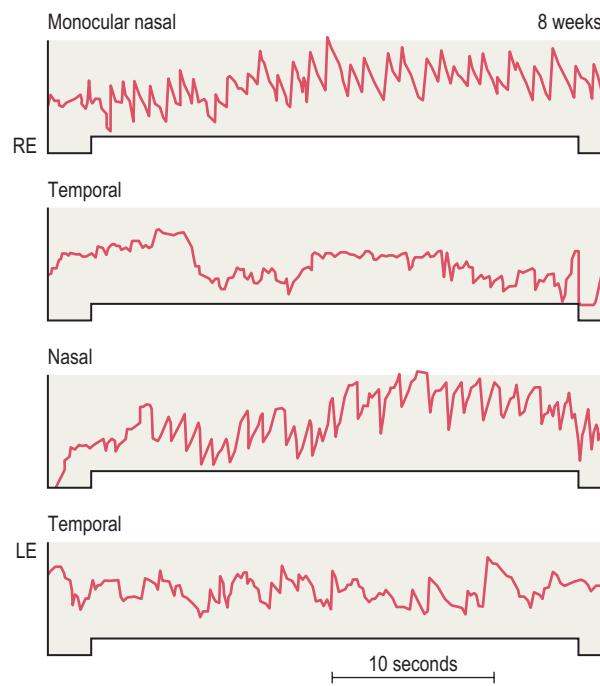

Figure 38.8 Directional asymmetry of monocular optokinetic nystagmus adapted from Naegele & Held.⁹⁹ Monocular OKN is robust for nasalward stimulus motion (left-ward motion in the right eye and right-ward motion in the left eye) but is weak for temporal-ward motion. This directional asymmetry declines during the first few months of life.

Motion direction asymmetries

On any measure, the adult visual system shows roughly equal sensitivity for all directions of motion.⁹⁸ Developing infants, on the other hand, show large, systematic biases in their monocular oculomotor and VEP responses. Monocular OKN is robust for nasal-ward motion, but is weak for temporal-ward motion during the first 3–6 months of life^{99–101} as shown in Figure 38.8. The time to attain a symmetric monocular OKN response may depend on the stimulus velocity¹⁰¹ with time to maturity being later for higher image velocities.

Young infants also show monocular VEPs response asymmetries suggestive of a nasal-ward/temporal-ward bias in cortical responses.^{18,19,102–105} These response asymmetries manifest themselves in the monocular steady-state VEP made in response to rapidly oscillating gratings. In adults, oscillating gratings produce responses primarily at twice the stimulus frequency (at the rate that stimulus direction changes, F2). In young infants, an additional response component is present at the stimulus frequency (first harmonic response, F1; see Figure 38.9). The first harmonic is 180 degrees out of phase in the two eyes. This pattern of response – a significant first harmonic that is of opposite phase in the two eyes – is consistent with a response bias that is in opposite directions in the two eyes. The absolute direction of the bias, nasal-ward or temporal-ward, cannot be directly determined from the steady-state response. It is not known at present whether the cortical motion asymmetry tapped by the VEP causes the oculomotor asymmetry or whether the two phenomena represent immaturities

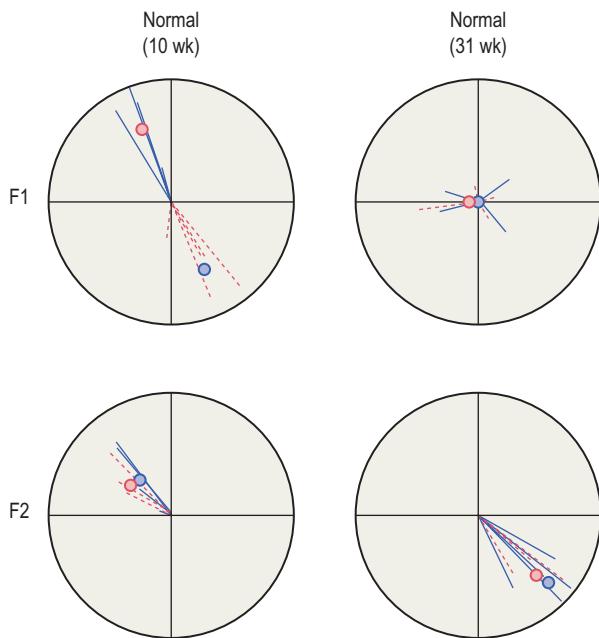

Figure 38.9 VEP motion asymmetry, adapted from Norcia et al.¹⁸ Steady-state VEPs to monocular oscillatory motion contain significant odd-harmonics in young infants (F1). The phase of these components is shifted by 180 degrees between the two eyes in an 8-week-old infant (top left plot, individual trials are indicated by separate lines radiating from zero). The presence of odd harmonics suggests that the response to left and right motion is asymmetric and that the dominant direction is opposite in the two eyes. The odd harmonic components decline in amplitude over the first 5–6 months of age as indicated by the data from a normal 31-week-old (right panels). Second harmonic response (F2) are present at both ages.

in independent mechanisms with similar developmental sequences.

Symmetric cortical motion responses develop during the first 6 months of life (Fig. 38.10) for 6 Hz oscillatory motion of low spatial frequency gratings. Figure 38.10 plots the ratio of amplitudes at the first harmonic to the sum of amplitudes at the first and second harmonics. This index runs from 1.0 for a completely asymmetric response to 0 for a completely symmetric response. Infants reach adult levels by about 5 months of age for low spatial frequency targets oscillating at 6 Hz.

The VEP motion asymmetry has been recorded in infants as young as 2 months of age,¹⁹ suggesting that cortical direction selectivity is present at this time. Interestingly, the motion asymmetry was undetectable in infants younger than 8 weeks at 6 Hz, 1 c/deg. Development of motion-specific VEPs over the neonatal period has also been observed¹⁷ in a different stimulation paradigm. Wattam-Bell¹⁷ also found that the age of first direction-specific responses was earlier for lower stimulus velocities. Box 38.2 describes applications of the motion VEP to patients with strabismus.

Binocular vision

This section explores the development of the sensory aspects of binocular vision, sensory fusion (the neurological combination of the image from each eye into a single percept) and stereopsis (the perception of depth based on a horizontal

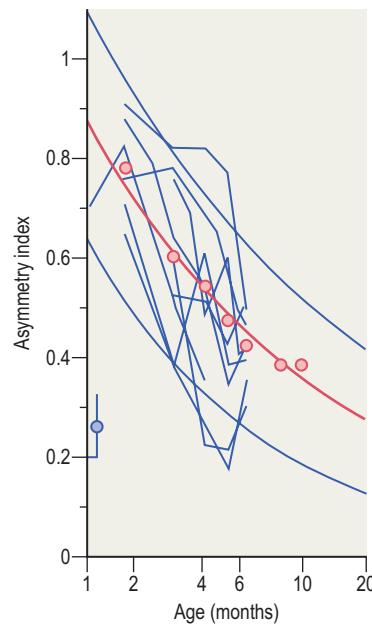

Figure 38.10 Developmental sequence for symmetric motion VEPs.¹⁹ The degree of motion response asymmetry can be quantified by calculating the fraction of the total response (first plus second harmonic) that is contributed by the first harmonic (asymmetry index). The monocular oscillatory motion VEP is dominated by the first harmonic in early infancy (asymmetry index greater than 0.5), but the degree of asymmetry declines rapidly over the first 6 months for 6 Hz, 1 cpd targets. Red circles indicate mean responses for infants between 1.5 and 10 months. Longitudinal recordings are indicated by the thin lines. The smooth curves indicate a fit to the mean growth function ± 1 standard deviation. The blue circle indicates the average asymmetry index for five infants between 0.5 and 1 month of age.

Box 38.2 Motion asymmetries in strabismus

The monocular motion VEP asymmetry persists in patients with early-onset esotropia,^{18,19,104,106–108} but is not present in patients with late-onset esotropia.^{109,110} Levels of VEP motion asymmetry can be reduced by alternate occlusion therapy¹⁰³ or by early, successful surgical alignment.^{102,104,111,112} The development of motion-processing mechanisms is thus dependent on the presence of normal binocular interactions during early visual development and can be disrupted by abnormal binocular interactions that are secondary to strabismus. Early and accurate correction of strabismus appears to restore a degree of binocular interaction that is sufficient to promote more normal development of motion-processing mechanisms.

disparity between the retinal images in each eye). As with all visual processes, the parameters of the stimulus and the method of measurement may limit the infant's performance as well as our understanding of the developing visual system. Dichoptic stimulus presentations and the need to eliminate confounding monocular cues present unique challenges to studies of the development of fusion and stereopsis and have guided the selection of the studies reviewed.

Fusion

The most direct approach in determining the onset of sensory fusion in human infants has been to record a "cyclopean" VEP using one of two different stimuli. The first approach

popularized by Baitch & Levi¹¹³ and applied to infants by France & Ver Hoeve¹¹⁴ presents a uniform field to each eye that is modulated at two different temporal frequencies (e.g. 8 Hz right eye, 6 Hz left eye). A cortical response recorded at either the sum (14 Hz) or the difference frequency (2 Hz, also termed the beat frequency) suggests the presence of binocular neurons that integrate and respond to the input from both eyes. Using this approach, France & Ver Hoeve¹¹⁴ reported that a binocular response was present in the majority of normal infants by 2 months of age. The two-frequency approach has also been used to study the development of fusion and rivalry by Brown et al.¹¹⁵ In that study, beat frequency responses were recordable only for stimuli that had the same orientation in the two eyes.

The second approach to identify the integration of information from the two eyes employs dynamic random dot correlograms. Correlograms consist of separate fields of random dots presented in a dichoptic manner to the two eyes. Correlograms alternate between two different phases – correlated and anticorrelated. In the correlated phase, the dot patterns are identical in the two eyes. In the anticorrelated phase, a dark dot in the pattern presented to one eye corresponds to a bright dot in the pattern presented to the fellow eye. The cortical response to the alternation between the two phases is recorded. The “cyclopean VEP” response to these correlated/anticorrelated stimuli has been interpreted as fusion without stereopsis since horizontal disparities are not induced by the stimuli.^{116–118} Using this approach, the onset of sensory fusion has been reported to occur between 3 and 5 months of age.^{21,22,119}

Stereopsis and disparity sensitivity

Adult observers are able to associate the sign of disparity, crossed or uncrossed, with a percept of whether a stereoscopic target appears to be nearer or farther than fixation. These “signed” perceptual reports are definitive evidence for perceptual stereopsis. Unfortunately, perceptual reports of this nature cannot be obtained from pre-verbal subjects, and other less definitive criteria must be used to determine whether stereopsis, *per se*, is likely to be present. Most studies of the development of stereopsis in pre-verbal subjects have taken sensitivity to horizontal disparity as being synonymous with the presence of adult-like stereopsis. However, recent studies in macaque have suggested that cells that can support a signed percept of depth are found in higher-level visual areas, rather than in V1. Cells in V1 and MT respond in a disparity tuned fashion to stimuli (reverse contrast images in the two eyes) that do not support a percept of depth.^{120,121} Disparity tuning *per se*, while necessary for stereopsis is thus not entirely sufficient to support depth from disparity percepts (stereopsis). Higher-level cortical areas do distinguish these two stimuli and are also tuned for relative disparity (differences in the disparity/distance of different surfaces in the visual field), whereas cells in V1 and MT are not.^{122–124} Relative disparity sensitivity underlies form perception based on disparity, while absolute disparity processing may underlie the control of vergence eye movements (see Neri¹²⁵ and Parker¹²² for reviews of disparity processing in different cortical areas). Additional criteria beyond simple sensitivity to disparity that can be used in non-invasive studies in humans will be needed to fully

understand the developmental sequence for stereopsis in humans. In the meantime, the existing studies of the development of stereopsis will be interpreted conservatively – as being indicative of the development of disparity sensitivity – leaving open the possibility that development of more complex disparity processing mechanisms may occur at later ages.

Age of onset of disparity sensitivity

Due to the limited number of reports that have investigated disparity sensitivity in the developing visual system with the visual evoked potential, this section will emphasize studies that have applied the behavioral techniques of preferential looking and ocular following movements. Behaviorally, studies of the onset of disparity sensitivity have used real depth tests, local or linear stereograms and global or random dot stereograms.¹²⁶ However, real depth targets and local tests of stereopsis contain monocular cues that can yield a positive response and confuse the interpretation of the results. Since many of the early reports that investigated the onset of disparity sensitivity relied on real depth tests with multiple cues to depth, these will not be reviewed (see Daw³¹ for review). Studies employing random dot stereograms that rely on the detection of a horizontal displacement in the image presented to each eye without monocular cues will be emphasized. Results obtained from linear stereograms with adequate controls will also be summarized.

There is remarkable consistency among the various laboratories and techniques concerning the onset of disparity sensitivity in random dot patterns that have no monocular cues. Sensitivity emerges between 3 and 5 months of age whether determined with the VEP^{22,119,127,128} or by behavioral methods.^{119,127,129–131}

Several reports from the same laboratory using disparities ranging from 58 to 32 minutes of arc, have also reported the onset of local or linear stereopsis to be between 3 and 5 months of age.^{132–135}

The age at which at least 75% of infants demonstrate sensory fusion or disparity sensitivity is summarized across studies in Figure 38.11. Details concerning the stimulus and the measurement method for each study are provided in the figure legend.

Development of disparity sensitivity

Following the emergence of measurable disparity sensitivity between 3 and 5 months of age, the improvement in sensitivity for line stereograms during the first year of life has been reported to be quite rapid. For a small sample of infants followed longitudinally ($n = 16$), sensitivity for crossed disparities improved from 58 min at 14.8 weeks of age to 1 min of arc by 20 weeks of age.¹³² A similar time course was noted for uncrossed disparities that emerged slightly later at 16.8 weeks and improved from 58 min of arc to 1 minute by 23.2 weeks. Since the five adults tested on the same apparatus averaged 97.6% correct for the 1 min crossed disparity stimulus and 80.2% for the 0.5 min crossed disparity stimulus but only 62.6% correct for the 0.5 min uncrossed disparity target, the authors suggested that the performance of the 5–6-month-old infants was adult-like.¹³²

However, it is important to recall that stereoaucuity belongs to a family of localization tasks known as hyperacuities.

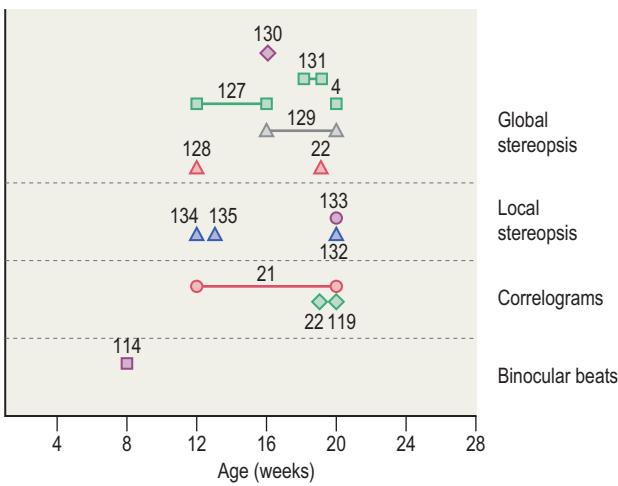

Figure 38.11 Age at which at least 75% of those tested demonstrated fusion or stereopsis. Filled symbols represent studies using the visually evoked potential (VEP), open symbols show studies using behavioral paradigms (FPL), gray symbols indicate both FPL and VEP. 1.¹¹⁴ 6 & 8 Hz dichoptic presentation, 2.¹¹⁹ correlograms, 20 min disparity (FPL), 30 min disparity (VEP), 3.²² correlograms, 40 min disparity, 4.²¹ correlograms, 5.¹³⁴ 45 min crossed disparity, 6.¹³⁵ 32 min crossed disparity, 7.¹³² 58 min crossed and uncrossed disparity, 8.¹³³ 58 min disparity, 9.¹²⁸ alternation of 100 min crossed to 100 min uncrossed disparity, 10.¹²⁷ < 1735 disparity, 11.¹²⁹ 30 min crossed disparity, 12.¹³⁰ 60 min disparity, 13 random dot stereogram.¹³¹

Hyperacuities provide finer localization than predicted based on either the optical or anatomical^{49,51} properties of the eye. Adult stereothresholds obtained with real depth stimuli are extremely fine and range from about 2 to 5 seconds with the Howard Dolman apparatus.^{70,136,137} Similar stereothresholds of about 5 seconds have been reported with the diastereo test^{138–140} another real depth test of stereopsis. Adult stereothresholds with random dot stereograms have been reported to range from 5.37 sec,¹³⁷ to about 30 sec¹⁴¹ with Simons¹⁴² reporting 15.1 sec. Thus, a closer look at the time course for the development of stereoacuity appears warranted. Based on the number of behavioral studies available from a variety of laboratories covering a large age range, the development of global stereopsis was selected for review. As mentioned previously, global stereopsis has the additional advantage of being based solely on the detection of the horizontal image displacement between the two eyes since the stimulus contains no monocular cues.

Figure 38.12 shows the development of disparity sensitivity during the first 18 months of life. The red symbols indicate the mean stereoacuity measured behaviorally in response to random dot stereograms.¹²⁷ The blue symbols are taken from Birch et al¹³² and represent the smallest linear disparity at which 50% or more of the infants tested reached criterion. Over the first year of life, global stereopsis improves by a factor of 8, to about 120 seconds of arc, but has not yet reached adult levels. This improvement is greater than the factor of 4 or 5 reported for the development of spatial resolution over the same time period.

Figure 38.13 illustrates the continued development of global disparity sensitivity during the preschool years. All show continued improvement during the pre-school years. Two studies also report thresholds from normal adults under similar test conditions. Ciner et al¹⁴³ (cyan triangles) indicate

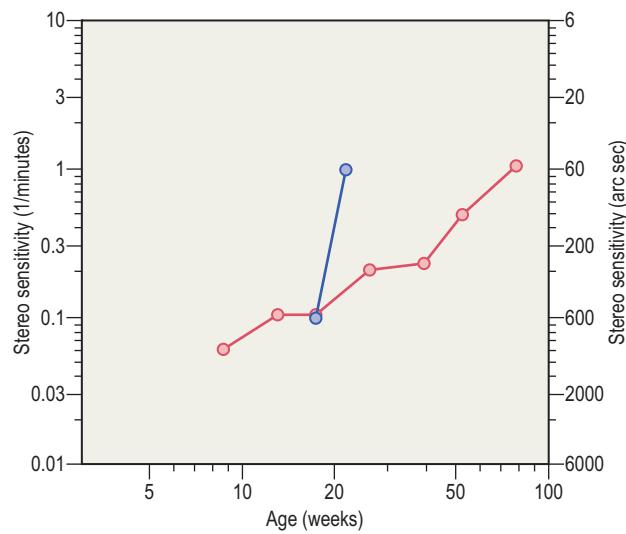

Figure 38.12 The development of disparity sensitivity (seconds of arc) as a function of age (months). Global disparity sensitivity with Polaroid random dot stereograms (red circles)¹²⁷. The smallest linear disparity that 50% or more of the infants tested reached criterion (blue circles)¹³².

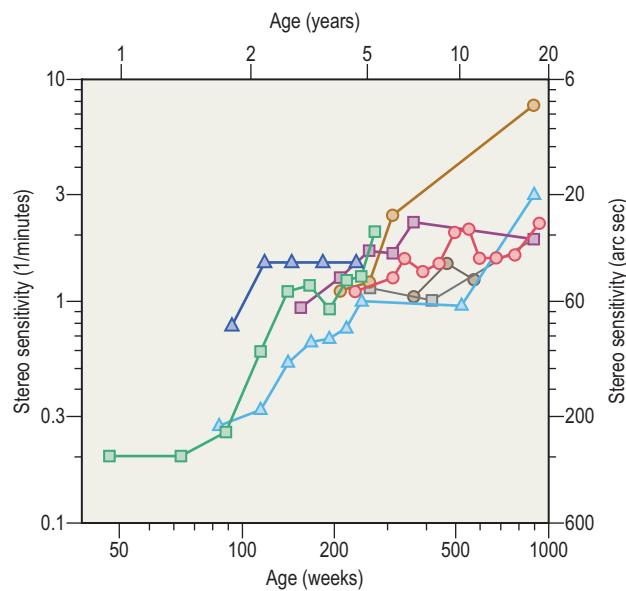

Figure 38.13 The development of global stereopsis (seconds of arc) as a function of age (years). All studies are based on a behavioral response to a random dot stereogram during the preschool years. Cyan triangles,¹⁴³ green squares,¹⁵⁷ tan circles,¹⁴² blue triangles,¹⁵⁸ purple squares,¹⁴⁵ grey squares,¹⁴¹ olive circles,¹⁵⁹ red circles.¹⁴⁴

that at age 5 disparity sensitivity is still about a factor of 3 poorer than the adult. Simons¹⁴² (tan circles) also finds sensitivity is a factor of 3 poorer for 6-year-olds compared to adults.

Four studies that measured disparity sensitivity with the commercially available TNO test in school-aged children are illustrated in Figure 38.13. Walraven & Janzen¹⁴⁴ (red circles) report that the ability to detect disparity in random dot stereograms improves by a factor of 2 between the ages of 4 and

12 years. The data also suggest additional improvement up to 18 years of age, the oldest reported in the study. When the small number ($n = 4$) of 6–10-year-olds tested by Sloper & Collins¹⁴¹ (purple squares) are compared to 12 adults with normal vision, disparity sensitivity remains a factor of 2 poorer than that measured in the adults. Heron and co-workers¹⁴⁵ (red circles) report that disparity sensitivity as measured by the TNO was adult-like at 5 years of age. These investigators also noted that among the 4 stereotests evaluated in the report, the TNO gave the poorest thresholds and the largest variability in their sample. Using a real depth test, the Frisby Stereo Test, they found that disparity sensitivity was not yet adult-like at 7 years of age. Fox et al¹³⁶ reported that with the Howard–Dolman real depth test, children 3 to 5 years of age were about 2.5 times less sensitive to disparity than adults (12.6 versus 4.9 seconds of arc). The Howard–Dolman task involves a depth alignment judgment where the presence of stereopsis is indicated when the binocular threshold is better than the monocular threshold.

In summary, sensory fusion has been demonstrated as early as 2 months of age while disparity sensitivity emerges no later than 3 and 5 months of age. Although there is about a factor of 8 improvement in disparity sensitivity for globally defined targets over the first year of life, disparity sensitivity does not reach adult levels until some time after age 5. At age 5 or 6, disparity sensitivity is still about 3 times poorer than that of the adult. Box 38.3 discusses the clinical implications of multiple developmental sequences.

Summary

Maturation of visual function in humans occurs over very different time scales, depending on the particular aspect of function that is being measured. Within a particular visual function, development may proceed at quite different rates during different post-natal periods. In several of the functions reviewed above, there is an early, rapid period of development that is followed by a long, slow second phase that lasts into childhood or even adolescence. Low spatial frequency contrast sensitivity appears to be the most precocious function yet measured. Flicker sensitivity, another function that is measured with low-spatial-frequency targets also matures relatively quickly, reaching adult levels during the first 6 months. Grating acuity measured with mid-frequency contrast reversal has its initial rapid period of development during the first 8 months, while Vernier acuity appears to develop at a different rate over this period and is far from adult levels.

Variations in the developmental sequences across visual functions presumably reflect limitations imposed at different levels of the visual hierarchy shown in Figure 38.1. The critical immaturity limiting contrast sensitivity, grating acuity and temporal resolution may lie in the early part of the pathway comprised of the retina and early cortical visual areas. Functions such as Vernier and stereo acuity are known to be quite sensitive to contrast in adults and thus some of the immaturity in these functions is likely to be secondary to the reduced contrast sensitivity of the infant. However, other factors must also limit infant Vernier and stereoacuity, since their developmental sequences are longer than those underlying contrast sensitivity and grating acuity.

Box 38.3 Sensitive and critical periods in visual development

Periods of rapid maturation in many sensory systems are associated with high levels of sensitivity to the quality and structure of the inputs from the environment¹⁴⁶. Periods during development in which the effects of visual experience on development are particularly strong are referred to as “sensitive periods”. If visual experience during a sensitive period is essential for development and permanently alters performance, this type of sensitive period is referred to as a “critical period”¹⁴⁷. Sensitive and critical periods differ in the extent to which experience has a permanent effect. If normal experience is not present during a critical period, restoration of normal input cannot rehabilitate normal function. Abnormal visual experience either before or after this period is not effective in disrupting development.

The presence and timing of a sensitive/critical period for the development of binocular vision in humans has been inferred from studies of explicitly binocular functions such as the inter-ocular transfer of the tilt-after effect¹⁴⁸ or stereoacluity¹⁴⁹ in patients who had strabismus with onset at different times after birth and in whom the strabismus persisted for different durations. Banks and co-workers¹⁴⁸ developed a simple descriptive mathematical model that they used to infer the time during development that the binocular visual system is most sensitive to disruption by strabismus. Using interocular transfer of the tilt after-effect as the endpoint measure of binocular development they found that abnormal visual experience around 1.7 years of age was maximally deleterious to final development for patients with infantile esotropia, but that the peak occurred at 1.0 year in patients with late-onset esotropia. The same model was used to locate the sensitive period for the development of stereopsis¹⁴⁹. Patients with infantile esotropia showed peak sensitivity to abnormal experience around 0.36 years, but that patients with accommodative esotropia had maximal sensitivity around 1.7 years. The fact that different outcome measures yield different estimates of the sensitive period, as do different kinds of strabismus suggests that there are multiple binocular subsystems within the visual system, as a whole, and that these each have different developmental sequences. The existence of different sensitive periods for different visual functions is well established in both animal¹⁵⁰ and human models¹⁵¹.

