Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary. Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

The 11th edition of Adler's sees a significant reorganization based on function and function/structure relationships within ocular cells, tissues and organs. Prior editions had been organized largely anatomically, but in the eight years since the 10th edition, basic, translational and clinical knowledge has increased exponentially. Capturing, synthesizing, organ-

izing and conveying vast amounts of this new information in the context of a new organizational strategy has been both challenging and stimulating. We hope that the readers, especially our younger scientists and clinicians who represent the future of our field, will find this approach, material and presentation conducive to learning, retention and referral.

Acknowledgements

We are grateful most especially to our authors who took on our challenge to make a classic text into a new entity with a different organizational and contextual approach, to our editors (Leonard Levin, Siv Nilsson, James Ver Hoeve and Samuel Wu) who undertook the hard task of selecting, over-

seeing and coordinating these stellar authors and to our editorial executives at Elsevier (Ben Davie and Russell Gabbedy) who were supportive, tolerant, flexible and stern taskmasters all at once. All were essential to create a book that we hope will be useful to our readers and worthy of its tradition.

To our spouses who provided their never-failing support and sustenance,
to our readers who are the reason we undertook this,
and especially to our students, who are our hope for progress in our field.

Optics

Paulo Schor & David Miller

The young eye

Primate and human infants must normally pass head first through their mother's pelvis to accommodate the limited opening determined by the bony configuration. Therefore the size of the mother's pelvis limits the head and brain size of the infant. Specifically, the brain of an infant ape is 55 percent of its full size, and the brain of a present-day human infant is only 23 percent of the adult size.¹ The result is a human infant who is neurologically immature.² Notice that the baby monkey can immediately cling tightly to the fur on its mother's stomach, whereas the human infant has poor muscle strength, has little motor control, and is completely dependent on the mother for survival. While immature, the human infant lives in a restricted and artificial reality, interacting primarily with the mother. The human infant interacts little with the forces of life in the outside world.

It is possible that this early immaturity and restricted world contact are naturally beneficial. The infant's restricted curriculum concentrates on a few priorities necessary for survival. Without words, the infant must be able to announce all his or her needs and encourage a high level of motherly devotion. To communicate with the mother, the infant must be able to read facial expressions and respond with a non-verbal vocabulary. If this speculation is correct, what vision equipment does the infant have to perform these functions?

Relevant anatomy

Axial length

Larsen³ noted that the axial length of the neonate's eye was 17 mm and that it increases 25 percent by the time the child reaches adolescence. The size of the normal infant's eye is about three-fourths that of the adult size. Geometric optics teaches us that the retinal image of the normal infant eye is therefore about three-fourths the size of the adult's image.* A smaller image also means that much less fine detail is

recorded. The small retinal image may be but one reason why an infant's visual acuity is poorer than that of the adult. In fact, experiments have shown that the neonate's visual appreciation for fine detail at birth is one-thirtieth, or approximately 3 percent, of the development of the adult,* yet the neonate appreciates large objects (e.g. nose, mouth, eyes of close faces) as does the adult.

Figure 1.1 shows that visual acuity swiftly improves, and by the age of 12 months, the infant's level of visual acuity is 25 percent (20/80) of optimal adult visual acuity. This improvement in acuity seems to parallel eyeball growth. By the age of 5 years, the child usually has 20/20 vision.^{1,5-8} What other factors beyond eye size account for the young child's lowered visual acuity? As the eye grows, the optical power of the eye lens and cornea must weaken in a tightly coordinated fashion so that the world stays in sharp focus on the retina. Patients with myopia highlight the developmental process of balancing the growth of the eye while maintaining a sharp retinal image. Most cases of myopia have an elongated eye. The stretching and weakening of the sclera seems to depend on two major factors. First, that the intraocular pressure maintains a constant force on the sclera. Second, there is digestion of sclera architecture (collagen I fibers and extracellular matrix) by metalloproteinase enzymes.⁹ This idea of strengthening the sclera to prevent myopic expansion is supported experimentally. In one series of experiments, 7-methylxanthine (a caffeine metabolite) was used to enhance concentration and thickness of collagen fibers in the posterior sclera of animals. In humans, scleral collagen fibers were cross-linked using riboflavin activated by ultraviolet light.