Development of Retinogeniculate Projections

S. M. Koch & E. M. Ullian

The dorsal lateral geniculate nucleus of the thalamus (dLGN) is the gateway through which visual information is transmitted from the retina to the cortex; therefore, visual perception relies on the ability of dLGN neurons to faithfully relay the specific features of the visual world that are encoded by the retina. Accordingly, the connections between retinal ganglion cells (RGCs) and dLGN neurons are highly precise and organized.^{1,2} For instance, RGC projections are arranged such that neighboring cells in the retina innervate neighboring cells in the dLGN creating a retinotopic map in the thalamus that is capable of maintaining the spatial features of the visual scene.³ Furthermore, the resolution of the retinal map is also maintained in the dLGN since at maturity few RGCs converge onto dLGN neurons; consequently, dLGN receptive fields are similar to those of RGCs in their size and structure.⁴ Another key feature of retinogeniculate organization, which is important for binocular vision, is that the axons arising from each eye are segregated within the dLGN.¹ As a result, mature dLGN neurons are monocularly driven.^{1,2} Finally, some cell-type-specific organization also exists in the dLGN since different types of dLGN neurons reside in distinct laminae and receive inputs from different subtypes of functionally distinct RGCs.^{2,5–8}

How does precise retinogeniculate circuitry get established during development? Numerous experiments have demonstrated that many aspects of retinogeniculate connectivity are initially imprecise, and that the immature circuit must subsequently undergo refinement in order to achieve its finely tuned mature form.^{9–16} Much of this refinement occurs before the onset of vision,^{10,11} and it is now well established that this early refinement requires both spontaneous retinal activity and molecular cues that are present over development.^{11,17–19}

Retinogeniculate projections are refined during development

Anatomical studies have shown that when the axons from the two eyes initially invade the dLGN their arbors are extensively overlapped,^{13,20} and functional studies have demonstrated that these overlapping projections give rise to binocularly innervated dLGN neurons.^{14,21} After this initial connectivity is established there is a specific developmental

window during which the axons from each eye segregate into non-overlapping territories.^{15,16} This “eye-specific segregation” results in a pattern of ipsilateral and contralateral projections that is highly stereotyped both in size and placement within the dLGN. Eye-specific inputs also segregate functionally. As RGC axons become restricted to the appropriate region of the dLGN their functional synaptic connections in the inappropriate region are lost, resulting in monocularly driven dLGN neurons.^{14,21} In mouse, electrophysiological recordings have demonstrated that dLGN neurons are initially weakly innervated by 12–30 RGCs which get refined down to 4–6 inputs from each eye as segregation proceeds, and finally to just 1–3 strong inputs from a single eye at maturity.^{14,21,22} While the convergence of RGC inputs onto individual dLGN neurons gets reduced, the nearest neighbor relationships among RGCs are maintained, and thusly, the retinotopic map is sharpened.²³

In addition to eye-specific segregation, RGC axons undergo further restriction of their arbors into functionally distinct sublaminae. For example, each major class of ganglion cell consists of two subtypes: cells that are depolarized (ON ganglion cells) or hyperpolarized (OFF ganglion cells) by light onset.²⁴ At maturity these parallel ON and OFF pathways are segregated in the dLGN at the level of single neurons; individual dLGN neurons generally respond to increments or decrements in light but not both. In some species, such as the ferret, dLGN neurons receiving ON input and OFF input reside in two distinct sublaminae within each eye-specific layer,²⁵ and these sublaminae develop just after eye-specific segregation and before opening.²⁶ The emergence of On and Off sublaminae before the onset of vision precludes a physiological assessment of whether dLGN neurons transiently receive converging ON and OFF synaptic inputs. However, this is likely because before these On and Off sublaminae form RGC axons initially arborize over both the inner and outer half of each eye-specific layer.²⁶

Among the classes of RGCs that project to the dLGN are Y cells which process movement, X cells which are responsible for image acuity, and a heterogeneous population of W cells.^{2,10,27} Whether individual dLGN neurons initially receive synaptic input from these multiple classes of ganglion cells is unclear.¹⁰ In the primate, however, magnocellular and parvocellular pathways project to distinct regions of the dLGN from early stages as their axons innervate

targets.^{28,29} This suggests that during primate development single dLGN neurons may receive inputs from just one class of RGC. This specificity could be due, at least in part, to the generation of different retinal ganglion cell classes at different times during development,³⁰ and to the fact that the axons of parvo cells reach the dLGN before those of magno cells.²⁸ In addition, in primates the axons from the two eyes may initially innervate the dLGN in a somewhat eye-specific manner; thus, the primate retinogeniculate connection may require less refinement than that of other mammals.³¹

Interestingly, studies also suggest that once the mature pattern of anatomical and functional connections has been established they must be actively maintained.^{32–35} Taken together, these data indicate that the mature retinogeniculate connection must be sculpted out of an initially over-connected circuit, and that the extent of this refinement may vary from species to species. These data also suggest that retinogeniculate development occurs over several stages beginning with the segregation of eye-specific inputs, followed by a more fine-scale refinement phase that sharpens the retinotopic map, and a final maintenance phase during which this connection remains malleable.³⁶

Activity-dependent refinement of retinogeniculate projections

Once it was appreciated that much of the initial development and refinement of retinogeniculate projections occurs before the onset of vision, these findings raised the question of whether synaptic transmission and/or neuronal activity are required for refinement. The first demonstrations that action potentials are required for eye-specific segregation came from studies in which tetrodotoxin (TTX) was used to block sodium channels in fetal cat brain. This activity blockade prevented the formation of eye-specific domains.^{37,38} Further experiments found that spontaneous activity is generated in the retina during eye-specific segregation and when spontaneous retinal activity is disrupted eye-specific layers do not form.³⁹ In addition, activity disruptions that prevent axon refinement also lead to larger than normal receptive fields.^{40–42}

After eye-specific segregation, neural activity also contributes to the refinement of ON and OFF inputs in the dLGN. In the ferret visual system either blockade of retinal activity or postsynaptic N-methyl-D-aspartate (NMDA) receptor activity disrupts the formation of ON and OFF sublaminae.^{43,44} This suggests that synaptic transmission from the retina to the dLGN is necessary for at least this one aspect of retinogeniculate refinement; although the specific role of synaptic transmission and plasticity in this and other aspects of retinogeniculate refinement warrants closer investigation.

After retinal inputs are segregated within the dLGN neural activity continues to be required for maintaining the precision established during development. For example, blockade of retinal activity after eye-specific layers have formed in the ferret causes the silenced projections to lose the territory that they had previously occupied.³² Similarly, blockade of late stage activity in mice with TTX disrupts synaptic refinement, preventing the elimination of weak inputs and the strengthening of remaining inputs.³⁵ In addition, analysis of a mutant mouse that develops excessive retinal activity after

eye-specific segregation found that this increased activity is capable of desegregating retinal inputs. This mutant mouse, termed nob1 (no b wave), lacks a protein necessary for photoreceptor to bipolar cell synaptic transmission and at the time when vision through photoreceptors would normally ensue it instead develops abnormally high rates of spontaneous retinal activity. Since spontaneous retinal activity is unaltered in these mice during the period when eye-specific segregation normally occurs, their axons initially segregate normally.^{33,45} However, with the onset of the abnormally high-frequency activity the eye-specific inputs desegregate, leading to increased axonal overlap. In addition to this late requirement for normal spontaneous activity, visual input also appears to play an important role in the maintenance of retinogeniculate refinement. If animals are deprived of visual input when the late stages of within-eye refinement are nearly complete, dLGN neurons will become multiply innervated again, essentially reverting to a more immature innervation state.^{34,35}

Together these experiments indicate that spontaneous activity is required for driving both eye-specific and On-Off segregation and that both spontaneous and visually evoked retinal activity are necessary for maintaining segregation.

What parameters of activity drive refinement?

Retinal activity is necessary during each stage of retinogeniculate development, but what aspects of activity are required? Theoretical studies propose that patterned activity that preferentially correlates the spiking of nearby cells but not distant cells is likely to be essential. In the visual system, patterned retinal activity is known to be present before vision,^{46,47} and developmental mechanisms within the retina produce a pattern of activity that meets these theoretical criteria for segregation. For instance, both multielectrode array recordings and calcium imaging experiments have revealed that bursts of activity are correlated among neighboring RGCs and these bursts propagate in a wave-like fashion across the retina.^{18,48–50} These “retinal waves” have now been observed in many vertebrate species suggesting that this activity pattern may be a conserved mechanism governing vertebrate visual system development (Fig. 39.1).

Three stages of patterned wave activity have been described in the developing retina. Interestingly, at each stage the activity is mediated by distinct mechanisms and displays unique properties, such as the frequency of the activity, the area of the retina involved in the correlated activity, and the speed of the propagating wave.^{51–53} These studies suggest that the unique features of these stages might contribute to the specific aspects of refinement that occur during each stage. The first stage of retinal activity, stage I, consists of infrequent bursts of patterned activity which appear embryonically and are largely mediated by communication through gap junctions.⁵⁴ The bulk of retinogeniculate refinement occurs during stage II waves. Stage II waves are mediated by acetylcholine release from starburst amacrine cells^{48,55} and occur embryonically in mammals born with their eyes open and postnatally in mammals born with their eyes closed.^{54,56} The final stage of patterned spontaneous activity, stage III, is mediated by glutamatergic transmission from bipolar cells, spans the period of eye opening, and is propagated, at least in part, due to glutamate spillover.^{18,33,54,56–59} Interestingly,

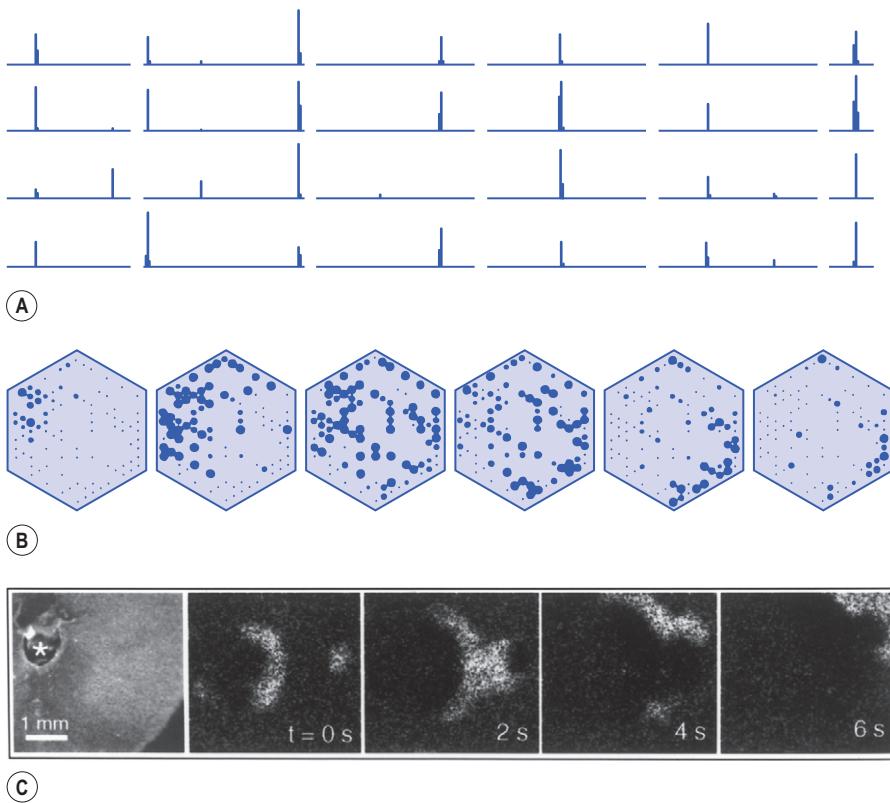

Figure 39.1 The immature retina generates a pattern of synchronized bursting activity before vision. **(A)** Multielectrode recording of the spike activity from many cells in the isolated but intact ferret retina reveals the presence of rhythmic bursting in individual cells (each line). The bursts of four neighboring cells (shown by the vertical histograms) are correlated in time. **(B)** During a burst of activity, retinal ganglion cells are activated sequentially as a wave propagates across the recording electrodes. Shown here is an example of such a wave propagating across the hexagonal multielectrode array. *Left to right:* Sequential “snapshots” of the activity recorded every 0.5 second. Each dot is a cell, and the size of the dot is proportional to the spike rate. **(C)** Retinal waves are easily observed using calcium imaging. Changes in fluorescence intensity over time detected using a low-light camera show two waves that collide in a neonatal mouse retina. First panel shows the fluorescence labeling by fura-2, and white regions in the subsequent images show elevations in intracellular calcium. * = Optic nerve head.

during stage III waves, ON and OFF RGCs fire at different rates and are anti-correlated^{60–62} as do other subtypes of RGCs such as X, Y, and W, which could play a role in the segregation of these distinct types of inputs.⁶³

By what mechanisms do retinal waves drive changes in retinogeniculate connectivity? A common mechanism that appears to underlie the development of connection specificity throughout the nervous system is activity-dependent competition among presynaptic inputs for postsynaptic space.^{64,65} This competition is driven by neural activity, but how? Evidence that eye-specific segregation involves competition among RGC inputs comes from studies in which activity was either blocked or enhanced in one eye resulting in alterations to the pattern of ipsilateral and contralateral projections. In these studies when epibatidine was used to block cholinergic transmission in just one eye, the projections from the blocked eye lost territory in the dLGN while the projections from the active eye expanded their coverage.³⁹ The converse was also true; that is, when activity was increased in one eye by intraocular administration of either forskolin or the cyclic AMP analog, CPT-cAMP (which increase the size, frequency, and speed of waves), the projections from the more active eye gained territory in the dLGN at the expense of the non-enhanced eye’s projections.^{66,67}

Both experimental and theoretic studies suggest that in addition to overall activity levels, specific aspects of patterned spontaneous activity may drive segregation through Hebbian mechanisms that strengthen and eliminate synaptic inputs over time.⁶⁸ This Hebbian model of synaptic competition predicts that ganglion cells that “fire together, wire together”.⁶⁹ For Hebbian mechanisms to drive segregation, neighboring RGCs must fire in a correlated manner while

more distant RGCs or RGCs from different eyes must exhibit less correlated spiking; thereby allowing for the strengthening of the temporally correlated neighboring inputs and the weakening of the uncorrelated inputs. Indeed, these requirements are met as a consequence of wave propagation. For example, during a wave neighboring RGCs are co-activated causing their firing to become more synchronized than that of non-neighboring RGCs. In addition, the random nature of wave initiation and the relatively long refractory period between waves results in a low probability of coincident firing of more distant ganglion cells or ganglion cells in separate eyes. This favors the segregation of inputs from different eyes, and could simultaneously remodel both the connectivity between the two eyes and refine the retinotopic map within each eye.^{70,71}

Anatomical studies in mice have shown that stage II waves are of particular importance for eye-specific segregation since this segregation occurs during stage II waves and disruption of stage II waves through binocular injections of epibatidine prevents eye-specific segregation during this period³⁹ (Fig. 39.2). These data show that stage II waves are required for eye-specific segregation – but are they permissive or instructive for segregation? The data regarding this question are somewhat conflicting. Studies of mice lacking the nicotinic acetylcholine receptor subunit $\beta 2$ have suggested that retinal wave structure is critical for driving segregation since in these mice, which retain retinal activity but have severely altered wave structure,^{54,72,73} eye-specific refinement does not occur during stage II.^{54,73,74} On the other hand, the first study to abolish retinal waves without disrupting the overall level of retinal activity did not find any deficit in eye-specific segregation.⁷⁵ In addition, studies of other

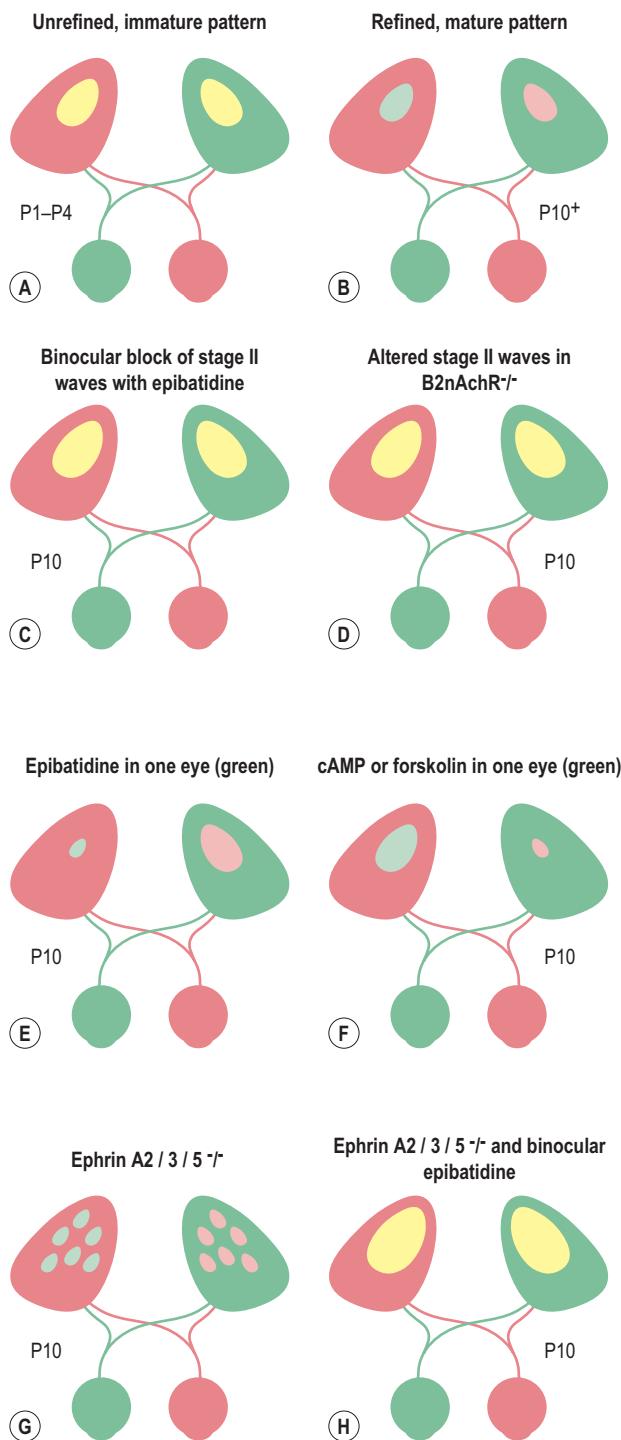

Figure 39.2 Both spontaneous retinal activity and ephrin signaling are required for the normal segregation of eye-specific inputs in the dLGN. Diagram illustrates projection patterns in the rodent dLGN. (A) Initially the projections from both eyes overlap in the dLGN. In rodents this pattern can be seen between P1–P4. (B) During stage II retinal waves the inputs from each eye segregate into non-overlapping regions with their mature pattern emerging around P10. (C) Pharmacological ablation of stage II waves prevents segregation during this period. (D) In the $\beta 2nAChR$ knockout mouse, waves with altered correlation structure and frequency also prevent segregation during stage II. (E, F) Eye-specific segregation involves activity-dependent competition. (E) When stage II waves are blocked in one eye with epibatidine the projections from the blocked eye lose territory in the dLGN while the projections from the normally active eye expand. (F) When stage II waves are increased in size and frequency in one eye, the projections from the enhanced eye gain territory in the dLGN at the expense of the other eye's projections. (G) Ephrin As are required for the normal size, position, and pattern of eye-specific layers. Mice lacking ephrin A2, A3, and A5 undergo eye-specific segregation but do not form normal eye-specific laminae. (H) When activity is blocked in both eyes of ephrin A2, A3, and A5 knockout mice eye-specific segregation does not occur, and ipsilateral and contralateral projects are overlapped throughout most of the dLGN.

mice with disrupted waves indicated that although these animals display defects in eye-specific segregation,⁷⁴ when certain aspects of the waves were rescued this did not lead to the rescue eye-segregation.⁷⁶

In an effort to determine the specific parameters of waves that might be necessary for eye-specific segregation the Feller laboratory analyzed a number of mutant mice with different retinal wave disruptions and varying degrees of eye-specific segregation.⁷⁷ Based on these comparisons they concluded that several aspects of retinal waves are likely to be essential

for driving eye-specific segregation, such as the amount of correlated firing that occurred in bursts with frequencies greater than 10 Hz. In addition, they found the relative difference in the correlation strengths between neighboring and distant RGCs to be critical, rather than the overall activity of the RGCs or the precise time window of RGC firing. This study suggests that retinal waves encode information that instructs retinogeniculate refinement, though this topic remains controversial. As mentioned above, in the nob1 mouse the onset of altered late-stage waves causes eye-specific inputs to desegregate. Interestingly, the altered waves in the nob1 mice display correlations that are stronger between neighboring RGCs than distant RGCs, similar to the correlation structure found by Feller and colleagues to promote eye-specific segregation. This suggests that, at least for stage III waves, the levels of activity can also affect retinogeniculate development. In the nob1 mouse it is likely that very high frequency of waves leads to increased co-incident firing of RGCs in different eyes, thus leading to the re-growth of new inputs and/or the strengthening of residual inputs.^{33,36}

Synaptic inputs change strength with segregation

Electrophysiological recordings have shown that the convergence of functional synaptic inputs onto individual dLGN neurons dramatically decreases over development.^{14,21,22,78} As discussed above, evidence suggests that specific aspects of retinal wave structure likely play an instructive role in retinogeniculate refinement by driving Hebbian learning rules at retinogeniculate synapses. Presumably, the correlated firing of neighboring RGCs leads to increased synaptic strength which in turn stabilizes the axon arbors containing the strengthened synapses. Conversely, uncorrelated firing leads to decreased synaptic strength which ultimately leads to the elimination of the weak synapses and the axon collaterals on which they reside. So, what are the synaptic learning rules that operate at retinogeniculate synapses, and what molecular mechanisms translate changes in synaptic strength into

altered morphology? The answers to these questions are still largely unknown; however, some insight has been gained and is discussed below.

The first study to demonstrate that retinogeniculate synapses can undergo synaptic plasticity stimulated RGC afferents in a retinogeniculate slice preparation with high-frequency trains and showed that this strengthened retinogeniculate synapses in an NMDA receptor-dependent fashion. However, one caveat to this study was that the high-frequency trains were faster than those typically observed during retinal waves.⁷⁹ Using a preparation containing intact retinal inputs to the dLGN combined with patch-clamp recordings Mooney et al demonstrated that, during segregation, retinal inputs are capable of driving postsynaptic dLGN spiking, a prerequisite for Hebbian-based learning.⁸⁰ More recently, Butts and colleagues, using stimulation that more accurately reflects endogenous activity patterns, described a burst-timing-dependent plasticity protocol that was capable of both strengthening or weakening retinogeniculate synapses depending on whether presynaptic and postsynaptic bursts (10–20 Hz) were coincident or non-overlapping.⁸¹ In addition to this homosynaptic learning rule, synaptic weakening may also occur via heterosynaptic depression. In support of this idea, trains of synaptic stimuli from one eye were shown to lead to depression of the opposite eye inputs.⁸² Undoubtedly, future studies will further elucidate the types of plasticity mechanisms that influence the development of this connection. In particular, since the distinct stages of retinal activity differ in their wave parameters it will be interesting to find out whether the synaptic plasticity rules operating in the dLGN change over these stages. For instance, in ferrets it was reported that NMDAR activation is not required for eye-specific segregation, but is required for On-Off segregation.⁴³ Interestingly, toward the end of the period of stage III waves, both spontaneous activity and vision were shown to preferentially drive the glutamate receptor subunit 1 into retinogeniculate synapses.⁸³

While, as previously mentioned, the number of RGCs innervating individual dLGN neurons decreases dramatically over development,^{21,22,78} the total number of synapses made onto individual dLGN neurons seems to remain fairly constant.²² This finding is analogous to the refinement of motor neuron inputs at the neuromuscular junction where a single motor neuron takes over the synaptic territory of multiple motor neurons.⁶⁵ The mechanisms controlling total synapse number are not known. In addition, some mutant mice retain excess retinal inputs into adulthood, yet these extra inputs do not drive aberrantly large synaptic currents.^{35,84} These studies suggest that the total synaptic drive received by dLGN neurons is under homeostatic regulation.

Molecular mechanisms involved in activity-dependent axonal segregation

A major area of research that remains is to elucidate the molecular mechanisms that translate changes in synaptic drive into altered synapse and axon morphology. The use of transgenic mouse lines has led to tremendous advancement in our understanding of these molecular mechanisms. Screening of mutant animals that display fairly normal retinal waves yet have severely disrupted eye-specific segregation has demonstrated that several types of immune-related

molecules are likely to be involved in this process. The first such example was the class I major immunohistocompatibility complex (MHC). This protein is upregulated by activity in the dLGN during the time of eye-specific segregation, and MHC I knockout mice display overlapping eye inputs.^{85–87} The neuronal pentraxins (NPs) are another example of activity-regulated genes shown to be involved in eye-specific segregation, and interestingly, NPs are also immune-related molecules that share some sequence similarity to the short pentraxins, C-reactive protein, and serum amyloid P. Like MHC, NPs are highly expressed during retinogeniculate refinement, and animals lacking two NPs, NP1 and NP2, display overlapping eye inputs past the normal period of segregation.⁸⁸ Both MHC and NPs may directly affect synaptic function.^{85,89,90} Another example of molecular mechanisms that may couple functional and structural changes in the dLGN comes from studies of the complement pathway. Several strains of mice with deletions of protein in the classical complement pathway have overlapping eye-specific input in the dLGN. The complement pathway is well known for mediating phagocytosis of dead or infected cells. Because complement appears to co-localize with a subset of synapses in the dLGN, one possible role for the complement pathway is that it may tag weak inputs that are slated for removal during the period of eye-specific segregation.⁸⁴

Molecular mechanisms guiding the formation of eye-specific axonal territories

In addition to the molecular mechanisms discussed above, activity-independent molecular mechanisms also play a role in shaping the mature pattern of retinogeniculate connections. Because the size and position of the eye-specific regions in the dLGN are highly stereotyped from animal to animal and symmetrical on both sides of the thalamus, it has long been speculated that molecular cues must determine where inputs from each finally coalesce.¹¹ What cues might guide the inputs from the two eyes into their distinct territories? Interestingly, in achiasmatic sheep dogs with uncrossed eye projections, inputs from the normally crossed nasal and the uncrossed temporal retina still segregate in the dLGN,⁹¹ strongly indicating that molecular cues direct eye-specific segregation by marking the temporal and nasal retina. Work on retinotectal mapping has shown that the nasal and temporal retina can be distinguished by their differing expression of EphAs⁹² and both the EphAs and their binding partners, ephrin-As, play a critical role in eye-specific segregation in the dLGN. Mice lacking three of the ephrins, A2, A3, and A5 still display activity-dependent segregation of eye-specific inputs, but the eye-specific regions are fractured and do not form distinct layers in the dLGN.⁹³ If these triple knockout mice are subjected to activity blockade during the period of eye-specific segregation their retinal inputs form a permanent salt and pepper pattern of intermingled inputs. In addition, retinal overexpression of EphA3 or EphA5 can lead to mistargeting of retinal inputs to the incorrect eye-specific layer despite normal retinal patterned activity.⁹⁴ These data indicate that EphA-EphrinA interactions shape the final pattern of eye-specific inputs. These also indicate that activity and ephrin signaling act in parallel and are both required for the normal organization of retinogeniculate inputs. In addition, activity manipulations do not

seem to affect ephrin expression, nor does the loss or over-expression of ephrins impact activity levels, further suggesting that these pathways act largely independently from one another.^{19,94}

Summary

The mature retinogeniculate pathway is highly organized in structure and function, and a clearer understanding of how this precise organization develops continues to emerge. It is now well established that both activity-dependent and -independent mechanisms shape this final organization. Specific features of spontaneous retinal activity appear to be critical, suggesting that activity may work in an instructive fashion. An important task for future studies will be to further elucidate the synaptic and molecular mechanisms that turn activity into structural changes in this pathway. The use of transgenic animals and additional genetic and molecular screens will allow for greater molecular insight into the mechanisms that underlie both the activity-dependent and -independent aspects of this process. Each stage of refinement, between eye, within eye, ON vs OFF, may employ some similar and unique mechanisms to mediate refinement. In summary, the retinogeniculate projection has proven to be a fascinating example of central nervous system development, and further studies in this system will continue to advance our understanding of the processes leading to developmental refinement throughout the nervous system.

Developmental Visual Deprivation

Yuzo M. Chino

The vision of newborn infants is crude. As infants experience the normal visual environment, their vision rapidly improves with different visual capabilities emerging at different ages. Determining the exact timing for the behavioral onset of specific visual functions and identifying the critical factors that limit their development have been the primary focus of perceptual and physiological studies on vision development. Although immaturities of the physiological optics and ocular motility are known to affect the infant's vision soon after birth, the maturation of the retina and, to a greater extent, the visual cortex largely set a limit on their normal perceptual development.^{1,2}

The neuronal connections of the visual cortex are malleable for a considerable time after birth, the "critical" or "plastic" period of development. The postnatal development of the visual cortex, therefore, requires normal visual experience and precise matching of the images in the two eyes. Experiencing binocularly discordant images early in life, a binocular imbalance, has devastating effects on the development of the visual system because after eye opening, the neurons in the highly plastic visual cortex receive robust signals from the two eyes that do not match. Prevalent abnormal visual conditions that can cause binocular imbalance are early monocular form deprivation, unilateral defocus, and ocular misalignment. Experiencing binocular imbalance during early infancy causes binocular vision disorders, and if untreated, amblyopia is likely to develop.

Topics in this chapter cover what we currently know about the perceptual consequences of early abnormal visual experience, the neural basis of altered vision, and the synaptic and molecular mechanisms of cortical plasticity.

Macaque monkeys are ideal animal models for exploring the neural mechanisms underlying developmental vision disorders in humans. The anatomical and physiological organizations of their visual system are nearly identical to humans. Perceptual studies in normal mature monkeys have extensively documented the striking similarities in monocular and binocular visual capabilities between macaque monkeys and humans.^{3,4} The relative (scaled) time course of normal visual development in macaque monkeys parallels that of humans.^{5–8} The primate visual cortex is structurally⁹ and functionally^{10,11} more developed at or near birth than the visual cortex in lower species.

Many important discoveries on vision development have been made on sub-primate species (e.g. cats, ferrets, rats, and mice).^{12–16} However, in lower animals it is not always possible to establish a link between neural and perceptual deficits resulting from early abnormal visual experience. This chapter, therefore, will primarily review studies on non-human primates. Studies with human infants are mentioned when appropriate, and research in sub-primate species is described in detail mostly where the neural and molecular basis of cortical plasticity is discussed.

Effects of early monocular form deprivation

Constant monocular form deprivation

Monocular form deprivation can result from an occlusion of the image in one eye or from a severely degraded image in the affected eye. Congenital dense cataracts and ptosis are the common causes of monocular form deprivation in human infants. To create primate models of monocular form deprivation, the eyelids of infant monkeys are surgically closed,¹⁷ or more recently, by wearing diffuser lenses in front of one eye.¹⁸

Perceptual deficits

All binocular functions including local/global stereopsis and binocular summation of contrast sensitivity are severely compromised or lost following early monocular form deprivation.^{17,19} The visual sensitivity of the deprived eye is dramatically reduced or virtually lost, *form deprivation amblyopia* (Fig. 40.1A).^{17,19,20} Importantly, the severity of the contrast sensitivity loss resulting from monocular form deprivation is directly related to the degree of retinal image degradation during early infancy (Fig. 40.1B).¹⁸

Monocular deprivation also leads to an abnormal elongation of the eyes, hence, the development of myopic refractive errors.^{18,21,22} The deleterious effects of early monocular deprivation on spatial vision development are generally far more severe than the anomalies resulting from form deprivation in both eyes, *bilateral form deprivation* (Fig. 40.2).^{23,24} As in monkeys with monocular form deprivation,

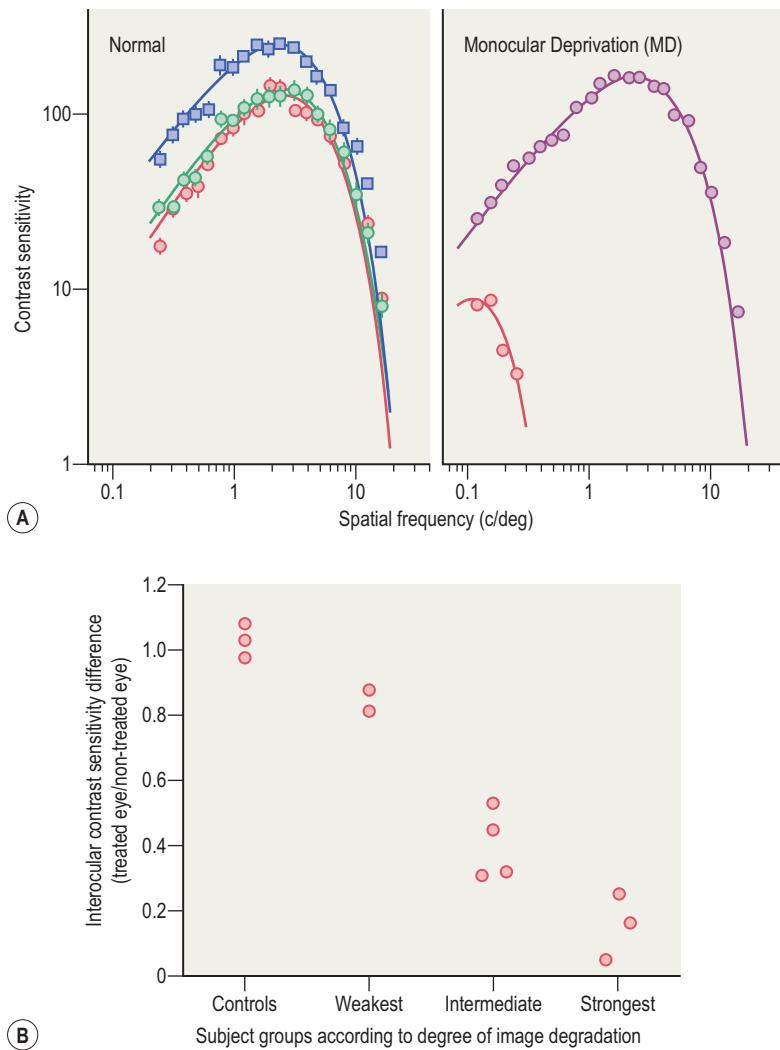

Figure 40.1 Effects of early monocular form deprivation on contrast sensitivity in macaque monkeys. **(A)** Spatial contrast sensitivity functions from normal (left) and monocularly form-deprived (right) monkeys. Red circles indicate contrast sensitivity for the left eye in the normal and the affected eye in the deprived monkey. Green circles in Normal and purple circles in MD indicate contrast sensitivity for the fellow eyes. Blue squares show binocular contrast sensitivity. (Modified from Harwerth et al 1981.¹⁷) **(B)** Effects of the degree of image degradation on contrast sensitivity loss. (Redrawn from Smith et al 2000.¹⁸)

bilateral form deprivation leads to a significant loss of binocular functions including the detection of stereoscopic cues and binocular summation of contrast sensitivity (Fig. 40.2). In these binocularly deprived monkeys, the binocular contrast sensitivity function (square symbols) overlaps with the better monocular sensitivity function (open circles).²³

Neural changes

The most consistent effect of early monocular form deprivation on development is anomalous changes in the ocular dominance distribution of V1 neurons (*ocular dominance plasticity*). During the critical period of development, the afferent fibers from the LGN representing the two eyes compete for consolidation of functional connections in V1 (*binocular competition*).^{25,26} This early binocular competition is activity dependent; hence, depriving normal signals from one eye puts the affected eye into a competitive disadvantage and leads to a severe loss of functional connections in V1 from the deprived eye. The ocular dominance columns of the input layer in V1 (layer IVC) representing the deprived eye exhibit a substantial shrinkage.^{26–28} The axon arbors of the afferent fibers from the LGN in the deprived columns show abnormal structural changes²⁹ and

the intrinsic long-range horizontal connections extending over multiple ocular dominance columns reorganize their wiring pattern in the cat primary visual cortex.^{30,31}

Electrophysiological studies consistently report the severe loss of binocularly driven cells, i.e. neurons that can be activated by stimulation of either eye. In addition, there is a clear shift in the ocular dominance distribution of cortical neurons away from the deprived eye. Specifically, the percentage of V1 neurons that can be activated or dominated by stimulation of the deprived eye is significantly decreased (Fig. 40.3).^{26,27,32} The reduced functional innervation from the deprived eye is, at least in part, the neural basis for “undersampling” of visual scenes by the affected eye in form deprivation amblyopia.³³

For subcortical structures, there is a mild shrinkage of cell bodies of LGN neurons that receive input signals from the deprived eye.^{25,26,34} However, the response properties of these primate LGN neurons are largely unaffected by early monocular form deprivation.^{26,35,36} Interestingly, there is considerable evidence for functional alterations in the cat LGN due to early abnormal visual experience.^{12,37–39} For the primate retina there are no significant structural or functional abnormalities due to early monocular form deprivation. Together, major neural changes resulting from early

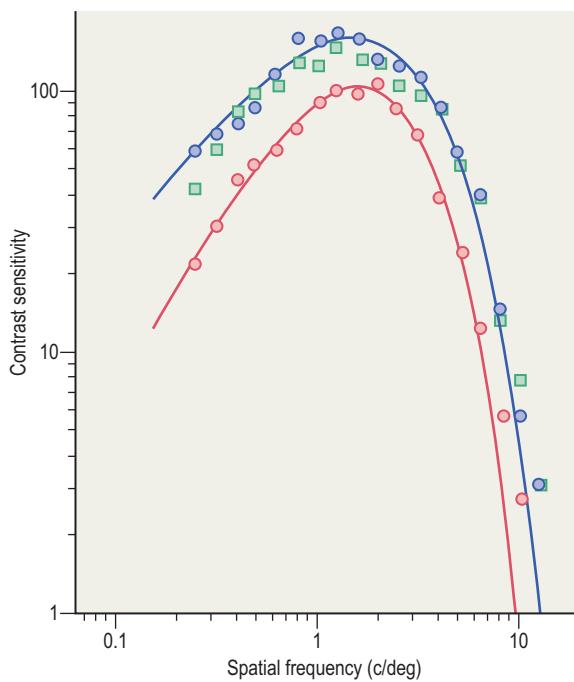

Figure 40.2 Contrast sensitivity and binocular summation after binocular form deprivation. Spatial contrast sensitivity function of the right (red circle) and left (blue circle) eye after 16 weeks of deprivation beginning at 3 weeks of age. Green square symbols indicate contrast sensitivity under binocular viewing conditions. (Modified from Harwerth et al 1991.²³ Reproduced from Association for Research in Vision and Ophthalmology.)

monocular form deprivations in primates occur beyond the LGN, i.e. begins in the primary visual cortex.

Intermittent monocular deprivation

Experiencing “normal vision” during early monocular form deprivation (*intermittent monocular form deprivation*) reduces some of the deleterious effects of early *constant* monocular form deprivation.^{32,40–42} The effects of early intermittent deprivations have been studied using different rearing regimens including daily alternating monocular deprivation, reverse occlusion, and monocular form deprivation with daily brief periods of unrestricted vision.

Alternating monocular deprivation

Daily alternations of form deprivation between the two eyes have very little impact on the perceptual development of either eye in cats.^{41,42} Consistent with this observation, the spatial receptive-field properties such as orientation selectivity are normal. However, the same daily alternating deprivation devastates the development of binocular vision. Local stereopsis is lost and the proportion of binocularly driven neurons in area 17 is severely reduced. In monkeys, daily alternating monocular occlusion beginning *at birth* leads to a variety of abnormal eye positions and eye movements including strabismus and/or saccadic disconjugacy, i.e. the amplitudes of saccades in the occluded eye are less than that in the viewing eye.^{43,44}

Reverse occlusion

The effects of constant form deprivation in one eye, including spatial contrast sensitivity loss and ocular dominance

shift in V1 away from the deprived eye, can be reversed if vision of the originally deprived eye is restored early in development and the fellow non-deprived eye is occluded, *reverse occlusion*^{45,46} (Fig. 40.4). The timing of the reverse occlusion is critical in determining the effectiveness of this procedure because the “recovery” of functions in the originally deprived eye may occur at the expense of the originally non-deprived eye. For example, contrast sensitivity can be restored if reverse occlusion occurs relatively early in the critical period, i.e. if the original deprivation is short. However, this early reversal leads to a loss of contrast sensitivity in the newly deprived (or originally non-deprived) eye (red circles in Fig. 40.4A)⁴⁵ and causes a corresponding shift in the ocular dominance distribution of V1 neurons favoring the initially deprived eye.⁴⁶ There is an optimal time for the reversal of monocular occlusion in order to achieve near normal contrast sensitivity for both eyes (Fig. 40.4B).^{13,45} In all cases, the binocular functions are diminished.⁴⁵ Similar effects of reverse occlusion have been extensively studied in cats, and the results have contributed in advancing our understanding of the neural mechanisms underlying the breakdown and recovery of visual functions from early monocular form deprivation.^{13,14,47}

The clinical significance of these findings is that this kind of animal study can provide key information for developing an effective clinical strategy for treating amblyopia with various patching regimens.

Brief unrestricted vision during monocular deprivation

Providing brief daily periods of normal vision to the deprived eye during early monocular deprivation prevents or reduces the severity of form deprivation amblyopia in monkeys (Fig. 40.5A).⁴⁰ Constant form deprivation (0 hour of unrestricted vision), as previously described, causes severe amblyopia of the deprived eye and a large shift in the ocular dominance of V1 neurons away from the deprived eye (Fig. 40.5B). However, only *one hour* of unrestricted (normal) vision every day during the deprivation period (12 hours/day) dramatically improves the contrast sensitivity of the deprived eye, hence reducing the severity of form deprivation amblyopia.⁴⁰ In these monkeys the extent of abnormal ocular dominance shift in V1 is significantly reduced (Fig. 40.5B).³² In stark contrast, the same “preventive” measure, even with 4 hours of daily unrestricted vision during the 12-hour deprivation period, does not prevent a severe loss of disparity sensitive neurons, highlighting the extremely fragile nature of developing binocular connections in V1. However, one hour of unrestricted vision is effective in reducing binocular suppression in V1 (i.e. the binocular responses of V1 neurons are less than monocular responses) that is prevalent in monkeys reared with constant form deprivation (Fig. 40.5C).³²

Constant monocular form deprivation leads to an elongation of the eye, and hence, the development of myopic refractive errors in the deprived eye.^{18,48,49} However, a brief period of unrestricted vision during the deprivation period reduces the degree of myopic refractive error.⁵⁰

The clinical relevance of these studies is that the timely removal of the conditions that produce degradation of images or image occlusion (e.g. severe hyperopic anisometropia, cataract, or ptosis) is critically important for the prevention of amblyopia. If that is not immediately possible,

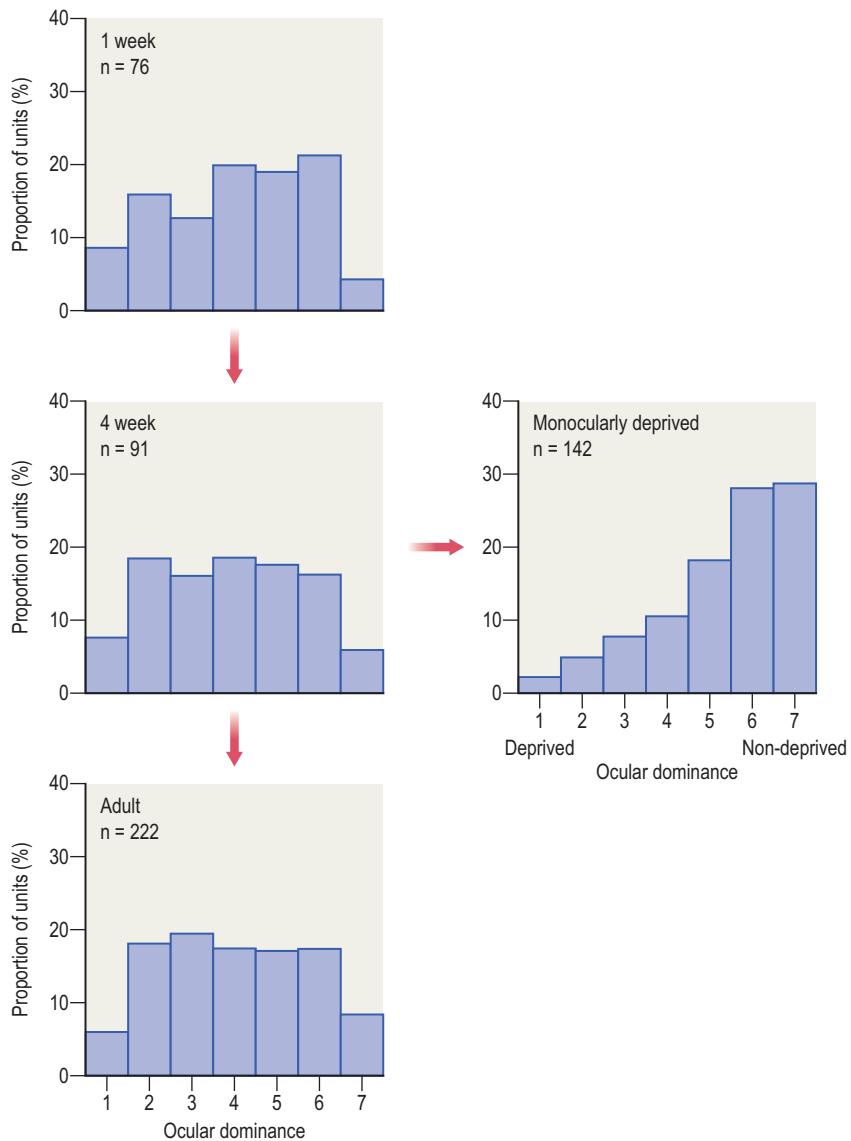

Figure 40.3 Ocular dominance (OD) distributions of V1 neurons in normal infant (1 week & 4 weeks), normal adult, and monocularly form-deprived monkeys. Cells in OD 1 and 7 are exclusively driven by the contralateral or ipsilateral eye, respectively. Cells in OD 4 are binocularly balanced and neurons in OD 2 and 3 or OD 5 and 6 are dominated by the contralateral or ipsilateral eye, respectively. (Data from Chino et al 1997,¹⁰ Sakai et al 2007.³²)

stop-gap manipulations such as lifting a drooping eyelid or keeping corrective lenses even for a short period of time every day are likely to have preventive effects against form deprivation amblyopia and development of myopic refractive errors.⁴⁰ Taken together, studies of this kind and those on the effects of temporal variations in image quality, e.g. alternating or reverse occlusion, can provide key information in developing effective clinical strategies for the management of amblyopia in human infants.^{40,47}

Critical period

The critical (plastic) period of vision development is traditionally defined as the postnatal period during which visual deprivation leads to long-term or permanent structural and/or functional changes of the visual system. The critical period differs substantially between species, the visual functions affected by deprivation, sites of neural alterations, and the nature of the visual deprivation, e.g. dark rearing, monocular form deprivation, monocular defocus, or ocular misalignment.¹⁴ For example, the critical period for primates, unlike

sub-primate species, begins at or near birth (Fig. 40.6).^{9,19,51} Binocular functions are generally more readily disrupted by early visual deprivations than monocular spatial vision. The critical period for experience-dependent changes differs between cortical sites, e.g. V1, V2, V4 or MT, and cortical layers within a given cortical site. The higher stages of processing, e.g. supra- and infra-granular layers compared to input layer within V1 or cortical sites later in the hierarchy of extrastriate visual areas, appear to have longer periods of plasticity.¹⁴

Critical period for monocular form deprivation

There are multiple “plastic” periods for different visual functions in macaque monkeys (Fig. 40.6).^{19,51} Spectral sensitivity functions have relatively short critical periods that begin soon after birth and last for 3 months for scotopic spectral sensitivity and 6 months for photopic spectral sensitivity. The critical period for visual acuity loss is much longer, lasting over 24 months. Binocular vision development can be disrupted by monocular deprivation starting as late as 25

Figure 40.4 Spatial contrast sensitivity functions after reverse monocular occlusion. The functions for the originally non-deprived (deprived after reversal) eye are shown with blue circles. The initial deprivation began at 21 days of age in all groups. (A) Reversal after 4 weeks of monocular deprivation. (B) After 3 months. Shaded area shows the normal range of contrast sensitivity in normal monkeys. (Modified from Harwerth et al 1989.⁴⁵ Reproduced by kind permission of Springer Science + Business Media.)

months of age (roughly equivalent to 8 years in humans).¹⁹ However, the "end" of the critical period for binocular functions has not been determined for monkeys.

Because the sensitivity of the visual cortex to deprivations varies substantially during the critical periods, the timing of deprivation, i.e. *onset and duration*, has significant effects on the severity of perceptual and neural deficits. At what age is monocular form deprivation likely to have the most damaging effects in monkeys? The perceptual development of contrast sensitivity and visual acuity in monkeys is most vulnerable to monocular form deprivation during the first 5 postnatal months. A sharp drop of sensitivity to deprivation occurs after this initial period of heightened sensitivity, followed by a gradual decline over an extended period of time, i.e. > 24 months (Fig. 40.6).^{19,51}

For ocular dominance plasticity in V1 of monkeys, the most severe shrinkage of ocular dominance columns for the deprived eye occurs with the *earliest onset age*, e.g. 1 week of age.²⁸ The degree of the shrinkage becomes progressively smaller as the onset of deprivation is delayed and there is no obvious shrinkage if the onset is set at the 12th postnatal week. Thus, contrary to a classic observation,²⁷ the ocular dominance columns in layer IVC of monkey V1 are most sensitive to monocular deprivation right after birth.