However, we do not know what activates the process of scleral weakening and stretching in myopia. Some human studies have shown that use of atropine drops in children partially inhibits the development of myopia. The reason is unclear. Some feel that atropine reduces the pull of the ciliary muscle on the sclera which otherwise allows the sclera to elongate. Another theory suggests that the atropine reduces vitreous pressure, thus reducing a stretching force. However, atropine has the same effect in chickens that have

*Specifically, the size of the retinal image depends on an entity known as the *nodal distance*, which averages 11.7 mm in the newborn and 16.7 mm in the adult emmetropic schematic eye, giving a ratio of adult to infant retinal images of 1.43.⁴

*The infant's visual acuity is about 20/600 versus the normal visual acuity of an adult, which is 20/20.

Figure 1.1 A graph showing the improvement of visual acuity in the infant as it ages. The method of preferential viewing was used to achieve these results. (From Teller DG: The development of visual function in infants. In: Cohen B, Bodis-Wollner I, eds. Vision and brain. New York: Raven Press, 1990.)

aciliary muscle unresponsive to the effects of atropine. Another school of thought is that retinal receptors somehow activate the process of scleral weakening, e.g. M1 muscarinic receptors present in the neural retina but not in muscle. Animal experiments using specific M1 blockers such as pirenzepine show the same effects as atropine, without blockade of accommodation. The presence of pirenzepine-inhibited receptors within the choroid and retina could also explain why elongation in eyes with transected optic nerves is inhibited by pirenzepine. Human use of topical pirenzepine was reported in two studies which showed a small but statistically significant reduction in myopia and axial length.¹⁰ These data suggest that during childhood the retina can record information concerning the sharpness of the retinal image and then use this information to control the eye's axial length via scleral stretching.

If this tight coordination of growth fails, the infant may become nearsighted or farsighted. Because the coordination of eye length growth and the focusing power of the cornea and eye lens may be imperfect, is there some compensation provided, early in life, guaranteeing that almost every child can process a sharply focused retinal image of the world? Accommodation is the safety valve that can help provide a sharp image, even if all the ocular components are not perfectly matched. In the young child the range of accommodation is greater than 20 diopters. This range, in addition to the farsightedness of almost all infants, means that most young eyes can focus almost any object by using part or all of this enormous focusing capacity.

Because of the infant's smaller pupil, a second factor that helps the infant achieve a sharper retinal image is an increased depth of focus.⁵ Photographers use this device when they use larger F-stops (F32, F64) to keep objects at different distances all in focus.

Figure 1.2 shows the importance of the nodal point in determining the size of the retinal image in a typical human eye. To help us appreciate the basic optical principles operating within the human eye and avoid being confused by their many details (e.g. the many different radii of curvature, the different indices of refraction), an all-purpose, simplified eye was developed. Such model eyes have many names (e.g.

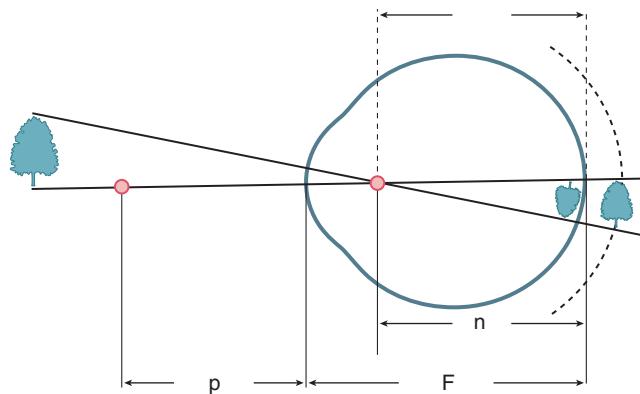

Figure 1.2 A diagram of a reduced human eye. F , Focal points; n , nodal point; p , principal point. The dotted line represents the retina of an enlarged eye.

reduced, schematic, simplified eye) and were developed by some of the true giants of physiologic optics.*

Figure 1.2 depicts such an eye with its cardinal points (the principal points, focal points, and nodal points). Knowing the location of the cardinal points of a lens system, the optical designer can calculate all of the relationships between an object and an image. For example, to determine the image size of the reduced eye, one simply traces the ray, starting from the top of the object, which goes undeviated through the nodal point and lands on the top of the inverted retinal image. As the distance between the nodal point and the retina increases, the image size increases. The addition of a plus spectacle lens to the eye's optic system moves the nodal point of the new system forward (increasing the nodal point to retina distance), thus magnifying the retinal image. The reverse is true with a negative spectacle lens. Therefore a contact lens or a refractive cornea on which surgery has been performed enlarges the image size for a person with myopia who previously wore spectacles. The change in retinal image size should be taken into account when evaluating the visual acuity results after corneal refractive surgery. From an optical point of view, an 8 diopter hyperope exchanges a larger image produced by their +8 spectacle lens for a smaller image after corneal refractive surgery. Thus, they should theoretically lose a line of visual acuity after refractive surgery, but instead often gain a line. A possible reason is that the aberrations of the high plus spectacle lens cancel the effects of the larger retinal image, but this area requires further study.¹¹