These behavioral and anatomical studies reinforce the *clinical view* that removal of dense congenital cataract combined with good optical quality lenses or correction of ptosis at the earliest possible postnatal time is essential to minimize the negative impact of monocular form deprivation in humans.^{52–54}

The critical period for ocular dominance in cats begins about 3–4 weeks of age when the optics of their eyes becomes relatively clear, peaks around 6–8 weeks, and gradually

decreases during the next 12–14 weeks.^{25,55,56} A similar timing of the critical period for monocular deprivation has been reported for rats and ferrets with minor variations.^{57–59} The critical period is longer for monkeys than that in lower species and appears to be generally correlated with animal's life expectancy.^{15,60} It is difficult to determine the precise critical period of vision development for humans in part because of the difficulties associated with conducting experiments on human infants and dependence on clinical observations for data collection. Although the critical period for humans varies considerably for specific visual tasks as evidenced in animal studies, the critical period for experience-dependent changes in humans is thought to begin soon after birth (within 6 months or earlier), peak around 1–3 years of age, and decline slowly until 8–10 years of age or later.¹⁴

Molecular mechanisms of ocular dominance plasticity

The molecular mechanisms of experience-dependent ocular dominance plasticity have been extensively studied in rodents because the visual cortex of rodents is in general organized similarly to that in higher mammals^{61,62} and a wide range of genetic manipulations are readily accessible in rodents.^{14–16,47,63,64} Synaptic events following monocular deprivation (*binocular competition*) consist of an initial reversible reduction in functional connections to the deprived eye⁵⁸ and rewiring of the upper layer long-range connections.^{30,31} These are followed by extended periods of strengthening of the responses to the non-deprived eye and an eventual structural reorganization (*consolidation*)^{15,16,25,29} (Fig. 40.7A). The initial rapid changes occur as a result of imbalance in the strength of the input signals between the deprived and

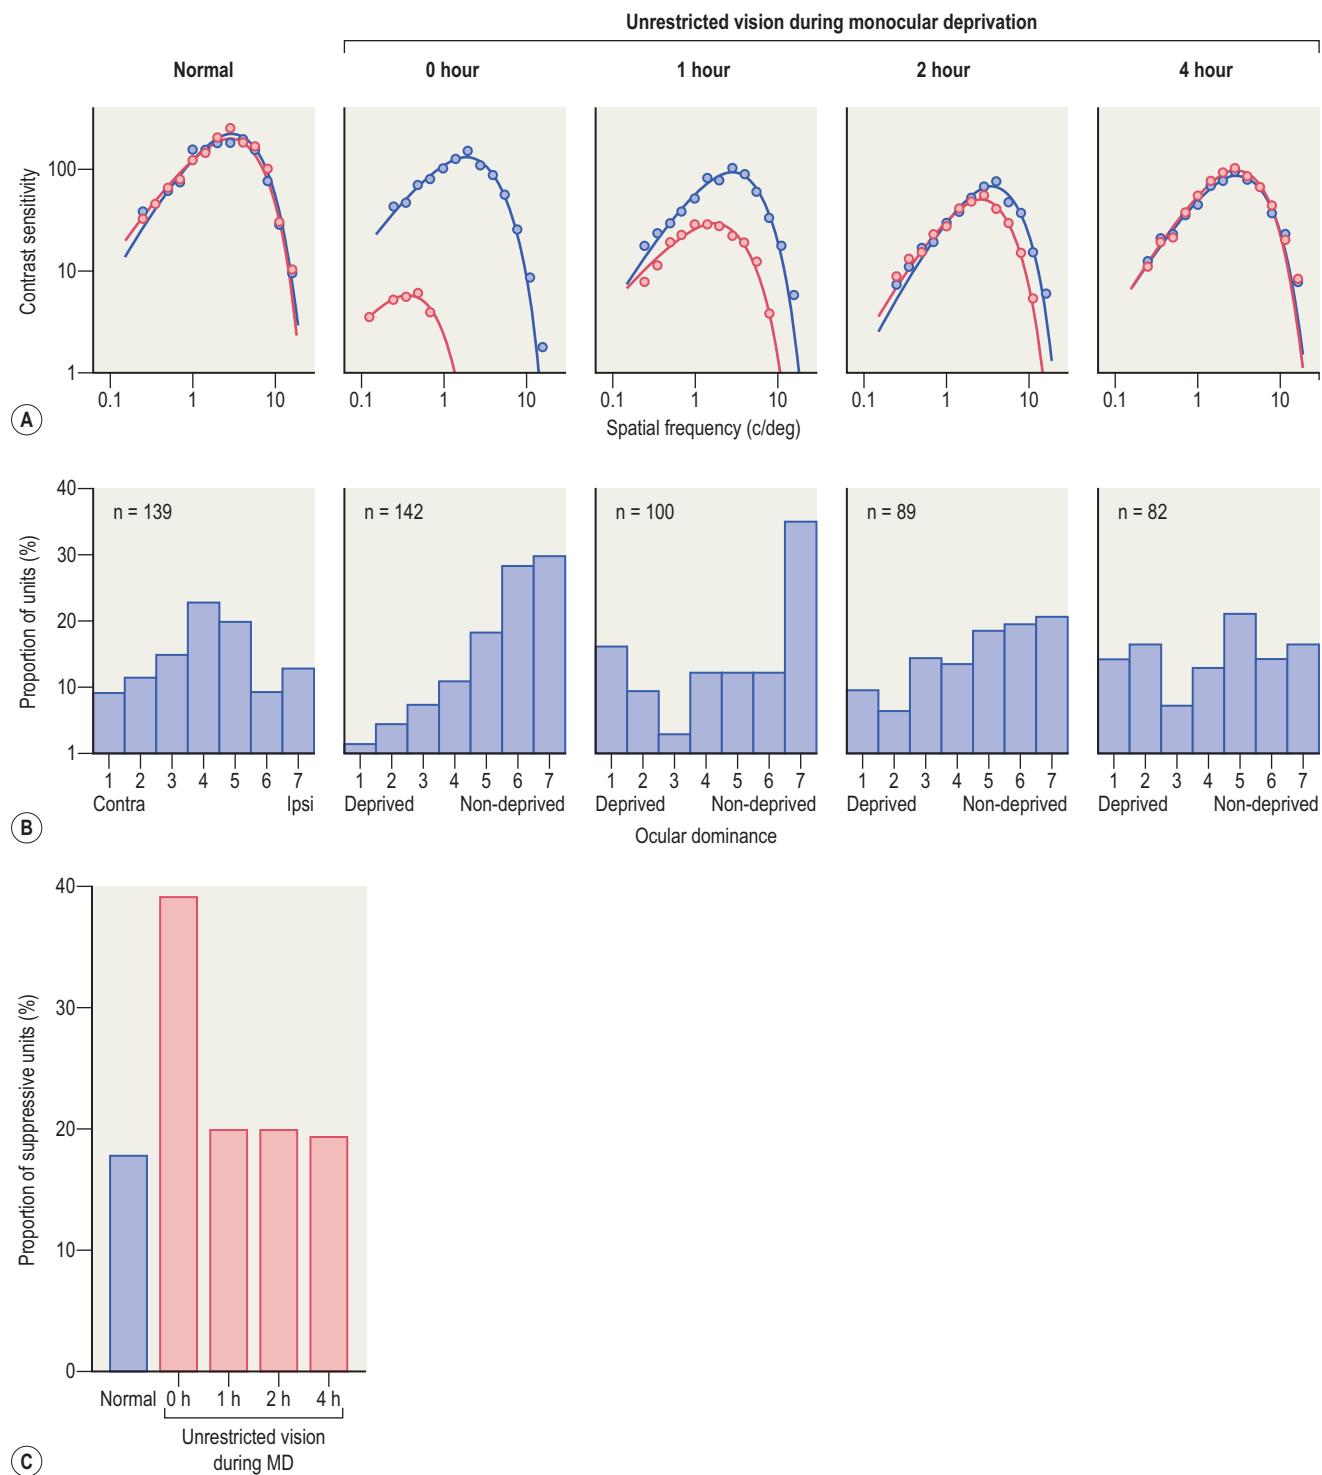

Figure 40.5 Beneficial effects of daily brief periods of unrestricted vision during monocular form deprivation. **(A)** Effects of duration of daily unrestricted vision on contrast sensitivity for representative monkeys. the non-deprived eyes. This imbalance disrupts the timing of the firing of action potentials between the pre-synaptic (LGN) and post-synaptic (V1) neurons for the deprived eye. Uncorrelated firing of action potentials between the pre-synaptic and post-synaptic neurons in V1 leads to a weakening of synaptic connections for the deprived eye while well-timed firing between the pre- and post-synaptic cells strengthens the synapses for the non-deprived eye ("Hebbian synaptic plasticity").^{65–68} The timing of pre-synaptic and post-synaptic neuronal spiking appears to be also modulated by inhibitory neurons in the circuitry.^{15,16,69} These activity-dependent changes in synaptic strength also involve long-term potentiation (LTP) of input signals from the non-deprived eye and long-term depression (LTD) of signals from the deprived eye.^{66,70,71}

Closely associated with LTP and LTD synaptic plasticity is the role of glutamate receptors in cortical neurons, in particular, *n*-methyl-D-aspartate (NMDA), α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), and γ -aminobutyric-acid (GABA) receptors (Fig. 40.7B). Excitatory

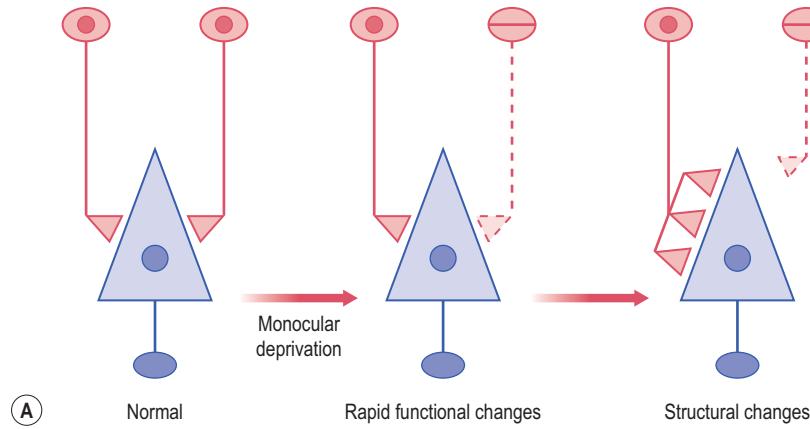

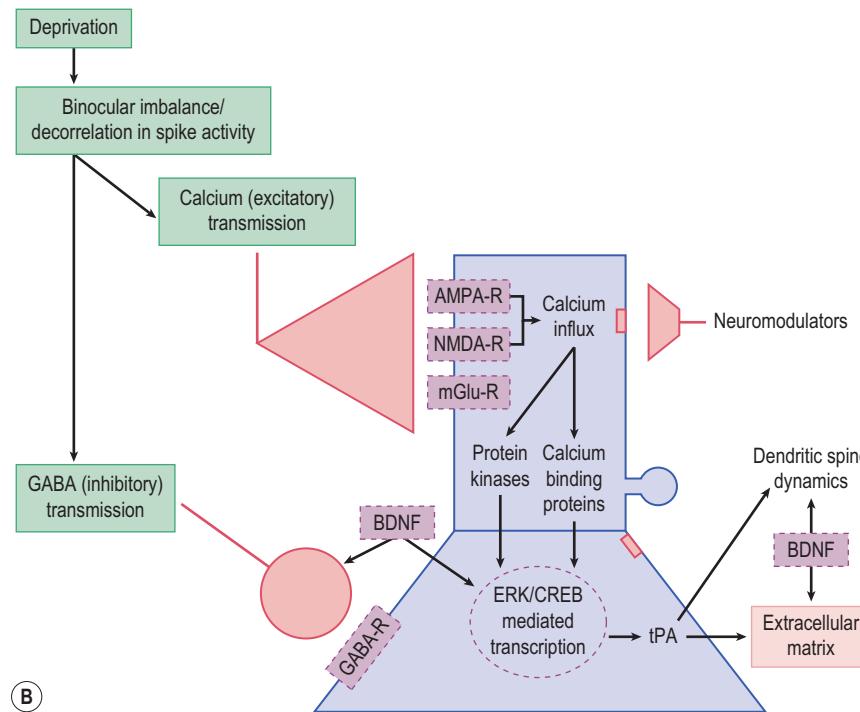

Figure 40.7 Cortical mechanisms of ocular dominance plasticity. **(A)** Classic view of "binocular competition" in the primary visual cortex following early monocular form deprivation. **(B)** Molecular mechanisms of experience-dependent cortical plasticity. (See reviews by Hensch 2005¹⁵ and Tropia et al 2009.¹⁶)

synaptic transmission is mediated by NMDA and AMPA receptors while inhibitory synaptic transmission is regulated by GABA-A α receptors. Each of these glutamate receptors has a broad range of critical roles in regulating the balance between excitation and inhibition and ocular dominance plasticity.^{15,16}

NMDA receptors are made up of three types of subunits (NR1, NR2A and NR2B). The normal postnatal changes in the expression of NR1 and NR2A or NR2B subunits, e.g. the NR2A/NR2B ratio is low at birth and gradually increases during postnatal development, are also experience-dependent. As a result, the developmental changes of the NMDA subunit expression due to monocular deprivation, i.e. the activity-dependent regulation of the NR2A/NR2B ratios, are intimately involved in regulating the plasticity of the visual cortex. For example, an increase in the NR2A or NR2A/2B ratios leads to the induction of LTP and to a heightened sensitivity of synapses to modification.⁷²⁻⁷⁴

AMPA receptors, composed of GluR2 and either GluR1 or GluR3 subunits, are also involved in synaptic plasticity.^{16,75-77} Synaptic strength is determined by the AMPA receptor density and calcium permeability. Repetitive activation of synapses leads to increased insertion of AMPA subunits into postsynaptic neuronal membrane resulting in LTP whereas reductions in synaptic activation, e.g. by monocular deprivation, remove AMPA receptors leading to LTD.^{14,16,78}

Synaptic depolarization via activation of NMDA and AMPA receptors induces *calcium influx* and activates an *intracellular signaling cascade*. The second messenger molecules that are directly involved in synaptic strength and ocular dominance plasticity include protein kinase (PKA), calcium/calmodulin-dependent protein kinase II (CaMKII), extracellular signal-regulated kinase 1,2 (ERK), cyclic AMP responsive element binding protein (CREB), and protein synthesis machinery. PKA, CaMKII, and ERK rapidly promote ocular dominance plasticity by modulating synaptic strength by phosphorylating plasticity-regulating molecules in glutamate or GABA receptors. This kinase signaling leads to the activation of CREB.⁷⁹⁻⁸¹ The changes initiated by activation of intracellular second messenger molecules along with the action of brain-derived neurotrophic factor (BDNF) leads to the enhanced expression of molecules that act on tissue plasminogen activation (tPA). BDNF and tPA can initiate the changes of dendritic spine motility,⁸² spine density,⁸³ and extracellular matrix¹⁶ that ultimately result in rewiring of cortical circuits favoring the non-deprived eye.

GABA-mediated inhibition is important in maintaining the balance between cortical excitation and inhibition, hence in regulating the timing of ocular dominance plasticity.^{15,69,83,84} Manipulation of the normal level of GABAergic transmission in the developing brain can delay or advance the onset of the critical period. Preventing the maturation of GABA mediated transmission or dark rearing delays the critical period. Enhancing GABA transmission by infusing GABA agonist, e.g. benzodiazepines,⁸⁴ or facilitating the growth of GABAergic interneurons by BDNF can advance the onset of the critical period.^{85,86}

The clinical significance of these manipulations to "reset" the excitatory and inhibitory balance in V1 by various pharmacological methods is that the results may provide new insights into the mechanisms underlying critical periods,

and thus, reveal potential means to promote functional recovery in adults with developmental vision disorders.^{63,64}

Another class of molecules involved in synaptic plasticity is the *neuromodulators* including norepinephrine (noradrenaline), serotonin, and acetylcholine. These molecules are abundantly present throughout the cortex. Enhancing adrenergic, serotonergic or cholinergic modulator systems facilitates the onset of ocular dominance plasticity.⁸⁷⁻⁹⁰ Changes in the expression of neuromodulators influence the level of LTP and LTD induction by modifying the intracellular calcium concentration by second messenger pathways and results in the associated structural reorganizations of local connections to the visual cortex.⁹¹

Effects of early monocular defocus

Constant monocular defocus

A less severe form of monocular image degradation results from large differences in refractive errors between the two eyes (*anisometropia*). Normal primates begin their life with modest but binocularly balanced hyperopic refractive errors that decline to a normal refractive state during early infancy (*emmetropization*).^{92,93} If infants have large differences in refractive state between the two eyes, they are unable to focus with both eyes. To avoid experiencing binocularly discordant images, infants begin to fixate with one eye (typically with the eye having a less severe refractive error) and as a result, the non-fixating eye experiences a defocused image. Monkey models of anisometropia are simulated by rearing infant monkeys with monocular defocusing lenses^{40,92-96} or by monocular atropinization.⁹⁷

Perceptual deficits

The perceptual consequences of untreated early anisometropia are generally similar to the anomalies found after early monocular form deprivation; impoverished binocular vision, reduced contrast sensitivity for high-spatial-frequency stimuli, and lower optotype acuity in the affected eye (*anisotropic amblyopia*).⁹⁵⁻⁹⁸ However, the perceptual deficits in anisometropes are generally less severe than in monocular form deprivation and are spatial frequency dependent (Fig. 40.8A). Anomalies vary substantially between individuals depending on the etiological factors and rearing histories, e.g. the degree of defocus.

Neural changes

Abnormal alterations in cortical physiology that result from early unilateral defocus are also similar to, but milder than cortical deficits in monocularly form-deprived monkeys. The ocular dominance distribution of V1 neurons is marked by a substantial loss of binocularly balanced cells (ocular dominance between 3 and 5) and by a milder but significant shift away from the affected eye^{95,96,99} (Fig. 40.8B). The sensitivity of V1 neurons to binocular disparity is substantially reduced and complex cells are more severely affected than simple cells⁹⁵ (Fig. 40.8C). The spatial resolution and contrast sensitivity of V1 neurons for the affected eye of a *severely* anisometric monkey are slightly lower than that of the fellow eye.^{96,99} However, the magnitude of deficits in the spatial receptive-field properties of V1 neurons is too small to

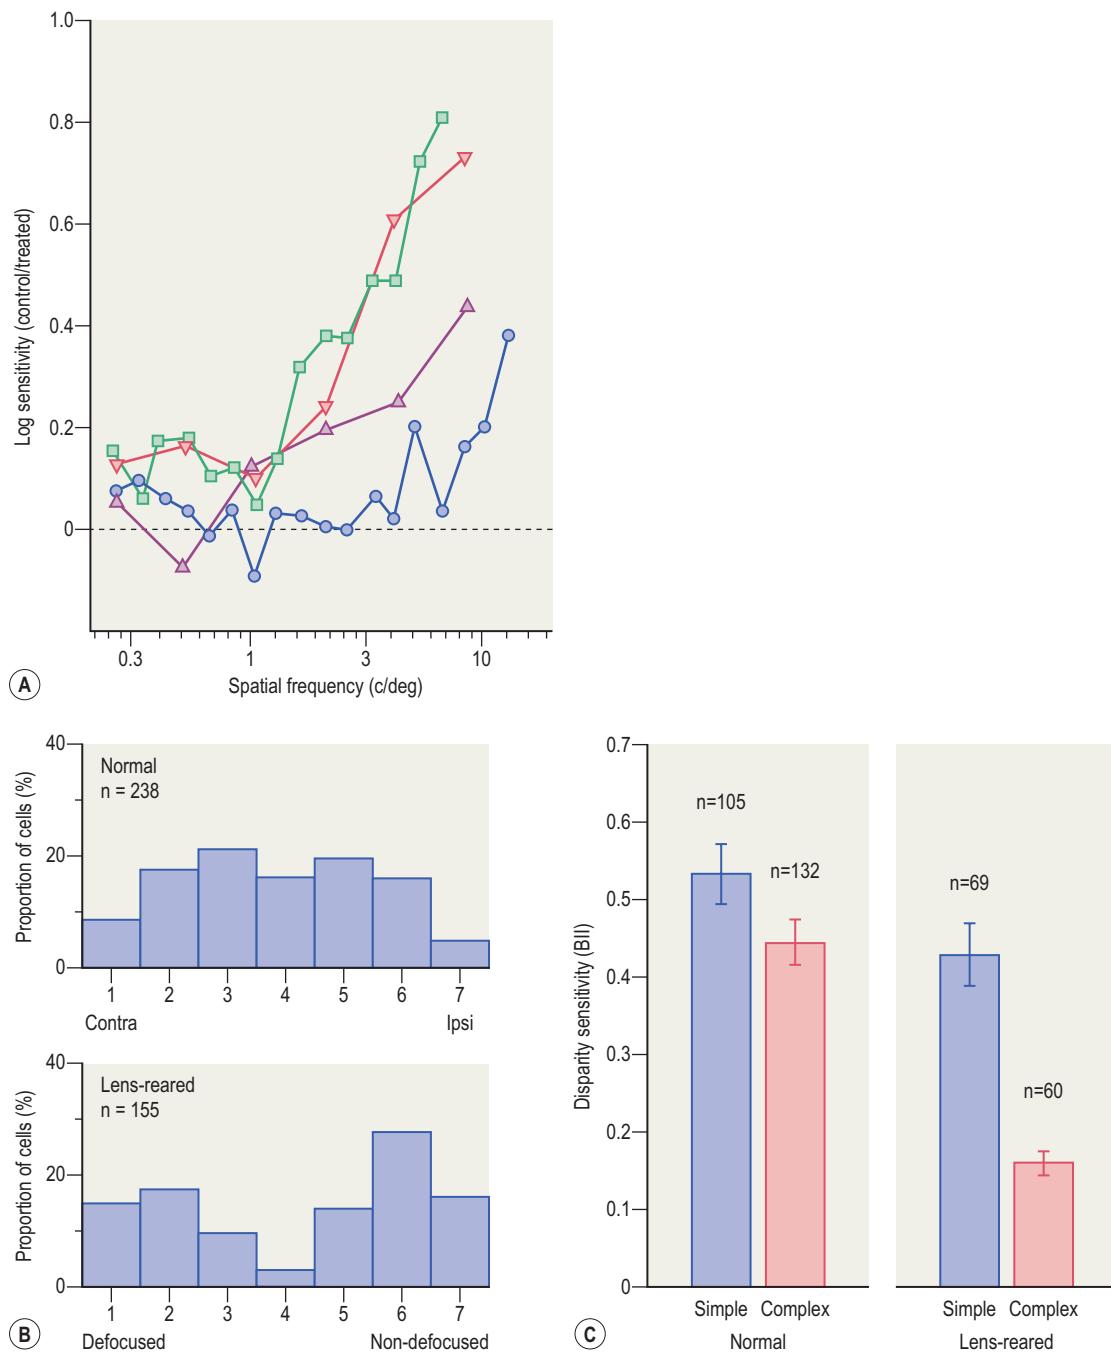

Figure 40.8 Perceptual and neural deficits in anisometropic amblyopia. **(A)** Interocular differences in contrast sensitivity as a function of stimulus spatial frequency in 4 different monkeys reared with unilateral lens-defocus. **(B)** Ocular dominance distribution of V1 neurons in normal (top) and lens-reared (bottom) monkeys. **(C)** Disparity sensitivity loss in V1 of anisometropic monkeys. Note that complex cells had more severe deficits. (Modified from Smith et al 1985,⁹⁸ 1997.⁹⁵)

account for their perceptual loss in acuity and contrast sensitivity.^{1,96}

Alternating defocus

Early monocular defocus can be alternated daily between the two eyes to prevent the development of amblyopia.^{94,100} If infant monkeys experience alternating defocus, the monocular response properties of V1 neurons, such as orientation selectivity, spatial frequency tuning, and/or spatial

resolution, do not show response alterations that favor one eye over the other because each eye receives uninterrupted vision on alternate days during early infancy.¹⁰⁰ However, daily alternating defocus leads to a spatial-frequency-dependent loss of local stereopsis (elevated disparity threshold) (Fig. 40.9B). This reduction of local stereopsis is exaggerated for high-spatial-frequency stimuli because larger defocus generates greater conflicts between signals coming from the two eyes.⁹⁴ Moreover, the disparity sensitivities of V1 neurons are significantly reduced in these

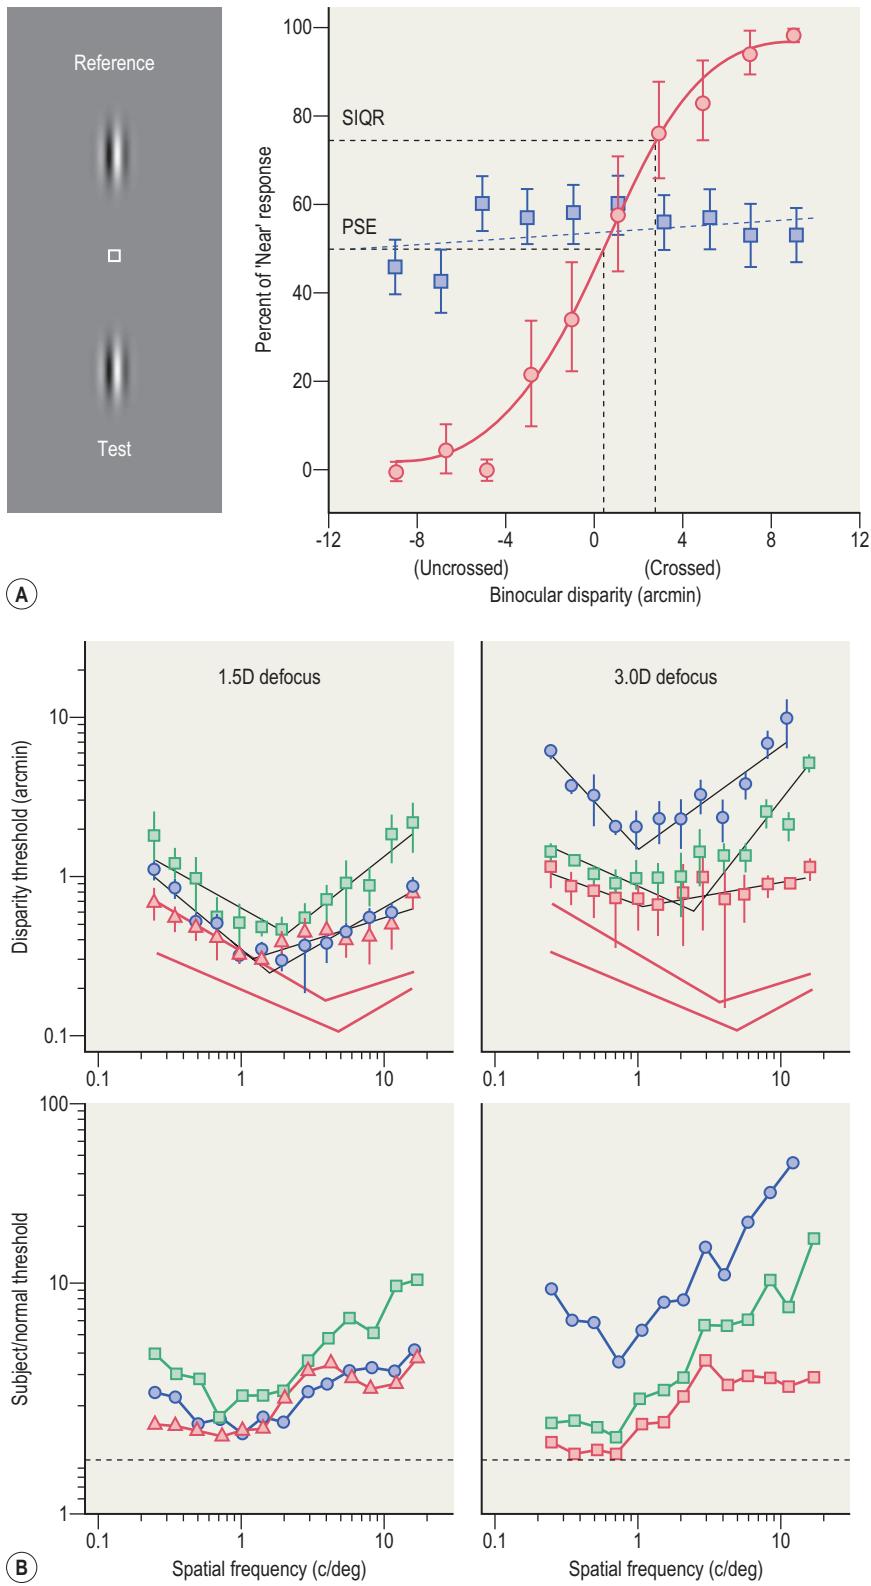

Figure 40.9 Effects of early alternating defocus on disparity sensitivity. **(A)** Stimulus used to test local stereopsis in monkeys (left), and a psychometric function for binocular disparity discrimination (right). Stereoaclity is defined by disparity differences between the point of subject equality (PSE) and the semi-interquartile range (SIQR). Monocular control data are illustrated with small squares. **(B)** Disparity sensitivity loss as a function of spatial frequency in monkeys reared with 1.5 diopter alternating defocus (left top) and interocular differences (left bottom), and comparable values for monkeys reared with 3.0 diopter alternating defocus (right column). Thick lines signify the range of threshold values for normal monkeys. (Modified from Wensveen et al, 2003.⁹⁴)

monkeys and this reduction is also spatial frequency dependent.¹⁰⁰

These observations support the traditional view that local stereopsis is spatial frequency dependent, and that binocular disparity information is processed by independent channels tuned to different spatial frequencies.^{101,102} It is also evident

that the local disparity processing mechanisms in V1 can be independently compromised by early abnormal visual experience depending on their spatial frequency tuning properties. Finally, the effects of early alternating defocus on binocular vision development underscore the importance of having the normal presence of disparity-sensitive neurons in

V1 for local stereopsis although disparity-sensitive V1 neurons alone are not sufficient to support fine stereopsis, i.e. it requires further processing by extrastriate neurons.^{103,104}

Effects of early strabismus

Strabismus is a chronic deviation of the visual axes that emerges shortly after birth.^{105,106} The direction of the axis deviation can be convergent (esotropia), divergent (exotropia), or vertical (hypertropia). The etiology of infantile or congenital strabismus is not known. There is a clear familial tendency of developing strabismus, but the genetic factors responsible for infantile strabismus are not well understood.¹⁰⁶ In primates, a high degree of uncorrected hypermetropia soon after birth is known to result in esotropia (accommodative esotropia).¹⁰⁷⁻¹¹⁰

Perceptual deficits

Strabismic infants experience double vision (diplopia) immediately after the onset of misalignment. If "normal" alignment is not achieved in a timely manner, binocular vision anomalies, such as deficient stereoscopic vision^{95,111,112} (Fig. 40.10), reduced binocular summation of contrast sensitivity,⁹⁵ and clinical suppression¹¹³ are likely to develop. Amblyopia may develop if strabismus is not treated for an extended period of time during the critical period.^{1,33,96} The effects of experiencing early strabismus have been extensively studied in monkeys by artificially creating ocular misalignment shortly after birth.