Emmetropization

The coordination of the power of the cornea, crystalline lens, and axial length to process a sharp retinal image of a distant object is known as *emmetropization*. In the United States, more than 70 percent of the population is either emmetropic or mildly hyperopic (easily corrected with a small accommodative effort).

*A partial list of giants of physiologic optics who have created schematic or reduced eyes includes Listing, Helmholtz, Wüllner, Tserning, Matthiessen, Gullstrand, Legrand, Ivanoff, and Emsley.

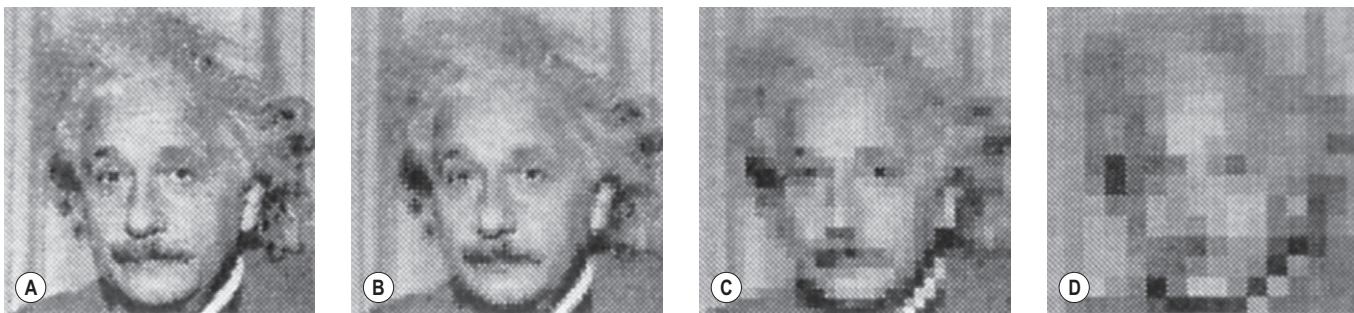

Figure 1.3 A computer display of the face of Albert Einstein, with pixels of different size. (From Lakshminarayanan V et al. Human face recognition using wavelengths. In: Vision science and its application. Santa Fe: Optical Society of America, 1995.)

With age, the cornea, lens, and axial length undergo coordinated changes. Essentially, the optical components (cornea and lens) must lose refractive power as the axial length increases so that a sharp image remains focused on the retina.

The cornea, which averages 48 diopters of power at birth and has an increased elasticity, loses about 4 diopters by the time the child is 2 years of age.^{12,13} One may assume that the spurt in growth of the sagittal diameter of the globe during this period pulls the cornea into a flatter curvature. The fact that the average corneal diameter is 8.5 mm at 34 weeks of gestation, 9 mm at 36 weeks, 9.5 mm at term, and about 11 mm in the adult eye supports this “pulling, flattening” hypothesis.¹⁴

On the other hand, other coordinated events also occur, such as the change of lens power and the coordinated increase in eye size (most important, an increase in axial length). The crystalline lens, which averages 45 diopters during infancy, loses about 20 diopters of power by age 6 years.^{15,16} To compensate for this loss of lens power, the axial length increases by 5–6 mm in that same time frame.³ (In general, 1 mm of change in axial length correlates with a 3-diopter change in refractive power of the eye.)

Now let us examine a possible mechanism that could account for most of the data.^{15,17} As the cross-sectional area of the eye expands, there is an increased pull on the lens zonules and a subsequent flattening of the lens (the anterior lens surface is affected a bit more and the posterior lens surface a bit less), thus decreasing the overall lens power. There also may be a related decrease in the refractive index of the lens, which also contributes to the reduction in lens power. Because the incidence of myopia starts to accelerate significantly around the age of 10,¹⁵ one may question whether there could be a decoupling of the previously described coordinated drop in lens power and increase in axial length. An increased amount of near work (e.g. school-work) is associated with a higher incidence of myopia.¹⁸ It is also well known that genetic predisposition influences myopia incidence, as evidenced by the fact that more Asian children than Caucasian children are myopic.¹⁸ Thus one might hypothesize that the long periods of accommodation that accompany schoolwork (ciliary body contraction) may tend to stretch and weaken the linkage between the enlarging scleral shell and the ciliary body. If this were to happen, the lens would flatten less during eye growth. Another way of looking at this phenomenon is to theorize that with the linkage weakened, the restraining effect of the lens-zonule

combination on eye growth is also weakened, which results in an increase in axial length in the myopic student. Many studies demonstrating that the myopic eye has a greater axial length than the emmetropic eye support this idea.¹⁹