Animal models of strabismus

In monkey models, human strabismus is commonly simulated by surgical^{96,112} or optical^{95,114-120} methods shortly after birth. As mentioned previously, alternating monocular occlusion from birth leads to strabismus and these monkey models have served primarily for studies on ocular

motility.⁴³ For the surgical method, the extraocular muscle of one eye (the medial rectus muscle for exotropia and the lateral rectus muscle for esotropia) is sectioned and the opposing muscle (the lateral or medial rectus muscle, respectively) is tied to induce the misalignment.^{96,112} The surgical method creates a period of non-comitant or paralytic strabismus, i.e. the angle of deviations changes with the field of gaze. This type of strabismus is less common in humans than comitant strabismus, i.e. the angle of deviation does not change with the field of gaze. In monkeys with surgical strabismus, the manipulated eye is immediately placed at a competitive disadvantage and the non-deviating fellow eye becomes the "fixating" eye. As a result, the deviating eye is likely to develop amblyopia.^{96,121}

For the optical method, infant monkeys are fitted with a helmet with a pair of base-in or base-out prisms. This method simulates comitant strabismus in humans. Neither eye is disadvantaged because their fixation frequently alternates between the two eyes, and thus, the prism-reared monkeys are less likely to develop amblyopia.^{95,114,121} However, the effects of early surgical or optical strabismus are quite devastating on the perceptual and neural development of binocular vision.

Neural changes

The proportion of V1 neurons that can be activated by stimulation of either eye (classically defined as "binocular cells") is dramatically reduced in monkeys reared with surgical^{96,122} or optical strabismus^{95,114,123} (Fig. 40.11A). In monkeys reared with paralytic strabismus, the ocular dominance distribution of V1 neurons may shift away from the deviating eye if strabismus is severe.⁹⁶ Similar but smaller changes in ocular dominance distribution are also found in the middle temporal visual area (MT) of monkeys with simulated paralytic strabismus.¹²⁴ Importantly, the proportion of disparity-sensitive neurons is drastically reduced in V1^{95,115-117} (Figs. 40.11B, C) of stereo-deficient monkeys reared with optical strabismus.

Clinical suppression is a pervasive adaptive mechanism that humans with untreated strabismus develop in order to eliminate the disturbing impact of diplopia and visual confusion.¹⁰⁶ Monkeys reared with optical strabismus exhibit binocular suppression that is similar to clinical suppression in strabismic humans.¹¹³ In these strabismic monkeys, V1 neurons have a higher than normal prevalence of binocular suppression (Fig 40.11B and see Fig. 40.13C below),^{95,115-117} thus, suggesting a link between abnormal binocular signal processing in V1 and binocular vision deficits for these strabismic monkeys.

Unless accompanied by consistent and extended periods of defocus in one eye, strabismus does not dramatically alter the monocular spatial response properties of V1 neurons.^{1,2,96} Even if V1 neurons exhibit mild reductions in contrast sensitivity and/or spatial resolution in the deviating eye of severely amblyopic monkeys, such deficits in V1 are too small to account for their sensitivity losses.^{1,96}

Effects of onset age and duration of strabismus

A critical issue for the management of infantile esotropia is at what age corrective measures should be taken to preserve

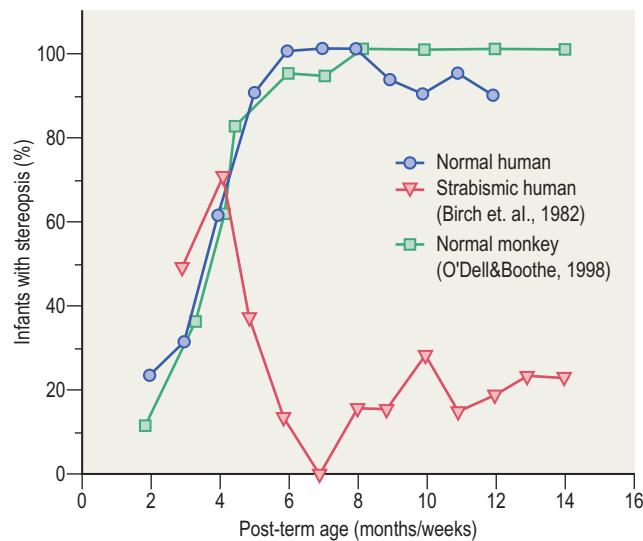

Figure 40.10 Perceptual deficits in strabismic amblyopes. Development of stereopsis in normal human (blue circles) and monkey (green squares) infants, and human infants with infantile esotropia (red triangles). (Data from Birch 2003¹⁰⁵ and O'Dell & Boothe 1998.⁸)

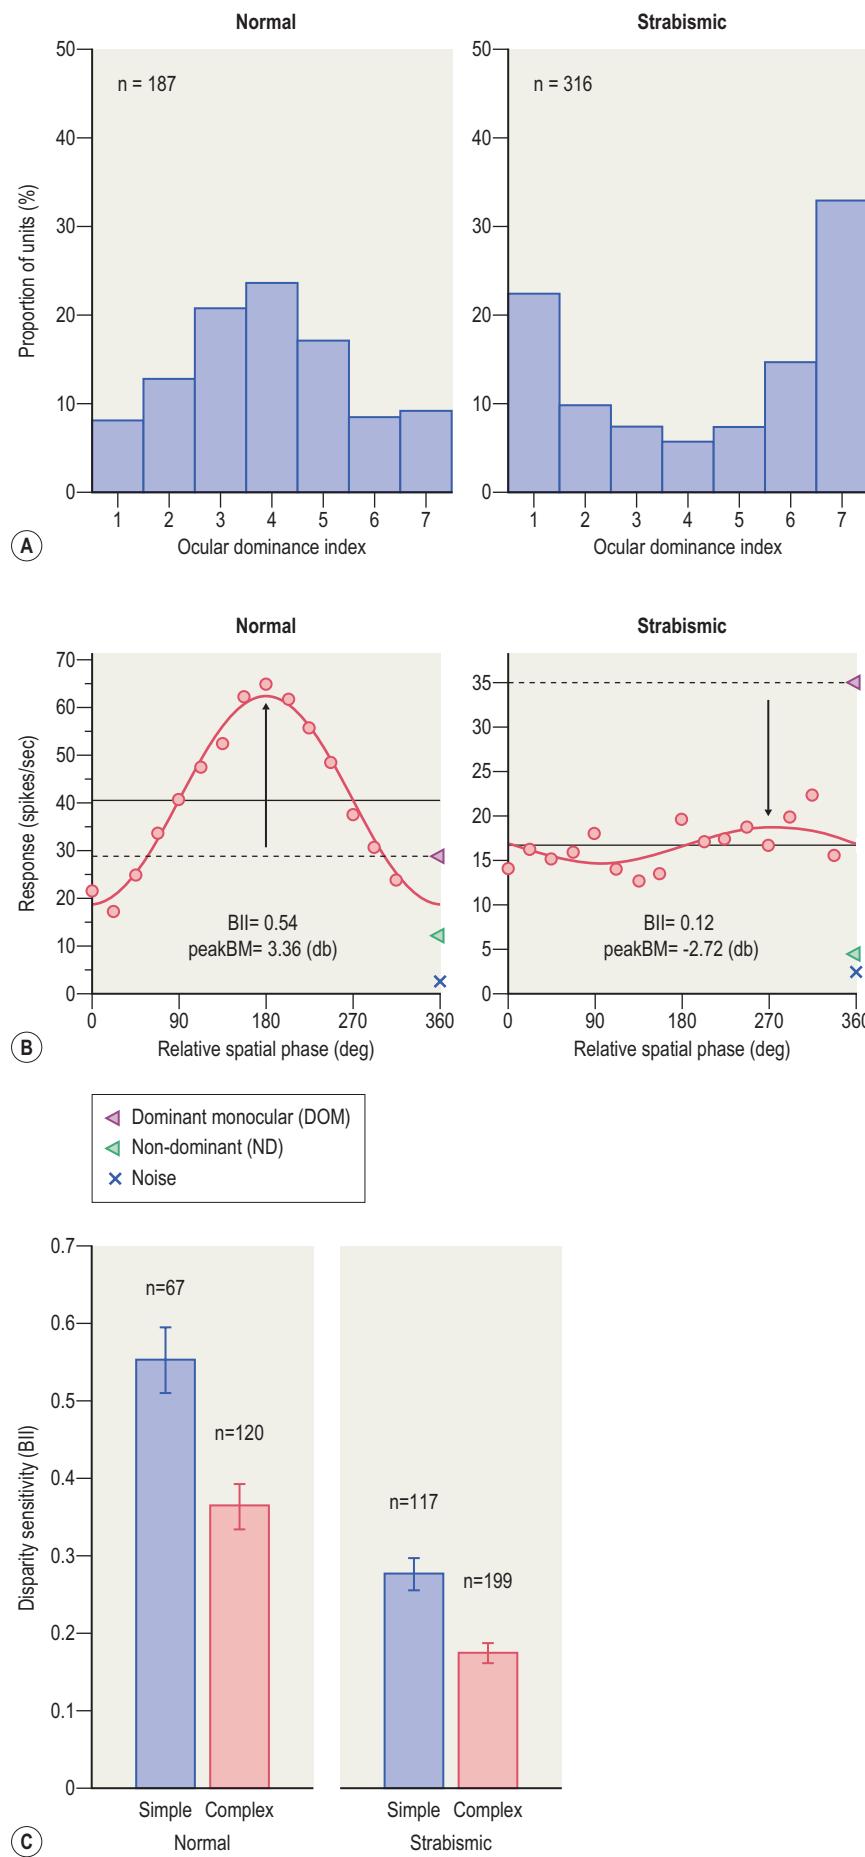

Figure 40.11 Neural deficits in monkeys reared with optically induced strabismus. **(A)** Ocular dominance distribution of V1 neurons in normal (left) and strabismic (right) monkeys. **(B)** Representative disparity tuning functions of V1 neurons for normal (left) and strabismic (right) monkeys. Note that the neuron from a strabismic monkey exhibited a severe loss of disparity tuning and robust binocular suppression (binocular responses < dominant monocular response). **(C)** The average disparity sensitivity (BII) of V1 neurons in normal (left) and strabismic (right) monkeys. (Modified from Smith et al 1997.⁹⁵)

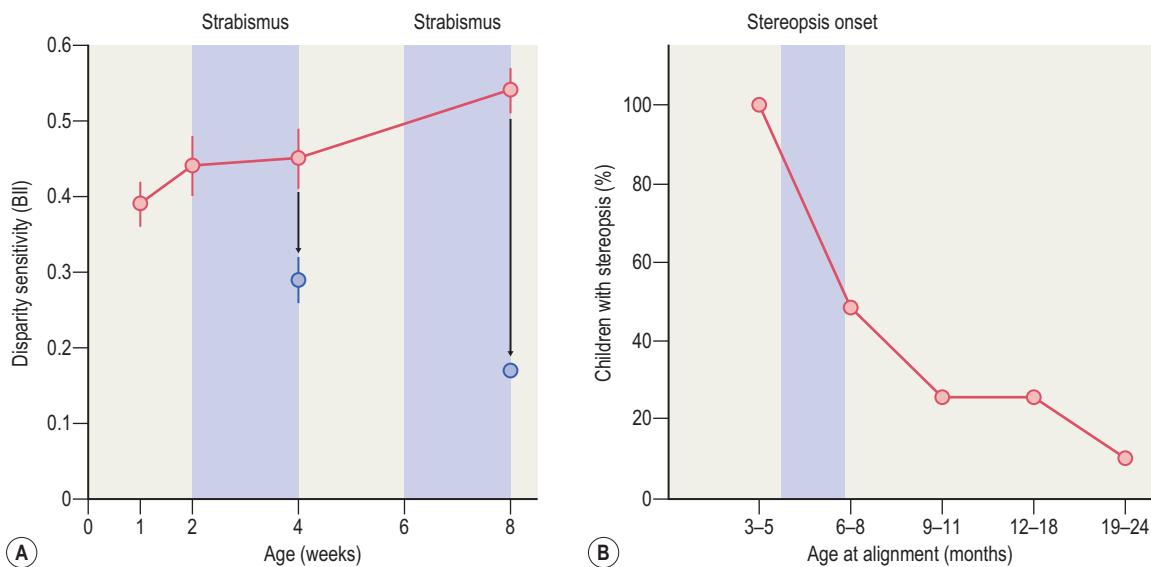

Figure 40.12 Effects of onset age of strabismus and timing of alignment on disparity sensitivity. **(A)** Effects of onset age of strabismus on disparity sensitivity of V1 neurons in infant monkeys. Duration of optical strabismus was kept for 2 weeks while the onset age of strabismus was set either at 2 weeks or 6 weeks of age. Normal development of disparity sensitivity in V1 is also illustrated (red circles). Note that the reduction in disparity sensitivity is far greater for the late-onset group than for the early-onset group. (Data from Chino et al 1997¹⁰ and Kumagami et al 2000.¹¹⁵) **(B)** Effects of alignment age on stereopsis in human strabismic infants. Blue shading indicates the known onset age of stereopsis for normal human infants (i.e. between 4 and 6 months of age). (Modified from Birch et al 2000.¹²⁷)

stereoscopic vision and establish alignment. Recent animal studies support the *clinical view* that surgical correction before the known onset age of stereopsis (4–6 months of age) should be beneficial for maintaining binocular sensory functions^{109,125–128} and reducing eye movement anomalies.^{118–120,129}

Onset age

Experiencing a brief period (2 weeks, equivalent to 2 months in humans) of optical strabismus beginning at 4 weeks of age (equivalent to 4 months in humans) drastically reduces the proportion of disparity-sensitive neurons and increases the prevalence of binocular suppression in monkey V1.¹¹⁵ These binocular response deficits are *more severe* when infant monkeys experience optical strabismus *after* 4 weeks of age (6 to 8 weeks) rather than *before* 4 weeks of age (2 to 4 weeks)^{115,116} (Fig. 40.12A). Optical strabismus creates well-focused images that do not match between the two eyes. Consequently, unlike monocular deprivation, the most sensitive segment of the critical period for binocular disparity sensitivity is not immediately after birth when spatial vision is still very crude. Instead, it is soon after the known onset age of stereopsis around 4 to 8 weeks of age (equivalent to 4 to 8 months of age in humans). By this time of normal development, V1 neurons attain the qualitatively adult-like monocular spatial tuning properties and responsiveness.^{10,11,130–132} Consequently, V1 neurons become more sensitive to small discrepancies in the images between the two eyes and as a result, their binocular response properties are more readily disrupted.

The *clinical relevance* of these findings is evident. As mentioned, the earlier the surgical or optical correction of infantile esotropia, the better the preservation of fine binocular vision and later alignment of the visual axes^{109,125–128} (Fig. 40.12B).

Finally, the latest onset age of strabismus that can cause substantial binocular vision deficits and/or amblyopia is yet to be determined in primates. However, there are substantial perceptual deficits and anomalous alterations in V1 and V2 even when surgical strabismus is induced as late as 6 months of age (roughly equivalent to 2 years of age in humans).

Duration

In human infants, longer durations of strabismus result in greater deficits of binocular vision (stereopsis).¹²⁷ For infant monkeys reared with prisms, a similar relationship holds for disparity sensitivity deficits in V1. However the duration of optical strabismus has little impact on the disparity sensitivity loss of V1 neurons if it is longer than 2 weeks (Fig. 40.13B).¹¹⁶ It is important to note that the effects of duration on disparity sensitivity reflect the combined effects of strabismus duration and the timing of interocular alignment, i.e. longer duration delays alignment and, hence the restoration of unrestricted “normal” visual experience during the critical period for binocular vision development.

What is the *minimum* duration of misalignment required to alter the binocular response properties of V1 neurons in infant monkeys? Only 7 days of prism-rearing (equivalent to 4 weeks in humans) beginning at 4 weeks of age are sufficient to disrupt the binocular disparity sensitivity of V1 neurons (Fig. 40.13B).^{115–117} Three days of optical strabismus (equivalent to 12 days in human infants) do not significantly alter the disparity sensitivity. However, after 3 days of experiencing optical strabismus, V1 neurons exhibit an abnormally high prevalence of binocular suppression (Fig. 40.13C). Importantly, binocular suppression in V1 after 3 days of prism-rearing is as strong as suppression in monkeys that experience much longer durations (months or years) of strabismus. Thus, the very first neural alteration in V1

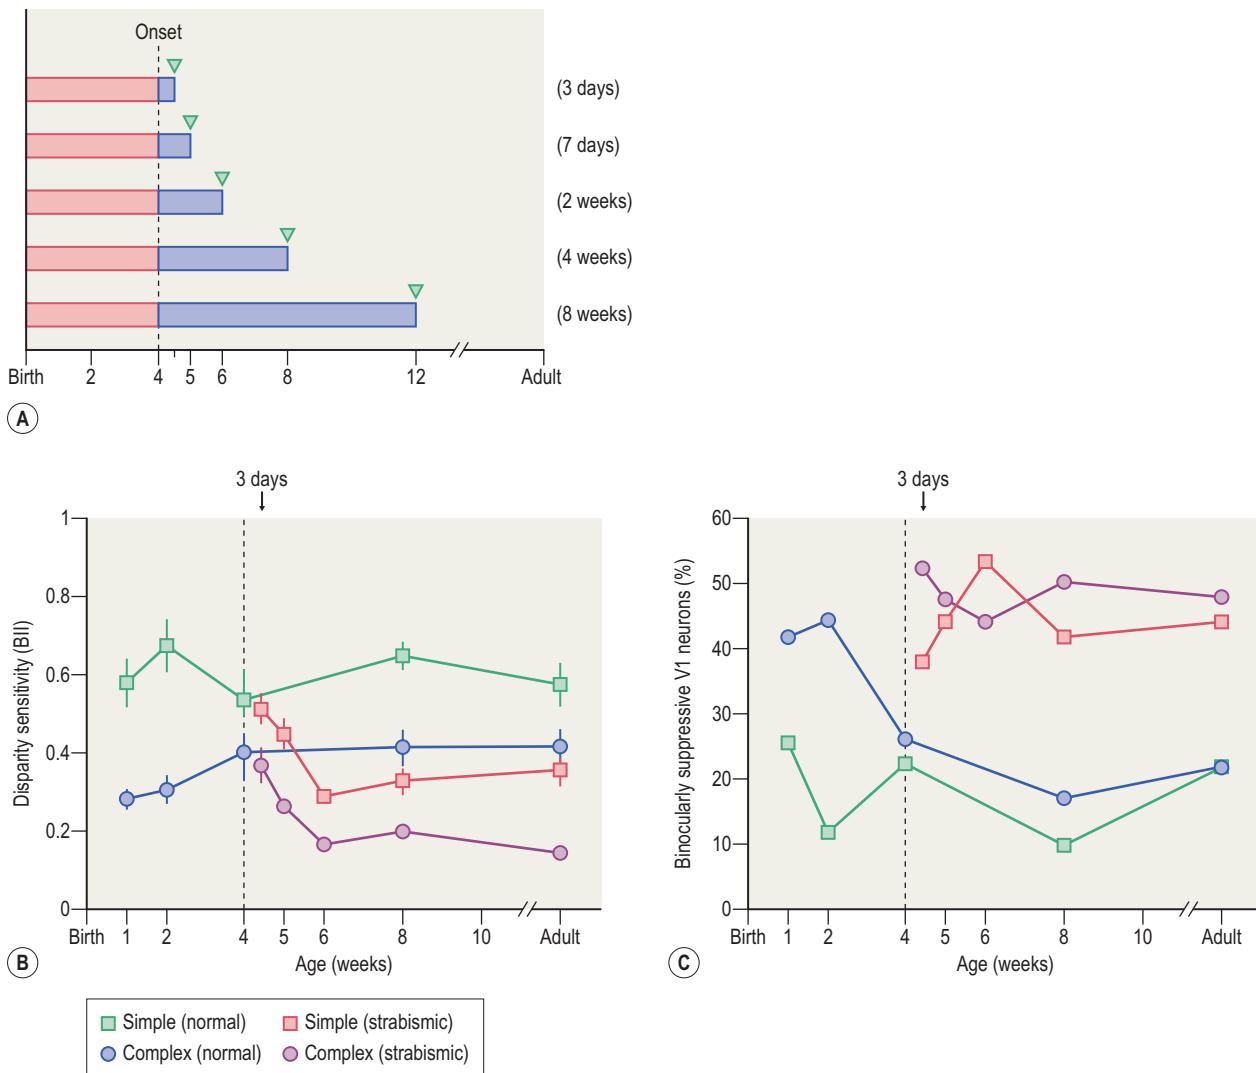

Figure 40.13 Effects of duration of optical strabismus on binocular responses of V1 neurons. **(A)** Rearing regimen. The onset was kept at 4 weeks of age. The duration of prism-rearing was varied between 3 days and 8 weeks. Green triangles indicate the time of V1 recording experiments. **(B)** Effects of duration on disparity sensitivity of V1 neurons. Normal data are also illustrated (blue and green symbols). Data for strabismic adults come from monkeys reared with surgically induced strabismus. **(C)** Effects of strabismus duration on the prevalence of V1 neurons exhibiting binocular suppression. (Data from Chino et al 1997,¹⁰ Mori et al 2002,¹¹ Zhang et al 2005.¹¹⁷)

following the onset of strabismus is the emergence of robust binocular suppression.¹¹⁷

Eye movement anomalies

Strabismic monkeys and humans exhibit temporal-to-nasal asymmetries in pursuit eye movement and visual tracking under monocular viewing,^{44,106,124,133} similar to those found in normal infants.^{133,134} Also, strabismic humans often exhibit latent nystagmus.^{120,135} These eye movement anomalies result from abnormal control of cortical neurons over the subcortical nuclei that support eye movements and visual tracking.^{44,119,124,133,134,136}

The timing of corrective measures for infantile esotropia has significant impact on preventing eye movement anomalies.^{118,120,129} In a series of recent studies by Tychsen and his colleagues, newborn monkeys were reared from birth with a goggle containing a 20-diopter prism in front of each eye

until either 3 weeks of age ("early repair") or 3 to 6 months of age ("late repair"). Monkeys in the "late repair group" exhibited temporal-to-nasal asymmetries of smooth pursuit and OKN under monocular viewing, latent nystagmus, and persistent ocular misalignment. However, monkeys in the "early repair group" did not exhibit any of these motor deficits.^{118,120,129} The motor deficits in the late repair group appeared to be linked to their abnormal visual cortical physiology and anatomy.^{95,115,116,119,120,133,137}

The clinical implications of these studies are that the earlier the corrective measures for infantile esotropia the better the normal maturation of oculomotor functions (see review¹⁰⁹).

Amblyopia

Amblyopia is a developmental disorder of spatial vision. Amblyopic primates show reduced contrast sensitivity that

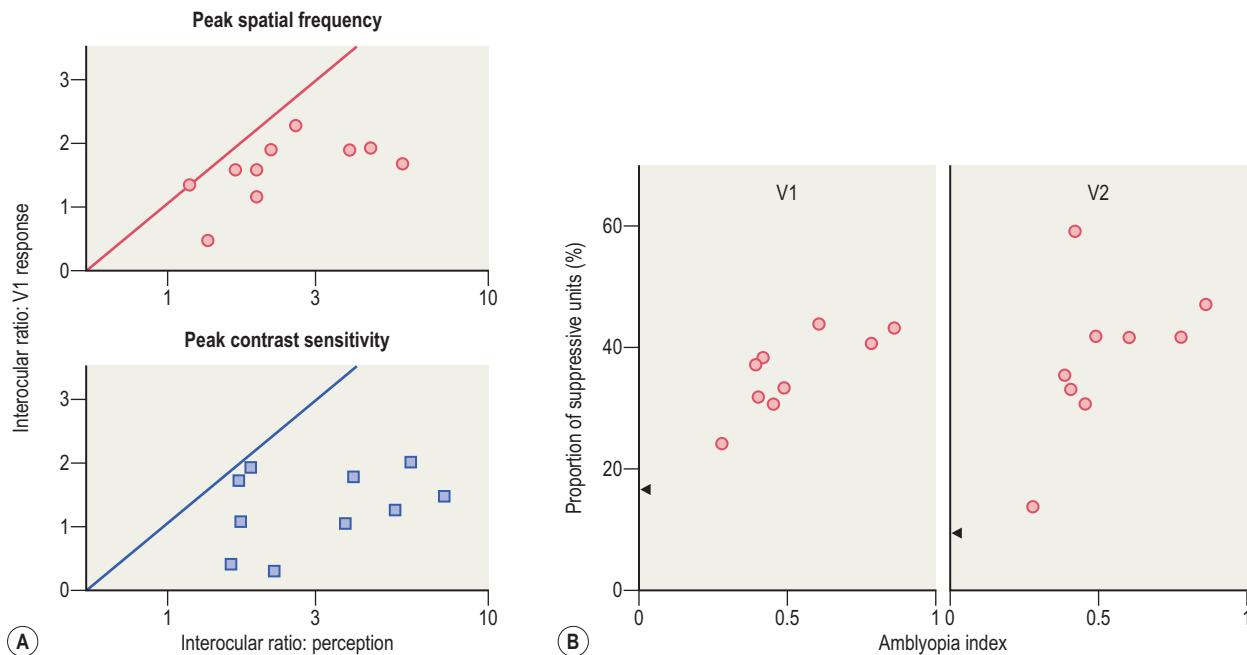

Figure 40.14 Amblyopia and cortical physiology in monkeys. **(A)** The average peak spatial frequency (top) and average peak contrast sensitivity (bottom) of V1 neurons as a function of perceptual differences in contrast sensitivity between the amblyopic and fellow eye of strabismic and anisometropic monkeys. Note that behavioral deficits are much greater than cortical deficits. (Modified from Kiorpes & Movshon 2003.¹) **(B)** Relationship between the degree of amblyopia and the prevalence of V1 and V2 neurons exhibiting binocular suppression. Triangles indicate normal control data.

is restricted to or exaggerated for mid- to high-spatial-frequency ranges of stimuli and exhibit lower optotype acuity for the affected eye.⁹⁶ The nature and extent of visual anomalies in amblyopes differ widely depending on the onset age, the status of binocular functions,¹³⁸ and the type of amblyopia, i.e. strabismic, anisometropic, or form deprivation amblyopia.^{33,138,139}

Perceptual deficits

In addition to acuity and contrast sensitivity losses in all types of amblyopia, the visual system of strabismic and anisometropic amblyopes is known to be intrinsically “noisy” and their visual performance is readily disrupted by introduction of noise in the stimuli.^{33,140} The sensitivity of amblyopic humans to second-order stimuli is also reduced.¹⁴¹ Strabismic and anisometropic amblyopes exhibit difficulties in global perceptual tasks that require precise pooling of neighboring local feature information over extended ranges of space. These perceptual difficulties emerge in the form of abnormal contour integration, motion integration, and/or object segmentation.^{142–145} As mentioned above, fixation instability is frequently diagnosed in the affected eye of amblyopes under monocular viewing. Without adequate control procedures, fixation instability could make testing sensory capacities of an amblyopic eye and the interpretation of results difficult.¹³⁵

Neural changes

Studies on the neural basis of *form deprivation amblyopia*, as we have reviewed, have given us a relatively clear view of how the form deprived eye loses its functional connections with the primary visual cortex (V1) and how the visual sensitivity of the affected eye is altogether lost even to the most basic, robust visual stimuli⁵⁶ (see also recent reviews^{13–16}).

For all types of amblyopic monkeys, lower sampling in V1 for the affected eye (ocular dominance shift away from the deviating eye) and/or reduced spatial resolution and contrast sensitivity of V1 neurons are commonly invoked to explain the mechanisms underlying “low-level” perceptual deficits, i.e. reduction in contrast sensitivity and acuity.^{1,2,33,139} Recent fMRI studies of amblyopic humans report substantial reductions in BOLD signals for stimulation of the amblyopic eye.^{146,147}

Unlike monocular form deprived monkeys, a relatively small percentage of V1 neurons in strabismic or anisometropic monkeys exhibit reduced contrast sensitivity at high spatial frequencies and/or lower spatial resolutions and *only in severely amblyopic monkeys*.^{1,96} Moreover, a shift in ocular dominance distribution of V1 neurons away from the affected eye is relatively mild in anisometropic amblyopes and often absent in strabismic amblyopes.^{1,96} Obviously the magnitude of the V1 anomalies is too small to account for the severity of perceptual losses for these amblyopic monkeys (Fig. 40.14A).^{1,96}

An emerging view on the neural basis of strabismic or anisometropic amblyopia, therefore, is that unlike in monocular form deprivation, the major cortical alterations that may limit a wide range of monocular performance of anisometropic and strabismic amblyopes are more likely to occur beyond V1 (in extrastriate visual areas), while relatively mild changes in monocular response properties may begin in V1 of severely amblyopic monkeys.^{1,2,33,139} Another emerging view is that interocular suppression highly prevalent in V1 and V2 of strabismic or anisometropic monkeys may play a critical role in the emergence of amblyopia (Fig. 40.14B).^{2,33,95} Finally, the neural basis of more complex anomalies in amblyopic monkeys, such as excessive crowding and position uncertainty,¹⁴⁵ deficits in contour

integration, abnormal topographic mapping of visual space or topographic "jitter"^{148,149} and higher-order cognitive disorders,¹⁵⁰ has not been systematically investigated for monkeys using electrophysiological or brain imaging methods. All of these higher-order perceptual deficits in amblyopes are more likely to involve abnormal signal processing in extrastriate visual cortex.

Improved visual performance in adult subjects with developmental disorders

Although the impact of early deprivations on the visual system development becomes increasingly small with age, the mature visual brain is not completely hard wired and exhibits limited plasticity.^{151–154} The nature and extent of adult plasticity in normal primate visual brain is still a matter of considerable debate.^{155,156} Another form of "adult plasticity" that is receiving increasing attention is "*perceptual learning*" where visual performance of primates improves with repeated practice. Moreover, such learning appears to occur as a result of alterations of specific functional connections in the extrastriate visual cortex.^{157,158} These discoveries raise the possibility that reduced visual performance of adults who had experienced early deprivations could be improved by training and practice. In human amblyopes, repeated practice significantly improves performance of adults and children for a variety of visual tasks including visual acuity (see review¹⁵⁹). In stereo-deficient adult monkeys reared with early optical strabismus, stereoacuity improves by several factors after extended periods of training and testing, and this improvement appears to be associated with the preservation of disparity sensitivity in extrastriate cortical neurons.¹⁶⁰

The clinical significance of these observations is that although the earliest intervention of abnormal visual conditions during infancy is most critical in preventing or minimizing the impact of binocular vision disorders, adults with certain developmental vision anomalies may benefit from well-thought-out treatment regimens (but see Helveston 2005¹⁶¹ and Horton 2005¹⁶²).

Summary

The primate visual brain is highly malleable during early infancy and the maturation of visual functions depends on normal visual experience during the critical period of development. Normal visual experience requires clear unrestricted images in each eye and precise matching of the images of the two eyes. If one eye is deprived of clear vision during the critical period, causing binocular imbalance, the infant's visual brain is abnormally reorganized. Binocular imbalance commonly results from monocular form deprivation, monocular defocus, and/or misalignment of visual axes. Anomalous reorganization of the wiring in the visual brain largely begins in the primary visual cortex (V1), but not in the retina. Neural deficits resulting from early abnormal visual experience are likely to be more extensive in the extrastriate visual areas. Binocular visual capacities, such as stereopsis and binocular summation of contrast sensitivity, are compromised or completely lost. If the visual conditions responsible for binocular imbalance are untreated, amblyopia is likely to develop in the affected eye. As reviewed,

animal studies are designed to reveal the neural basis of developmental vision anomalies and provide key information that is beneficial for establishing effective treatment strategies for binocular vision disorders in humans.

The Effects of Visual Deprivation After Infancy

Lindsay B. Lewis & lone Fine

Introduction

Blind individuals tend to show better performance than sighted individuals on a variety of auditory and tactile tasks. This is thought to be due both to *compensatory hypertrophy* – enhanced neuronal processing within auditory and somatosensory cortices, and to *cross-modal plasticity* – whereby regions of occipital cortex that normally only process visual information begin to process auditory and tactile stimulation. While there is an extensive animal literature examining the long-term effects of early visual deprivation, we still do not have a full understanding of the neurophysiological changes that underlie cross-modal plasticity within the human brain. Here we discuss what is currently known about the behavioral and neurophysiological effects of long-term visual deprivation, and discuss the potential of new imaging techniques to reveal new insights.

Over the last two decades it has been well documented that those who suffer from visual deprivation, especially early in life, show an enhanced ability to use tactile and auditory cues that seems to be accompanied by remarkable changes in the response properties of occipital cortex.

While there is a growing literature demonstrating behavioral differences and differential neural responses to auditory and tactile stimuli in occipital cortex, the neurophysiological changes that occur as a result of blindness in humans are still fairly unclear. There is of course an extensive literature examining the anatomical and neural consequences of visual deprivation using both primate and non-primate animal models. However the literature on the effects of blindness on humans and in animal models has perhaps not been as mutually informative as might be hoped. One reason for this is that it is possible to examine the effects of visual deprivation with high temporal resolution within individual or small groups of cells within animal models, but the tools for assessing the effects of visual deprivation on humans are limited to techniques with much lower spatial or temporal resolution (Fig. 41.1). This limitation in the tools available to study the effects on long-term visual deprivation in humans is of particular concern because it is not clear how easily the animal literature can be generalized to humans. Humans rely more heavily on vision than almost all other animals and have a far larger number of visual sensory areas.^{1–3} Fortunately, as illustrated in Box 41.1,

techniques such as functional magnetic resonance imaging, high-resolution structural imaging, transcranial magnetic stimulation, magnetic resonance spectroscopy, and functional connectivity analyses are now beginning to offer new ways of non-invasively studying the neurophysiological changes that occur as a result of blindness in humans. Table 41.1 summarizes research discussed in this article examining performance on and measuring brain responses to a wide range of auditory and tactile tasks.

The neuronal effects of visual deprivation

Cross-modal processing in visually normal development

During development, while much of sensory cortical architecture and connectivity is determined by genetically controlled factors, further refinement of connections, both within and between brain areas, appears to be dependent on early sensory input during a “critical” period.^{4–8} These experience-dependent effects are believed to be mediated by adjustments in the weighting/gain of pre-existing connectivity,⁹ the guidance of new projections to target areas,⁴ and the elimination of exuberant projections.¹⁰ A common underlying theme behind all these processes is that competition, based on experience, mediates connectivity; more active projections are strengthened at the expense of those that are less active.¹¹

In infant animals, there is substantial physiological evidence for exuberant connectivity within the layers of visual cortex itself (primates,¹² kittens^{13,14}); as well as between visual cortex and other cortical areas (primates,¹⁵ cats¹⁶) (Fig. 41.2). In kittens, there have been reports of projections from auditory/temporal areas to visual cortex,^{10,17–19} from somatosensory and fronto-parietal cortex to visual cortex,²⁰ as well as from the subcortical visual thalamus (lateral geniculate nucleus, LGN) to auditory cortex.^{4,21} These findings suggest that during early development the anatomical connections required for multisensory input to occipital cortex exist, even between primary sensory cortices.²² A variety of animal models of normal visual development have

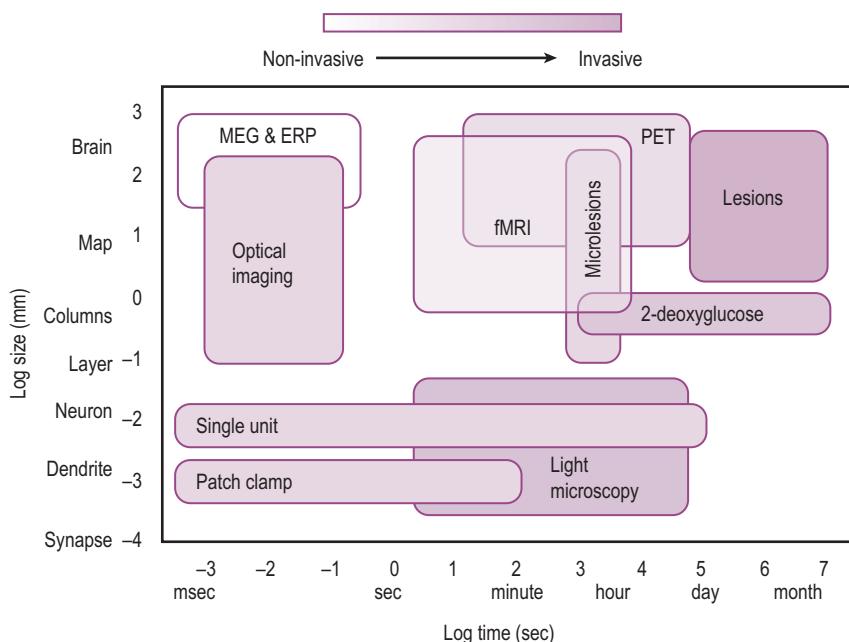

Figure 41.1 Schematic illustration of the ranges of spatial and temporal resolution of a subset of the various experimental techniques currently used for studying neural activity. The vertical axis represents the spatial extent of the technique, with the boundaries indicating the largest and smallest sizes of the region from which the technique can provide useful information. Thus, single-unit recording can only provide information from a small region of space, typically 10 to 50 μm on a side. The horizontal axis represents the minimum and maximum time intervals over which information can be collected with the technique. (Adapted from Churchland & Sejnowski.³)

demonstrated “pruning” (or re-allocation) of a large proportion of these cross-modal connections during the course of maturation.^{10,15}

A similar “pruning” is thought to occur in normal human infancy. As a result, it has been suggested that cross-modal connectivity may be more pronounced in infancy than in adulthood. A common technique for measuring brain responses in infants is by measuring event-related potentials (ERP) – the electrical activity of the brain through the skull and scalp. While auditory event-related potential (ERP) responses are usually small or absent in occipital (visual) regions of the human adult brain, large auditory ERP responses are found in occipital regions of 6-month-old infants.²³ These responses decrease as a function of age, implying a reduction in the strength of projections of auditory information to visual cortex.

As shown in Figure 41.2, and as will be described further below, many animal models suggest that, in the absence of visual input, the normal pruning process fails to occur. According to this model, cross-modal responses in early blind subjects might be mediated through the retention of an “infantile” pattern of anatomical connectivity. However, in contradiction to these results, recent examination of the volume of white and gray matter of early blind human subjects using voxel-based morphometry²⁴ suggests a reduction in connectivity between cortical areas.

Cross-modal processing in visually normal adults

Over the last three decades, improvements in neuroimaging techniques have made it increasingly easy to study neural processing within humans. Studies before the early 1990s tended to rely on positron emission tomography (PET), where a short-lived biologically active radioactive tracer isotope (such as FDG, an analog of glucose) is injected into the living subject and local neural activity is inferred based

on resulting tissue concentrations within the area of interest. Since the early 1990s, functional magnetic resonance imaging (fMRI) has become the technique of choice due to its low invasiveness, lack of radiation exposure, and relatively wide availability (Fig. 41.3). fMRI measures the hemodynamic (blood oxygen level-dependent, BOLD) response, which is proportional to blood flow and the relative concentrations of deoxygenated to oxygenated blood in the brain area of interest.

However, it should be noted that the precise relationship between neuronal signals and the BOLD response is still not clear. The relationship between blood flow, metabolic rate, and neuronal responses remains a matter of active research, and it is even possible that these relationships are altered within the occipital cortex of blind subjects. BOLD responses should not therefore be considered synonymous with neuronal activity.

While primary visual cortex has not been shown to exhibit cross-modal responses to purely tactile or auditory stimuli in visually normal adults, BOLD responses in primary visual cortex can be modulated by information from other senses.²⁵ Furthermore, many extrastriate visual areas do show cross-modal responses in sighted individuals. Area MT+ shows BOLD responses to tactile motion stimuli,^{26,27} and the lateral occipital complex (LOC)/inferior temporal (IT) gyrus shows BOLD responses during tactile object recognition tasks.^{28–30} Extrastriate visual areas also show BOLD activation during tactile embossed letter³¹ and tactile orientation discrimination³² tasks.

Recently, transcranial magnetic stimulation (TMS) has been used to examine whether responses to tactile stimuli within occipital cortex play a functional role in sighted subjects. Weak electric currents are induced in brain tissue by rapidly changing magnetic fields (electromagnetic induction), thereby triggering neuronal activity over a relatively well-localized region of the cortical surface (Fig. 41.4). TMS applied over regions of the occipital cortex interferes with

Box 41.1 Non-invasive techniques for studying neurophysiological changes that occur as a result of blindness

Diffusion tensor imaging (DTI). A magnetic resonance (MR) method in which image intensities are proportional to the strength of diffusion along the direction of the magnetic diffusion gradient. Currently, DTI is principally used for the imaging of white matter, since axons in white matter tend to have strong diffusion gradients. More recently tractography (also known as fiber tracking) algorithms have been applied to DTI data in order to estimate the pathways of white matter in the brain.

Electroencephalography (EEG) is the measurement of summed activity of post-synaptic currents produced by the brain as recorded from electrodes placed on the scalp. A surface EEG reading is the summation of the synchronous activity of thousands of neurons that have similar spatial orientation, radial to the scalp. Currents tangential to the scalp are not picked up by EEG, and activity from deep sources is more difficult to detect than currents near the skull. EEG has very high temporal resolution (~1 ms), but poor spatial resolution. Indeed, it is theoretically impossible (the “inverse problem”) to calculate the 3D spatial sources of EEG signals from the 2D electrode array. With assumptions, some estimates of spatial sources can be made but these estimates have spatial resolution on the order of a few centimeters. Recently EEG has been used in conjunction with MEG or fMRI in an attempt to achieve better spatial resolution.

Functional magnetic resonance imaging (fMRI). Hemoglobin is diamagnetic when oxygenated but paramagnetic when deoxygenated. The magnetic resonance signal of blood is therefore slightly different depending on the level of oxygenation. Hemodynamic or blood oxygen level dependent (BOLD) responses are proportional to blood flow and the relative concentrations of deoxygenated to oxygenated blood in the brain area of interest. It should be noted that the precise relationship between neural signals and BOLD remains a matter of active research. With sophisticated research paradigms fMRI can provide spatial resolution on the order of 1 millimeter and temporal resolution of less than a second, but generally has a spatial resolution of a few millimeters and temporal resolution of a few seconds. Since the early 1990s, fMRI has come to dominate the brain mapping field

due to its low invasiveness, lack of radiation exposure, and relatively wide availability.

Magnetoencephalography (MEG) is the measurement of summed magnetic fields produced by synchronous electrical activity in the brain as recorded from superconducting quantum interference devices (SQUIDS) placed on the scalp. It is only those magnetic fields generated by bundles of neurons that are perpendicular (as compared to radial in the case of EEG) to the cortical surface that can be measured. Like EEG, MEG has very high temporal resolution, but also suffers from the “inverse” problem. However magnetic fields are less distorted by factors like the skull, allowing somewhat better spatial resolution than EEG.

Magnetic resonance spectroscopy (MRS). An MR method in which levels of metabolites (such as myo-inositol, choline, creatine, N-acetylaspartate, choline, lactate, glutamate, glutamine, and GABA) associated with development and neuronal functioning are measured. Currently, because of the small concentrations of these metabolites, MRS is limited to a spatial resolution on the order of several millimeters and a temporal resolution on the order of minutes.

Positron emission tomography (PET). A short-lived biologically active radioactive tracer isotope is injected into the living subject and local neural activity is inferred based on resulting tissue concentrations within the area of interest. Provides spatial resolution on the order of millimeters, temporal resolution on the order of 10 seconds. Limitations to the use of PET include the high cost and the need to limit radiation exposure.

Transcranial magnetic stimulation (TMS). Weak electric currents are induced in brain tissue by electromagnetic induction due to rapidly changing magnetic fields. These electric currents can be used to trigger neuronal activity over a relatively well-localized region of the cortical surface. TMS is often used to demonstrate causality. If performance for a given task is suppressed by TMS stimulation to a particular brain area, this provides evidence that the region is used in performing that task.

the ability of sighted subjects to perform tactile orientation³² and tactile spatial distance³³ tasks, suggesting functional involvement of these areas in tactile processing. However, it should be noted that other studies have failed to find visual cortical activation for tactile tasks in sighted subjects using fMRI^{32,34–37} or show interference with tactile tasks using occipital TMS.^{33,38} It therefore remains unclear how important a role visual cortex plays in the performance of tactile tasks in sighted subjects.

The anatomical connections that underlie these responses in normally sighted individuals are still being determined. Until fairly recently cross-modal modulation within primary sensory areas was assumed to be mediated by feedback from multimodal association areas outside visual cortex, such as intraparietal and superior temporal sulcus cortex, insular cortex, and perhaps even frontal and prefrontal cortex.^{22,39,40} However, recent anatomical studies have found direct cross-modal projections between sensory cortices in adult primates. Direct projections have been found from auditory to visual cortex,^{41–43} from visual to auditory cortex,^{44,45} and from visual to somatosensory cortex.⁴⁶

Cross-modal processing in early blind individuals

Measurements of cross-modal responses within early and late blind subjects have tended to either focus on “basic stimuli”, such as simple tactile discrimination or auditory frequency tasks, or have focused on tasks which have strong functional significance, such as Braille reading, auditory localization, or auditory language. While cross-modal plasticity seems to be stronger for functionally relevant tasks, it should be noted that these tasks/stimuli also tend to be more complex, and are therefore more likely to evoke large brain responses.

The accumulation of evidence suggests that, in early blind subjects, primary as well as extrastriate visual areas are extensively recruited for processing of other senses. In contrast, for late blind subjects, there is only strong evidence for activation of extrastriate visual areas – and activation within these areas may not necessarily play a functional role.

Tactile performance

It is often suggested that blind subjects have enhanced tactile abilities. However it is still unclear to what extent differences

Table 41.1 Cross-modal plasticity in visual cortex: a summary of evidence for cross-modal plasticity discussed in this chapter

		Study type	Early blind	Late blind	Sighted
Tactile activation	Braille words (Sadato et al. 1996, 1998)	PET	P & E	–	–

in tactile performance between sighted and blind subjects should be attributed to blindness per se as compared to practice effects.

For obvious reasons, blind subjects tend to have more extensive experience with Braille than even well-trained sighted subjects (indeed, most sighted teachers of Braille read using vision rather than touch). As a result, non-Braille tactile tasks are typically considered a better measure of the direct effects of blindness (as compared to experience) on tactile abilities. Interestingly, it is not entirely clear whether blind subjects do exhibit enhanced acuity for non-Braille tactile discrimination tasks. In one study, no significant differences in sensory, touch, or two-point discrimination thresholds were found between early blind and sighted subjects.⁴⁷ However in several more recent studies, tactile acuity has been found to be significantly higher in early blind subjects than sighted subjects for embossed Roman letters³⁸ and grating orientation discrimination^{48,49} tasks. Taken together

these data suggest that visual deprivation in early blind subjects may only provide a weak or selective (for some types of task, but not all) advantage for tactile processing.⁵⁰

Most of the benefits in tactile discrimination abilities in blind as compared to sighted subjects are likely to be due to an interaction between blindness and the effects of increased experience and reliance on visual cues. In several studies, although blind subjects initially exhibit superior performance to sighted subjects on a range of tactile tasks, when practice is accounted for between blind and sighted subjects, these differences disappear.^{47,51} Experiments such as these support the notion that the superiority in tactile tasks found in the blind is driven at least in part by greater tactile experience.

However, in another recent study it has been shown that sighted subjects perform better at Braille letter discrimination when they are blindfolded during a preceding five-day period than when they are allowed normal vision during that five-day period, irrespective of the amount of training in Braille. Indeed, blindfolded subjects who have not been trained at all in the task perform better than non-blindfolded subjects trained in the task over a five-day period.^{52,53} These findings suggest that visual deprivation does play a role in the enhanced tactile abilities of blind subjects.⁵⁰ Furthermore, the fact that sighted Braille teachers read Braille visually (from the shadows of the letters) rather than by touch, suggests that loss of visual input is important for tactile fluency (Pascual-Leone, personal communication).

Given that both visual deprivation and tactile experience play significant roles in subserving the tactile performance benefits observed in blind subjects, an understanding of how deprivation and experience interact may be important in developing effective Braille instruction programs, especially in the partially sighted.

Braille tactile processing

Numerous studies have examined cross-modal responses to Braille reading in the visual cortex of blind subjects. In an early ERP study, early blind subjects were reported to show a more posterior/occipital distribution of response during Braille reading than sighted subjects who read embossed Roman letters.⁵⁴ Since then, several neuroimaging studies have demonstrated that early blind subjects consistently show greater responses to Braille words than to non-words (or other appropriate control stimuli) in primary as well as extrastriate visual cortex. In contrast, late blind subjects show greater responses than sighted subjects in extrastriate but not primary visual cortex^{34–36,55} (see reviews,^{50,56} though see^{57,58}). In early blind subjects the magnitude of BOLD responses to Braille in primary visual cortex is highly correlated on an individual basis with verbal memory ability, suggesting a relationship between the extent of cross-modal responses and Braille abilities,⁵⁹ at least in those who are visually deprived at an early age.

Several TMS studies provide clear evidence for the functional role of visual cortex in Braille reading in early blind subjects. TMS delivered to visual cortex while discriminating Braille letters (note that this is a somewhat simpler task than reading Braille text) induces significantly more errors than sham stimulation in early but not late blind subjects (Fig. 41.5).⁵⁵ This disruption of Braille performance suggests that the visual cortex does play a functional role in Braille reading

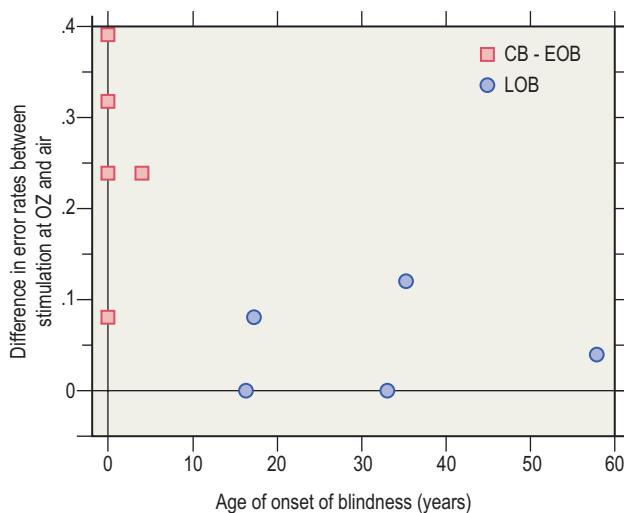

Figure 41.5 Errors in Braille letter discrimination for individual subjects during TMS stimulation over the mid-occipital region (OZ) and control (Air) as a function of age of onset of blindness. CB-EOB = congenitally blind and early onset blind; LOB = late onset blind. Subjects identified 25 Braille letters presented in five strings of five letters (all non-words) for each scalp position stimulated. Errors were identified as wrong identification or an inability to identify letters. (From Cohen et al.⁵⁵)

at least in early blind subjects^{38,55} (see reviews^{50,56,60}). Additionally, there is the interesting case study of an early blind woman who, following an occipital stroke, lost the ability to read Braille without loss of her ability to detect Braille letters or loss of her other somatosensory abilities.⁶¹

Similarly, while TMS delivered to the visual cortex of early blind subjects does not seem to interfere with the detection of Braille tactile stimulation, it does interfere with the reading of Braille.^{50,62,63} Collectively these studies provide strong evidence that the responses found to Braille reading in visual cortex are not epiphenomena, and in fact are functionally necessary for the comprehension of Braille. Furthermore, it seems that these responses in visual cortex belong to a later part of an extended network of areas subserving Braille processing. TMS applied to occipital cortex interferes with Braille processing only after a delay of 50–80 ms, as compared to lesser time periods of 20–40 ms when applied to somatosensory cortex⁶² (see reviews^{58,63,64}).

Overall, in early blind subjects the preponderance of evidence suggests that extrastriate and primary areas of visual cortex are recruited for Braille reading, and that cross-modal responses in visual cortex are functionally relevant. In late blind subjects, it is probable that extrastriate (though not primary) visual cortex is activated during Braille processing; however, it remains likely that activation in visual cortex during Braille reading in late blind subjects does not have a functional role.

Non-Braille tactile processing

Cross-modal responses in visual cortex of early as well as late blind subjects have also been shown for a variety of non-Braille tactile discrimination tasks. In an early ERP study, early blind subjects showed a more posterior/occipital distribution of response than sighted subjects during even a simple passive tactile task where subjects passed their finger over a random-dot pattern.⁵⁴ Furthermore, when performing

same/different judgments of grooves or embossed letters, early blind subjects showed an increase in visual cortex activation (as measured using PET), whereas sighted subjects showed a decrease in visual cortex activation. In this task, neither blind nor sighted subjects showed changes in visual cortex activation to these tasks when no response was required, suggesting that attention to the tactile stimulation may be necessary.

As is the case for Braille reading, it seems fairly certain that both primary and extrastriate visual areas respond to non-Braille tactile discrimination in early blind subjects, and extrastriate but not primary visual areas respond to non-Braille tactile discrimination in late blind subjects. Only early blind subjects show responses in primary visual cortex to a same/different Braille letter tactile discrimination task (letters were discriminated rather than read), whereas both early and late blind subjects show responses in extrastriate visual cortex. The recruitment of primary visual cortex for non-reading tactile discrimination may be limited to early blind subjects.⁶⁵ Interestingly, recently late blind subjects who are naïve to Braille also show BOLD responses to tactile discrimination in extrastriate visual cortex, suggesting that cross-modal responses to tactile input in extrastriate cortex may not be dependent on experience with Braille.^{37,56}

The tactile recruitment of visual cortex in early blind subjects seems to have a functional role. TMS delivered to the visual cortex of early blind subjects while performing an embossed letter discrimination task induces significantly more errors in early blind than in sighted subjects, suggesting a functional role of visual cortex even in non-Braille reading tactile tasks.³⁸ However, visual cortex may only play a functional role for certain types of tactile processing; in early blind subjects, TMS delivered to occipital areas interferes with performance during spatial distance, but not roughness judgments for raised dot stimuli.³³

There is also evidence for cross-modal responses in visual cortex to complex tactile processing. During tactile imagery, early blind subjects (none of whom ever had vision) exhibited ERP responses in extrastriate visual cortex.⁶⁶ ERP responses over occipital cortex were also shown during encoding of tactile stimuli, and mental rotation of those stimuli.⁶⁷ Moreover, early blind subjects show category-related patterns of BOLD response for tactile manmade objects in inferotemporal (IT) and fusiform areas of visual cortex.³⁰

Responses in visual cortex to tactile stimulation have been evoked in sighted as well as early and late blind subjects for certain stimuli. However one difficulty in studying the effects of tactile and auditory stimulation on occipital cortex is the possibility that occipital responses within sighted and late blind subjects may be due to visual imagery. Sighted, early and late blind subjects all showed BOLD responses to embossed Roman letter identification (a task likely to have elicited visual imagery in both sighted and late blind subjects) in visual cortex.³¹ In late, but not early blind subjects, tactile motion and tactile face perception evoke BOLD responses in area MT+ and fusiform face area (FFA), respectively – a finding, again, thought likely to be due to visual imagery.⁶⁸

Auditory processing

Most studies have found little evidence for overall improved auditory sensitivity in blind subjects.⁶⁹ However, there are

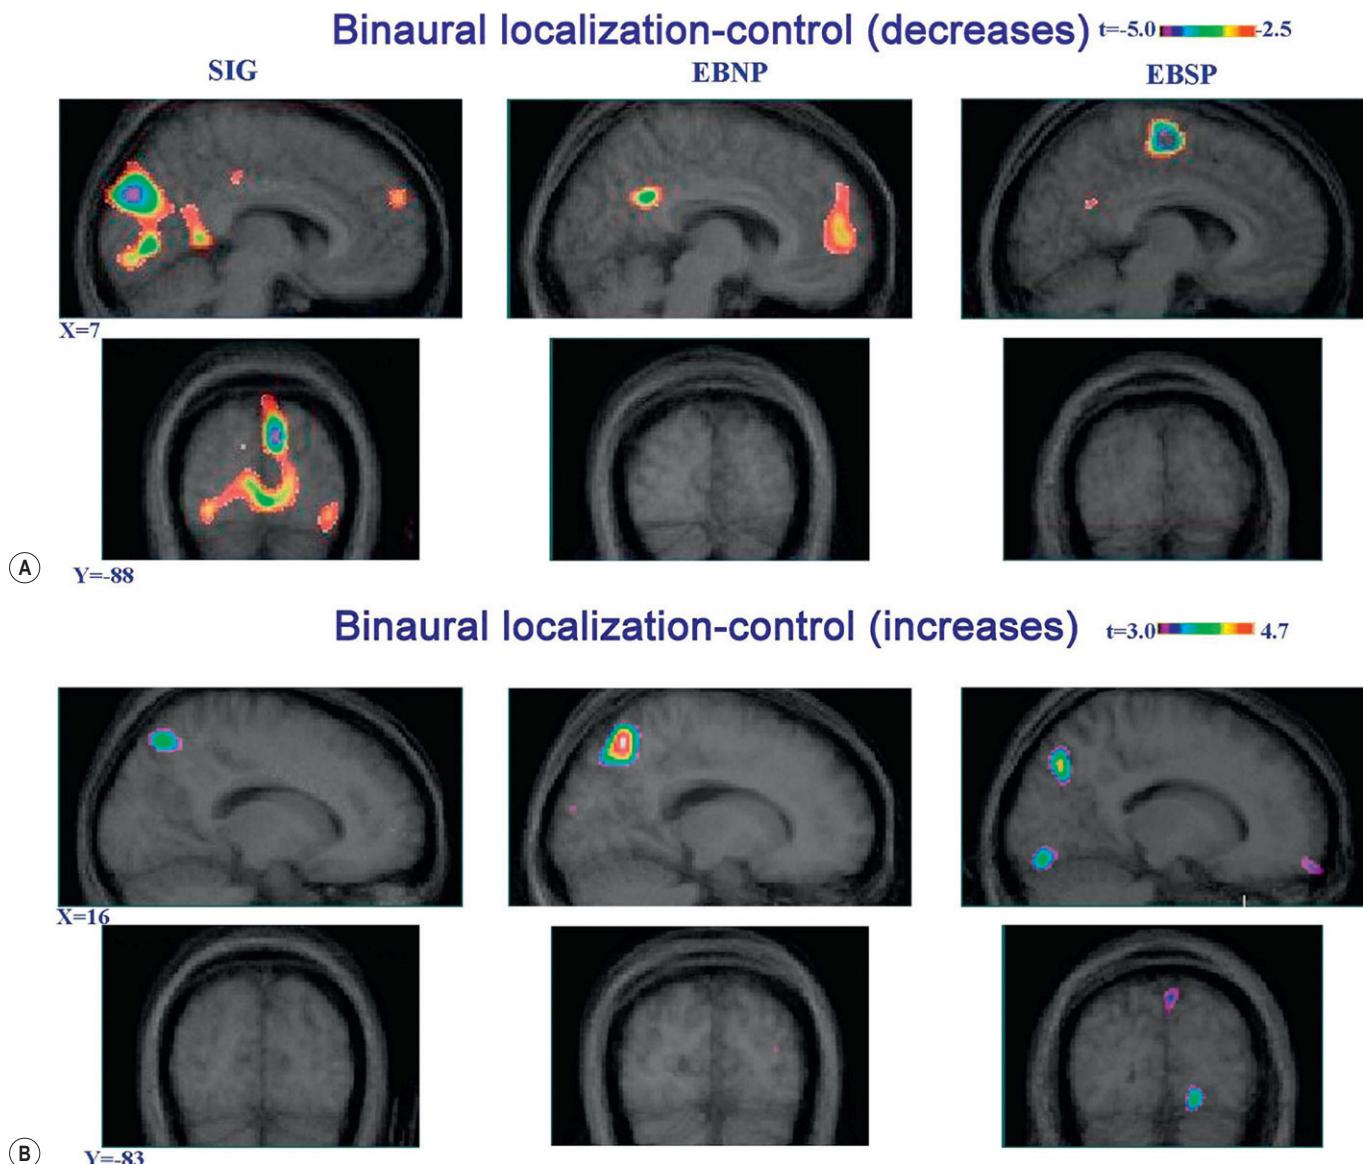

Figure 41.6 PET responses during a binaural sound localization task performed by sighted subjects (SIG), early blind subjects with normal performance on a monaural sound localization task (EPNP) and early blind subjects with superior performance (EBSP). Subjects were asked to localize a pair of sounds while they were lying within the scanner by pointing with a joystick, placed at the subject's side, toward the apparent source of stimulation. The control task consisted of pointing in alternation to the left and right after hearing a stimulus pair presented in the frontal position. **(A)** Decreased cerebral blood flow (CBF) is observed in the visual striate and extrastriate cortices. **(B)** Increased CBF is seen in the right ventral extrastriate cortex for the EBSP group, but not for the other two groups. X and Y coordinates refer to standardized stereotaxic space. The significance criterion was calculated as a t-value of 3–3.5. (From Gougoux et al.⁷⁴)

some selective benefits of blindness on auditory perception, as described below, and visual cortex seems to be recruited for at least certain aspects of auditory processing.

In early blind subjects there is evidence for generally superior localization abilities,^{70,71} particularly in peripheral space.^{72,73} Auditory BOLD responses in visual cortex may also be correlated with sound localization accuracy^{74,75} (Fig. 41.6).

In an early study, ERPs evoked by a dichotic listening task (where subjects were asked to listen to different auditory tones in each ear) were reported to have shown a more posterior scalp distribution in early blind than in sighted subjects. This was true for auditory input from both the

attended as well as the unattended ear.⁷⁶ This result suggests that visual areas may subserve auditory processing regardless of attention. However, more recently, auditory responses in visual cortex for auditory frequency discrimination have been shown in both early and late blind subjects, but only when attention is directed to the auditory stimulus (MEG,⁷⁷ ERP⁷⁸ and fMRI⁷⁹) (see review⁶⁰). In another attentional auditory ERP study, early blind subjects have been reported to exhibit larger and more posteriorly distributed N2 responses than sighted subjects, as well as faster auditory target detection times.⁸⁰

Recently, it has been shown in sight recovery subjects who were blinded at an early age (as well as in early blind

subjects) that visual extrastriate area MT+ responds selectively to auditory motion but not other stimuli,⁸¹ suggesting that cross-modal plasticity can be influenced by the normal functional specialization of a cortical region. Evidence for functionally relevant auditory processing in visual cortex of early blind subjects comes from studies of auditory localization and auditory language, as described below.

Visual cortex also seems to be recruited in blind subjects trained to use auditory sensory substitution devices (Box 41.2, Fig. 41.7).

Auditory localization

Auditory ERP responses in primary and extrastriate visual cortex have been shown in early blind subjects while performing sound localization tasks,⁸³ and these responses seem to be larger in those early blind subjects who behaviorally demonstrate superior sound localization accuracy. The extent of activation in early blind subjects is correlated on an individual basis with sound-source localization accuracy (PET,⁷⁴ see Fig. 41.6; ERP⁷⁵). This suggests that cross-modal responses to sound localization in visual cortex may have functional importance.

These cross-modal responses within visual cortex may also be lateralized; in another PET study, auditory responses in extrastriate visual cortex in early blind subjects to sound localization are reported in the right, but not the left, visual cortex.⁸⁴ Responses to sound-source localization have additionally been shown with PET in extrastriate visual cortex of late blind subjects, again with a seemingly right hemisphere dominance.⁸⁵ Moreover, TMS delivered to right occipital areas (TMS was not delivered to the left hemisphere) interferes with an auditory localization task, but does not significantly interfere with an auditory pitch or intensity discrimination task.⁸⁶ This finding suggests that in early blind subjects right visual cortex plays a functional role in auditory localization, and is perhaps specifically involved

Box 41.2 Sensory substitution: replacing vision with audition

The enhanced abilities of blind individuals to make use of auditory and tactile cues have inspired the development of a variety of sensory substitution devices. While few are currently in common use, it seems likely that as miniaturization and processing capacities improve, such devices will quickly become more commonplace. Interestingly, a few studies suggest that use of these sensory substitution devices may elicit occipital responses within blind subjects, and that these responses may be highly dependent on training.

In one early study, early blind and blindfolded sighted subjects were trained with an ultrasonic echolocation device which transduces ultrasonic echoes into auditory signals.¹ During a sound localization task without the device, larger PET activations were found in extrastriate (and probably primary) visual cortex of early blind subjects than were found within blindfolded sighted subjects. Moreover, while training with the device had no effect on visual cortex activation for blindfolded sighted subjects, in the case of early blind subjects training with the device resulted in an additional increase in extrastriate (and probably primary) visual cortex activation during sound localization.

In a second study, early blind and blindfolded sighted subjects were trained to use a visual-to-auditory sensory substitution device (prosthesis substituting vision with audition, PSVA) for spatial pattern recognition. After training with the device larger PET activations were again found in the extrastriate visual cortex of early blind than blindfolded sighted subjects (see Fig. 41.7). These findings suggest that differences between early blind and sighted subjects might be mediated by a pre-existing ability in early blind subjects to recruit visual cortex for non-visual spatial processing that extended relatively easily to the sensory substitution device.

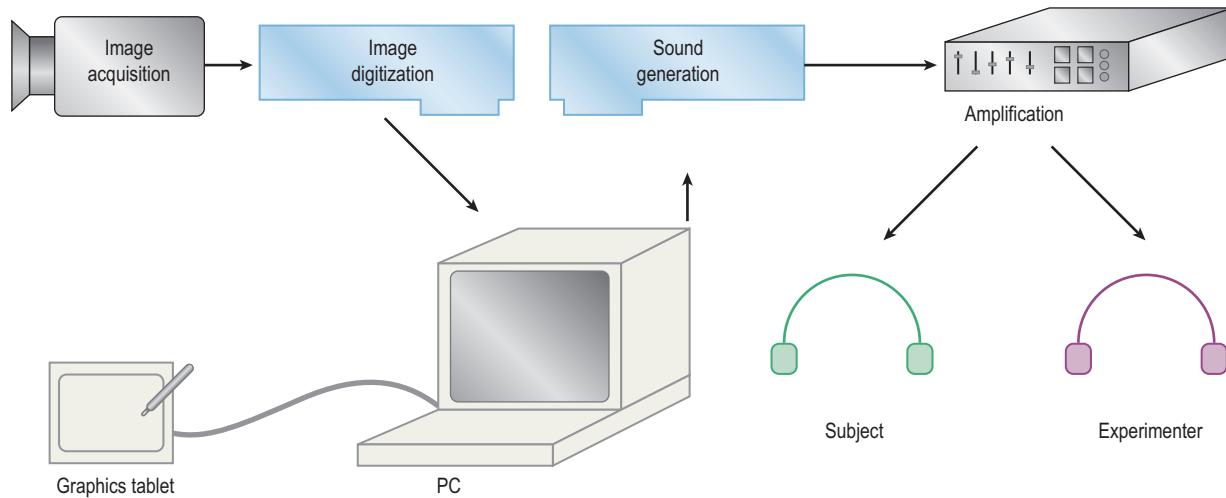

Figure 41.7 Schematic representation of the sensory substitution equipment used by Arno et al.⁸² Early blind and blindfolded sighted control subjects were trained to use a PSVA (prosthesis substituting vision with audition) device over the course of 12 one-hour training sessions, distributed over 8–10 weeks. Visual patterns were generated using a graphics tablet connected to a PC. The audio translation of these visual patterns (each pixel was associated with a specific frequency) was provided to the subject (and experimenter) via headphones. During each training session, subjects learned to move the pen on the graphics tablet to scan each pattern, and during each test session (before the first training session, and after the 6th and 12th training sessions), subjects were asked to reproduce each pattern via arranging metallic bars and squares in a frame. (Adapted from Arno et al.⁸²)

in the analysis of spatial components necessary for such tasks.

This right hemisphere bias for sound location in early and late blind subjects is consistent with laterality effects shown in auditory cortex of sighted subjects. In sighted subjects sound localization tasks result in right hemisphere engagement, based on measurements using magnetoencephalography (MEG; a method of measuring the magnetic fields produced by electrical activity in the brain).⁸⁷ Analogous laterality effects have been found in sighted subjects. For example, lesions of the right hemisphere can result in deficits in visuospatial processing⁸⁸ (see also⁸⁶).

Auditory language

Several studies have shown that both primary and extrastriate visual cortex in early blind subjects are recruited for auditory language, with a greater extent of BOLD activation for semantic tasks compared to phonological processing tasks or passive indecipherable sounds^{89–91} (see review⁸⁹). Similarly, BOLD responses in primary and extrastriate visual cortex have been shown for auditory language processing in late blind subjects who are naïve to Braille.^{31,89} Cross-modal responses to auditory verbal content in primary and extrastriate visual cortex seem not to be heavily dependent on the onset of blindness occurring early in life.

TMS delivered to visual cortex (particularly the left hemisphere) of early blind subjects during verb generation in response to auditory-presented nouns results in verb-generation errors, that seem to be primarily semantic,⁹²

consistent with left hemisphere lateralization for language processing (Fig. 41.8). It should be noted that the late timing of the TMS pulses (660 ms after word presentation onset), as well as subject reports indicating clear auditory perception of the stimulus, make it highly unlikely that the TMS affected the auditory processing of the stimulus per se, as compared to the processing of verbal content. It seems that visual cortex is involved in high-level verbal processing in early blind subjects.

Cross-modal connectivity within occipital cortex of early blind individuals

Most evidence for changes in connectivity in humans as a result of blindness has surfaced relatively recently, using a variety of techniques including fMRI (functional magnetic resonance imaging), TMS (transcranial magnetic stimulation), high-resolution MRI, and diffusion tensor imaging (DTI). Despite the growing interest in the connectivity underlying cross-modal plasticity, the routes by which auditory and tactile information reaches striate and extrastriate visual cortex in early blind individuals are still unclear. One possibility is that early visual deprivation results in a failure to prune early exuberant corticocortical and/or thalamocortical cross-modal connections. Alternatively, early deprivation may permit top-down connections from multimodal areas to extend into primary and secondary visual areas.

Functional evidence about the source of cross-modal plasticity is somewhat contradictory. Some functional evidence

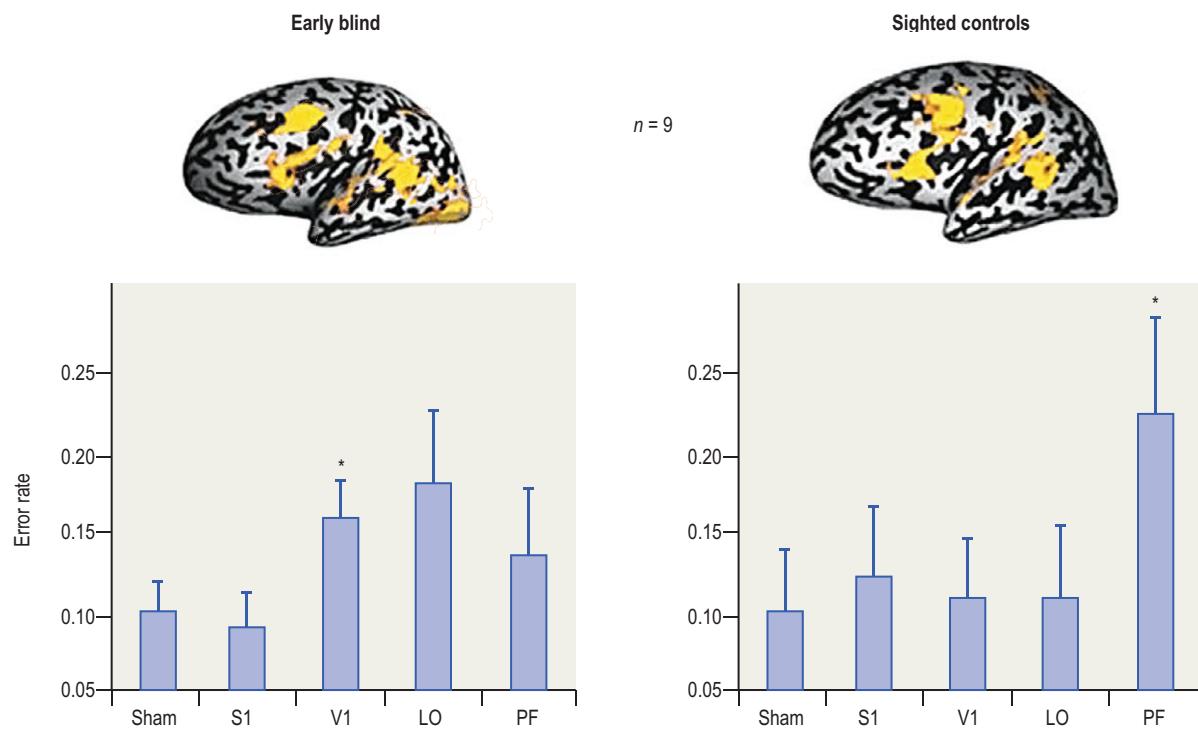

Figure 41.8 Verb-generation error rates in blind and sighted groups as a function of repetitive TMS (rTMS) site. In blind subjects, rTMS over left V1 increased error rates relative to sham and right S1 stimulation; a similar trend was observed with left prefrontal (PF) and lateral-occipital (LO) stimulation. In sighted control subjects only left PF stimulation increased error rates relative to sham and S1 stimulation. Insets on each graph show the group-average pattern of fMRI activation in the left hemisphere during verb generation versus rest.⁵⁹ Note that V1 only shows significant activation in the blind group, consistent with the larger error rates produced by rTMS over this region. Statistical parametric maps were thresholded at $p < 0.05$ and corrected for multiple comparisons with use of a random-effect general linear model. (From Amedi et al.⁹²)

suggests that the primary source of tactile cross-modal plasticity in visual cortex of blind subjects is corticocortical, not thalamocortical. Stimulation of primary somatosensory cortex in early blind subjects by TMS yields activation in primary visual cortex.⁹³ Tactile stimulation of one hand of blind subjects leads to bilateral activation of visual cortex.^{34,35,65} Because only the contralateral side of the body is represented at the thalamic level, the bilateral nature of these visual responses implies that tactile information must be delivered to visual cortex by cortical mechanisms beyond the thalamus. However, measurement of resting state functional connectivity (correlations between BOLD activity across the brain while a subject is at rest) suggests that early blind subjects show decreased functional connectivities compared to sighted subjects within the occipital visual cortices as well as between the occipital visual cortices and the parietal somatosensory, frontal motor and temporal multisensory cortices. Interestingly the greater the blind subjects' use of Braille, the stronger the functional connectivities between these brain areas, suggesting that increased functional connectivities are not dependent on visual deprivation per se, but rather caused by increased reliance on auditory and tactile modalities enforced by loss of vision.⁹⁴

Anatomical data seem to consistently show a decrease in corticocortical connectivity within early blind human subjects, though there are still a relatively small number of studies in the literature. A recent study using voxel-based morphometry based on high-resolution MR imaging²⁴ found that early blind subjects show significant atrophy of the geniculostriate system (Fig. 41.9). Loss of gray matter occurred within the dorsal lateral geniculate nucleus, primary and extrastriate cortex. White matter reductions were observed in the optic nerves, optic radiations, and optic tracts as well as within occipitotemporal projections and the posterior part of the corpus callosum (which links the visual areas of both hemispheres), suggesting large-scale atrophy of afferent projections to the visual cortex in early blind individuals. There was no evidence of any regions of increased white matter volume as might be expected if early blind subjects retained an "infantile" pattern of connectivity.

DTI is a magnetic resonance imaging technique which measures the restricted diffusion of water in tissue, thereby allowing the imaging of white matter tracts. In recent years the inclusion of fiber tracking algorithms in DTI analysis has been used to estimate tractography, the pathways formed

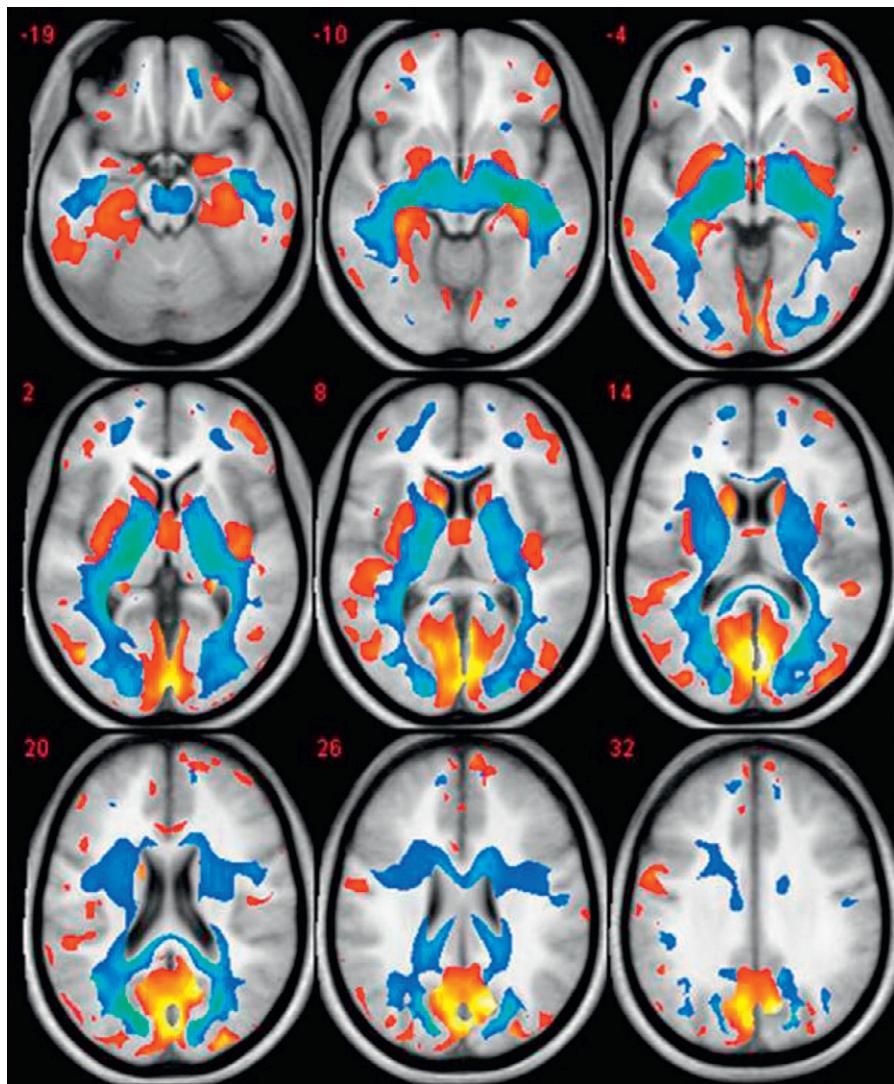

Figure 41.9 Regions showing a reduction in gray (red) and white (blue) matter in congenitally blind (CB) as compared to normally sighted (NS) individuals. No areas were found that showed a reduction in gray or white matter in NS as compared to CB (areas showing NS < CB). Volume differences are presented on horizontal sections, with the left side of the figure referring to the left side of the brain. Statistical parametric maps were thresholded at $p < 0.05$ corrected for multiple comparisons with the false discovery rate (FDR) algorithm implemented in SPM2. (From Ptito et al.⁹⁵ Reproduced by kind permission of Springer Science + Business Media.)

by white matter connections.⁹⁶ Currently there are only a few studies examining changes in tractography as a result of blindness. To date no differences in tractography have been found between late blind and sighted subjects, suggesting that optic pathways in late blind subjects remain intact.⁹⁷ However DTI, like high-resolution MRI, has found some evidence of optic pathway atrophy in early blind subjects.^{98,99}

In contrast, a large number of animal models suggest that visual deprivation leads to increased cross-modal connectivity between subcortical thalamic nuclei and visual cortex, as well as from other sensory cortical areas to visual cortex. In adult opossums early bilateral eye enucleation results in abnormal thalamocortical and corticocortical projections. Abnormal connections projecting to visual cortex have been noted from both auditory (medial geniculate nucleus, MGN) and somatosensory (ventral posterior nucleus, VP) thalamus.^{7,100} These same authors also noted abnormal corticocortical projections from auditory and somatosensory cortex to visual cortex.^{7,100} Similarly, in early bilaterally deprived cats, portions of the anterior ectosylvian area that are typically driven purely by visual input have been found to be almost completely taken over by auditory and somatosensory inputs,^{101,102} and in early bilaterally deprived monkeys, some primary and extrastriate visual cortical areas are found to be recruited by tactile input.^{103,104}

So, while functional and animal data support the notion that responses with the occipital cortex are driven by increased corticocortical connectivity, there is currently no evidence for any such increases in connectivity within early blind humans. One possibility is that early blind have similar (or weaker) thalamo-cortical or corticocortical anatomical connections than sighted individuals, but that these connections play a much stronger role in modulating functional responses in blind subjects.

Neuronal structure within occipital cortex of early blind individuals

In early blind subjects, primary and extrastriate visual cortical areas are generally shown to exhibit greater than normal glucose metabolism and regional cerebral blood flow.^{105,106} These findings support the notion that the visual cortex of early blind individuals remains "active" as a result of cross-modal plasticity.

However, in animal deprivation models the effects of deprivation seem to include a variety of neuronal changes including a retardation in the development of glial cells,¹⁰⁷ disruption of the inhibitory GABA pathway,^{108,109} disruptions in synaptogenesis and pruning,^{110–112} and losses of functional tuning.^{113–116} It should also be noted that many of these changes observed in animal models would not necessarily have an observable effect using techniques that have currently been used to examine neural deterioration in humans (MR imaging of macroanatomy, and PET measurements of glucose metabolism or blood flow). One interesting potential tool is magnetic resonance spectroscopy (MRS), a noninvasive technique capable of measuring changes in the levels of metabolites (such as myo-inositol, choline, creatine, N-acetylaspartate, choline, lactate, glutamate, glutamine, and GABA) associated with development and neuronal functioning.

Differences in cross-modal processing between the periphery and the fovea

Cross-modal connectivity seems to differ between peripheral and foveal representations of space. In primate models it has been shown that adult (non-deprived) anatomical connections between auditory and multimodal temporal areas and primary visual cortex map preferentially to peripheral rather than foveal representations.^{41,42} Consistent with this, many cross-modal interactions in visually normal individuals are stronger for peripherally presented stimuli.^{117,118}

Analogously, cross-modal responses seem to be stronger within regions of visual cortex that in sighted subjects subserve the peripheral visual field. Braille and auditory word responses within primary visual cortex are found within peripheral rather than foveal areas of primary visual cortex.⁵⁸ Moreover, in blind subjects cross-modal responses to sound source localization tend to be stronger for sounds originating from peripheral space.⁷²

One possible explanation for stronger cross-modal responses in the periphery is that cortical areas that normally represent peripheral representations have a greater potential for plasticity. For many aspects of visual processing, processing in the periphery is qualitatively different from processing in the fovea, even after scaling for acuity. For example, in sighted subjects visual perceptual learning effects tend to be larger in the periphery than in the fovea.¹¹⁹

Blindfolding studies

It has recently been shown that cross-modal responses to Braille and auditory stimuli can be elicited within the visual cortex of sighted individuals after relatively short periods of blindfolding. In a group of these experiments^{53,120} (see also reviews^{50,63}), sighted subjects were visually deprived via blindfolding for a period of five days, and BOLD responses in visual cortex were measured while they performed auditory and tactile tasks. In the auditory task, subjects listened to a series of tones and performed a same/different task on each tone compared to the previous tone. In the tactile task, subjects performed a same/different task on pairs of Braille symbols. On the first day of blindfolding, there was no response in visual cortex to either the auditory or tactile tasks. However, by the fifth day of blindfolding activation was seen in an anatomical region likely to include primary visual cortex during both the auditory and tactile tasks (Fig. 41.10).

In parallel to the findings of the effect of TMS on Braille letter discrimination abilities in early blind subjects,^{38,55} TMS applied to occipital cortex in blindfolded sighted subjects (but not sighted control subjects) on the fifth day also significantly interfered with performance on the tactile Braille discrimination task,⁵³ suggesting that BOLD responses in visual cortex during this task are functionally relevant. Furthermore, on the sixth day, just 24 hours after removal of the blindfold (the blindfold was used during scanning), the activation of visual cortex in response to tactile or auditory stimulation was no longer apparent, and TMS applied to occipital cortex no longer interfered with the tactile Braille task. These latter findings indicate that exposure to vision for a single day is sufficient to eliminate the visual cortical activation induced during the blindfolding period.

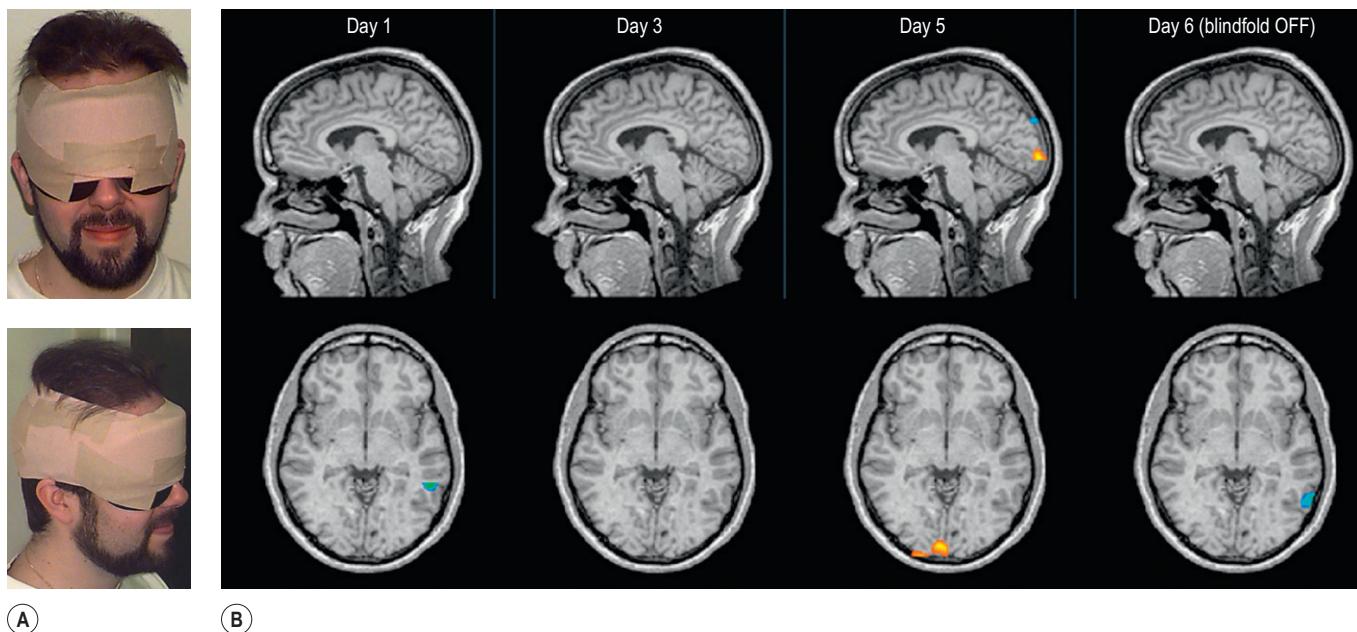

Figure 41.10 Normally sighted subjects were randomized to a blindfolded or non-blindfolded group. Both groups were immersed in an intensive tactile stimulation program that included formal Braille instruction over five days. Group difference tactile activation maps are shown (overlaid on the anatomy of a single representative subject) contrasting the blindfolded and non-blindfolded groups for each fMRI session of the study. Activation maps were corrected for multiple comparisons by a joint voxelwise significance/cluster size threshold of ($p < 0.05$; estimated through Monte Carlo simulation using Brain Voyager) in a procedure designed to allow detection of weak but spatially extensive activations. (From Merabet et al.⁵³)

Additional evidence for effects of short-term visual deprivation on cross-modal responses in visual cortex has been provided by a second research group. In this study, sighted subjects were blindfolded for two hours, and then cortical activation was assessed with fMRI as they performed several tactile discrimination tasks. A comparison of blindfolded subjects vs control subjects revealed a task-specific increase in activation in lateral occipital complex (LOC) for a tactile global form task (but not a gap detection task), as well as an unexpected decrease in activation in intermediate visual areas for both tactile tasks.¹²¹

These data imply that activation of visual cortex during processing of other senses is not necessarily an exclusive feature of blindness; some mechanisms that can mediate cross-modal plasticity are present even in the normal brain.⁵⁰ The rapid nature of these changes suggests that some connections between different sensory areas may be pre-existing, and simply latent until "unmasked" as a result of specific experiences such as temporary deprivation.^{64,120} In other words, when a sensory cortical area is deprived of its normal input, existent cross-modal connections allow this area to respond to input from other modalities.

However, it should be noted that the mechanisms uncovered by blindfolding paradigms do not necessarily represent the same mechanisms that mediate cross-modal plasticity in blind subjects. In blindfolded sighted subjects responses in visual cortex to input from other modalities could be a consequence of "unmasking" or release from inhibition (a fast, and easily reversed, effect), whereas in early blind subjects the same finding could be a consequence of the establishment of a different type of connectivity (not necessarily one involving an increase in white matter) – a slow effect that would be practically impossible to study in blindfolded sighted subjects.⁶⁴ This possibility seems particularly likely

given that the evidence for functional significance of cross-modal activations in late blind subjects is not very strong – indeed it is curious that TMS studies using Braille stimuli show functional significance of cross-modal activation in blindfolded sighted subjects, but not in late blind subjects.

One possibility is that during early stages of vision loss there may be a reinforcement of pre-existing connections (similar to what has been demonstrated in the short term in blindfolded sighted subjects) which may in the long-term lead to permanent structural modifications in pathways between visual cortex and other sensory areas.⁶³ Long-term connectivity patterns may fundamentally differ between early and late blind subjects – perhaps accounting for the generally weaker and less extensive cross-modal findings in late blind subjects, especially within primary occipital cortex.

Restoration of vision

The existence of cross-modal plasticity in visual cortex raises interesting questions regarding the effects of cross-modal plasticity on restoration of visual function. One possibility is that cross-modal responses to other forms of sensory input within visual cortex might be beneficial in maintaining neuronal functioning and preventing atrophy. On the other hand if allocation of visual cortex to other senses is irreversible, then cross-modal processing could reduce the ability of visual cortical neurons to process restored visual input.

TMS has been used in blind subjects to investigate the relationship between induced phosphene and neuronal function in visual cortex.¹²² The likelihood of phosphene elicitation is correlated with the amount of residual vision; subjects with severe blindness (no light perception, NLP) only rarely perceive phosphenes.

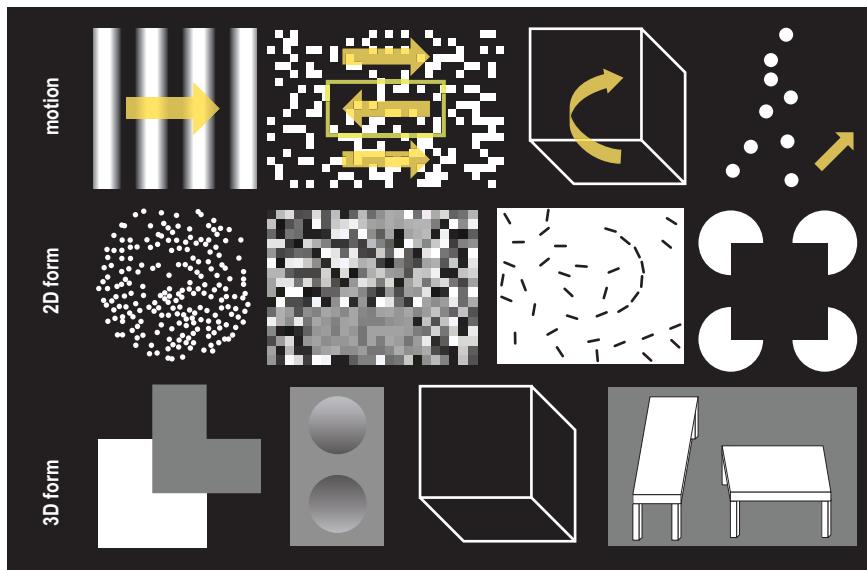

Figure 41.11 Stimuli used for tests of MM's form, depth, and motion processing. Stimuli shown to visually normal controls were always blurred using a low pass filter that was designed to match MM's acuity losses. (Adapted from Fine et al.¹²³)

These data are supported by the small number of studies examining restored vision in those who were blind since childhood. All these studies suggest severe losses in acuity and difficulties interpreting the visual world. The extent of visual processing deficits seems to depend in a complex way on the age and severity of blindness, and the age at which sight is restored, as illustrated by comparing two recent case studies.

For example, sight recovery subject MM was born with normal vision, but lost vision (leaving LP vision) at age 3 due to a chemical accident. At 43 he underwent corneal and limbal stem-cell transplant in one eye. Post-operatively MM's visual acuity was substantially impaired (due to neural losses) as were fMRI responses in primary visual cortex. When neural acuity losses were compensated for, his performance on 2D form, color, and motion tasks was remarkably good, as shown in Figure 41.11, and he showed strong MT+ responses to moving stimuli. However 3D form, depth, object, and face identification were extremely poor, and he showed no extrastriate responses to images of faces or objects.¹²³

SRD was blind from birth due to dense congenital cataracts which were removed at age 12.¹²⁴ When tested at age 34 this subject also showed acuity losses, and a lack of impairment for simple form processing. However SRD showed greater proficiency than MM at higher-level visual tasks such as 3D form, depth, and face vs non-face discrimination. Like MM, motion processing appeared relatively unimpaired.

The retention of visual motion processing in these subjects is surprising (while formal tests of SRD's motion processing are not reported, no deficits have been noted), especially given recent evidence that after early blindness MT+ selectively processes auditory motion information.⁸¹

One possibility is that MM had time to establish motion processing before becoming blind at the age of 3. While SRD's cataracts were congenital, her pre-operative acuity was not measured (it was LP or above) and she may have retained sufficient visual acuity while blind to subserve basic motion processing. One possibility is that to a certain degree

motion processing may be "hard-wired" and require relatively little visual experience; another (as discussed below) is that the ability to process motion was maintained due to the existence of auditory motion-selective responses with that brain area.⁸¹

There are several possible reasons for the difference in performance between these two subjects on 3D form tasks. Perhaps the residual visual input received by SRD while blind provided enough stimulation for extrastriate cortex to retain the potential to regain complex visual function once the cataracts were removed at age 12. Alternatively, SRD's better performance might be the result of recovering sight at a relatively early age. Finally, given that extrastriate cortex probably remains relatively plastic even into adulthood, it is possible that her ability to perform these tasks gradually improved in the decades that followed sight restoration.

More recently, a study of MM and another early blind subject who regained some vision in adulthood demonstrated robust activations in area MT+ to both auditory and visual stimulation.⁸¹ In these subjects MT+ responded to auditory motion, while in visually normal subjects MT+ did not show similar auditory responses. These auditory responses in MT+ were selective for motion as compared to other complex auditory stimuli, suggesting that cross-modal plasticity can be influenced by the normal functional specialization of a cortical region. These results further demonstrate that in the case of sight recovery, cross-modal responses can coexist with regained visual responses within the visual cortex (Fig. 41.12). The ability to process auditory input within MT+ as a result of visual deprivation does not seem to usurp the ability of MT+ to process visual input, and the restoration of visual responses does not seem to block auditory motion responses within MT+. These data therefore suggest that changes in neuronal function that occur as a result of cross-modal plasticity in visual cortex need not be detrimental to restored visual function. Indeed, the presence of functionally appropriate cross-modal responses may even help preserve the ability of an area to process visual information.

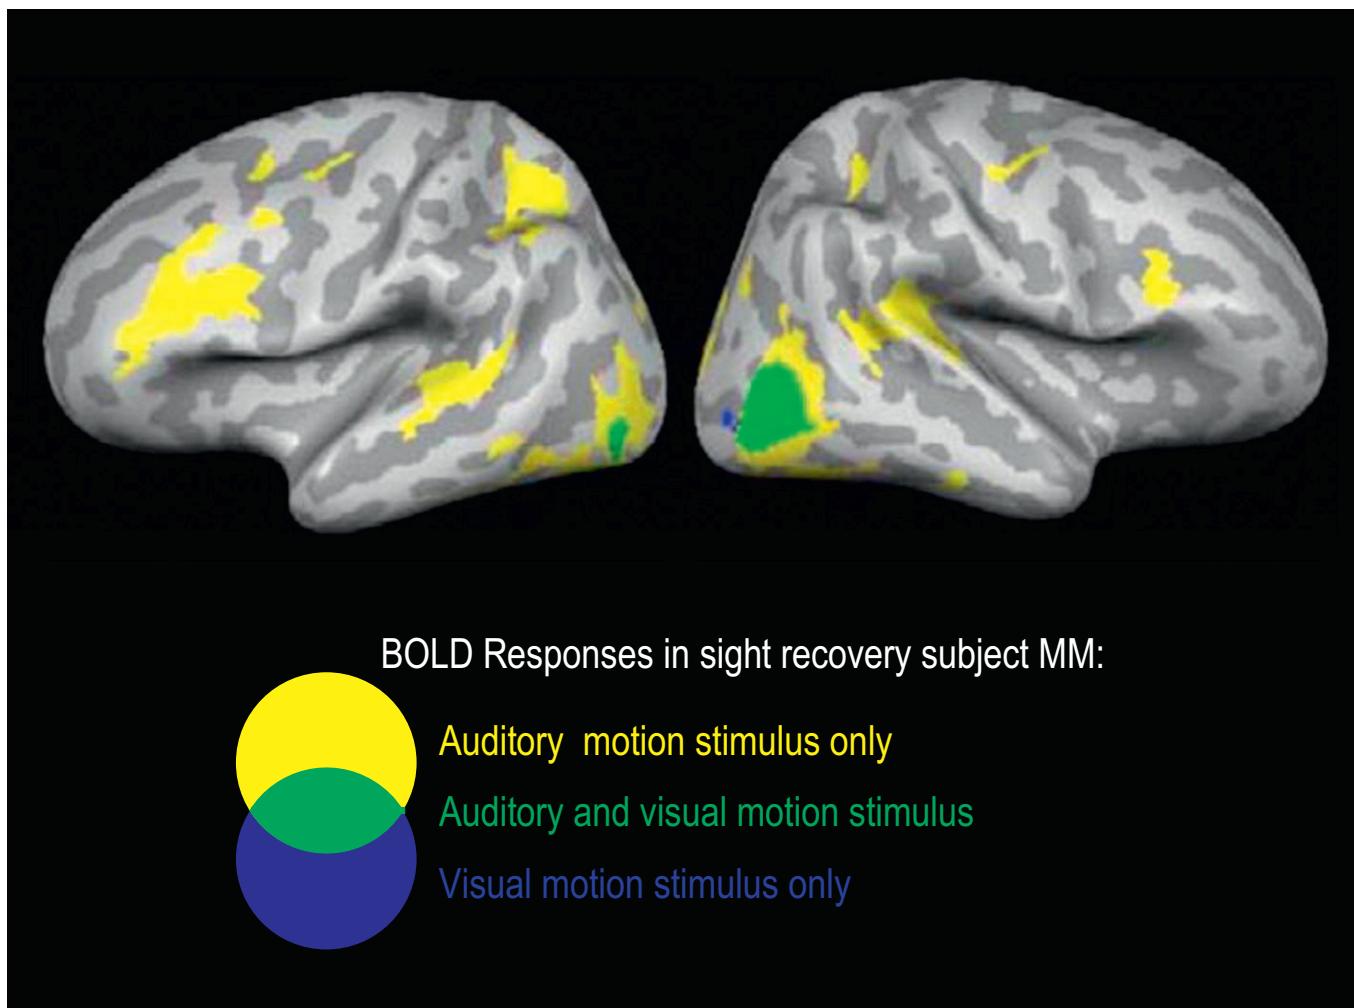

Figure 41.12 Responses to auditory motion stimuli and visual motion stimuli within sight recovery subject MM. Note the near-complete overlap between visual and auditory responses, indicating co-localization of auditory and visual motion responses. (Adapted from Saenz et al.⁸¹)

Concluding remarks

Over the last decade a wide variety of studies have established that blindness results in remarkable changes in the response properties of human occipital cortex, and have further shown that these changes in response properties underlie a variety of skill differences between blind and sighted subjects.

However at this present date there is still much to be learned about the neurophysiological substrates of human cross-modal plasticity. Potential sources of cross-modal responses in occipital cortex include thalamic input, direct input from primary auditory or somatosensory areas, and feedback connections from polysensory extrastriate cortex. These connections may be mediated by pre-existing anatomical pathways, deviations in developmental “pruning”, or entirely novel anatomical pathways. Patterns of connectivity are, of course, also likely to differ between early and late blind subjects, between foveal and peripheral cortex, and as a function of individual experience, such as the age of learning Braille. Fortunately, over the next decade the

increasing use of powerful non-invasive methods such as MRS, DTI, and TMS to examine the effects of blindness is likely to provide increasing insight into the biological foundations that underlie this remarkable example of plasticity within the human brain.

It is, of course, also likely that the factors that affect cross-modal plasticity interact. Early blind subjects tend to be much more fluent at skills such as Braille, use of a cane, or sign language than later blind subjects. One reason for this may be that these skills are easier to learn at an early age, when cortex is more plastic, and occipital cortex shows larger cross-modal plasticity. However the greater skills of the early deprived may also be partially due to behavioral and cultural factors – early blind subjects tend to learn Braille at school, and as a result learn to rely on Braille more heavily than those deprived at a later age. What is most likely is that these two factors may reinforce each other: Early blind subjects may learn sensory substitution skills more easily than those deprived later in life, this makes them rely on these skills more heavily, giving them practice and thereby further improving those skills, and this, in turn, increases the amount of cross-modal plasticity that occurs. In those

deprived later in life, this “circle of competency” may be much more difficult to establish.

A deeper understanding of how neural deterioration as a result of blindness and cross-modal plasticity might interact will also prove increasingly important as new sight restoration procedures (such as retinal implants, epithelial stem cell replacements, gene therapies, and retinal transplants) become available. The cross-modal plasticity that occurs as a result of sensory deprivation is of benefit to the blind individual, playing an important role in allowing them to make better use of his/her remaining senses. It is therefore important to be aware that restoring vision may have the unintended consequence of interfering with cross-modal abilities. This is of particular concern, because, as described earlier, the neural deterioration that occurs as a result of early blindness does seem to severely limit an individual’s ability to make use of restored vision.

Take, for example, the classic description of sight recovery subject SB’s inability to deal with crossing the road after sight restoration:¹²⁵

“He found the traffic frightening, and would not attempt to cross even a comparatively small street by himself. This was in marked contrast to his former behavior, as described to us by his wife, when he would cross any street in his own town by himself. In London, and later in his home town, he would show evident fear, even when led by a companion whom he trusted, and it was many months before he would venture alone.”

Clearly, new visual information interfered with SB’s ability to use cross-modal skills that he had relied on preoperatively. The decision to implant a prosthetic device or carry out a restorative surgery needs to consider not only the potential loss to any residual vision or hearing but also the potential of the device to interfere with the development of (in the case of children) or the use of cross-modal processing. Given that the ability to make use of the restored sense will often be limited, any potential deterioration in a patient’s ability to navigate with a cane or read Braille, must be treated as a serious concern.

Index

Notes

- vs. indicates a comparison or differential diagnosis
- To save space in the index, the following abbreviations have been used
 - IPL – inner plexiform layer
 - ipRGCs - intrinsically photosensitive retinal ganglion cells
 - LGN – lateral geniculate nucleus
 - RGC – retinal ganglion cells
 - RPE – retinal pigment epithelium