Retinal receptors

The cone photoreceptors of the retina are responsible for sharp vision under daylight conditions. The denser the cones are packed, the more acute the vision.^{1,7} To use a photographic analogy, film with the highest resolution has smaller photosensitive grains, packed tightly, whereas a film with large grains of silver halide yields a coarser picture.

The most sensitive part of the retina is the fovea.* Here the cones are even finer and are packed together even tighter. The fovea of the infant eye is packed less than one fourth the density of that of the adult. Furthermore, the synapse density in the neural portion of the retina, as well as the visual brain, is low at birth. The combination of these two anatomic configurations means that fewer fine details of the retinal image are recorded and sent to the brain.

Neural processing

Finally, the nerves that transmit the visual information to the brain, as well as the nerve fibers at the various levels within the brain, are poorly myelinated in the infant. Myelin is the insulating wrap around each nerve fiber. A normally myelinated nerve can transmit nerve impulses swiftly and without static or “cross talk” from adjacent nerves. To use a computer analogy, one might think of the infant brain as being connected with poorly insulated wires. Therefore sparks, short circuits, and static all slow or interfere with perfect transmission, and only the strongest messages get through. Figure 1.3 represents an appropriate analogy. The face of Albert Einstein is shown on a computer screen with larger and larger pixels. The infant’s early vision might be comparable to the picture with the biggest block pixels. With maturation of the brain processing elements, the neurologic equivalent of pixel size gets smaller and more details can be registered. Thus the equivalent of the photographic film grain size in the retina and the equivalent of pixel size in the

*F. W. Campbell²⁰ quotes Stuart Anstis’s clear analogy of how the fovea functions: “A retina with a fovea surrounded by a lower acuity periphery can be compared to a low magnification finder telescope with a large field of view which will find any interesting target and then steer on to it a high powered main telescope, with a very small field which could examine the target in detail.”

Figure 1.4 This photo shows a recently born infant mimicking the expression of psychologist Dr. A. Meltzoff. The baby is obviously able to perceive the different expressions in order to mimic them. (From Klaus MH, Klaus PH. *The amazing newborn*. Reading, Mass: Addison Wesley, 1985.)

brain processor both get smaller as the child grows. Lakshminarayanan, who created Figure 1.3, speculated that the immaturity of the infant's memory capacity may be one reason why its visual images have less detail. In other words, the coarseness of the infant visual system does not overtax the immature memory system.

Relevant early physiology

Experiments with infants reveal that good color vision does not appear for about 3 months. The infant also takes longer to "make sense" of the retinal image. Specifically, the infant must stare for relatively long periods (1–3 minutes), blinking rarely during this period.^{1,7}

Recognizing faces

The remarkable thing about the infant's eyesight is that the relatively poor level of resolution just described still allows the infant to recognize different faces and different facial expressions. We know this to be true in some newborn infants, who can accurately imitate the expressions of an

adult (Fig. 1.4), almost as if the baby uses his or her own face as a canvas to reproduce the facial expression of the onlooker.

Experiments with infants demonstrate that infants prefer to look at faces or pictures of faces rather than to look at other objects. By the age of 6 weeks, infants can discern specific features of the face. For example, they can lock in on the mother's gaze. By age 6 months, they can also recognize the same face in different poses. In fact, they are experts at recognizing a face, be it upside down or right side up, till the age of 6 years. After age 6, infants actually lose their skill at quickly recognizing upside-down faces.⁷

A closer examination of the eye at 6 months of age is worthwhile because an unusual change has started to take place in the optics of the eye at this time. Gwiazda et al²¹ found that a significant amount of astigmatism develops in 56 percent of the infants studied. This condition remains for only 1–2 years.^{18,19,21,22}

The transient astigmatism just described tends to elongate tiny dots of the retinal image into lines. In essence, these create the equivalent of a line drawing of the retinal image.

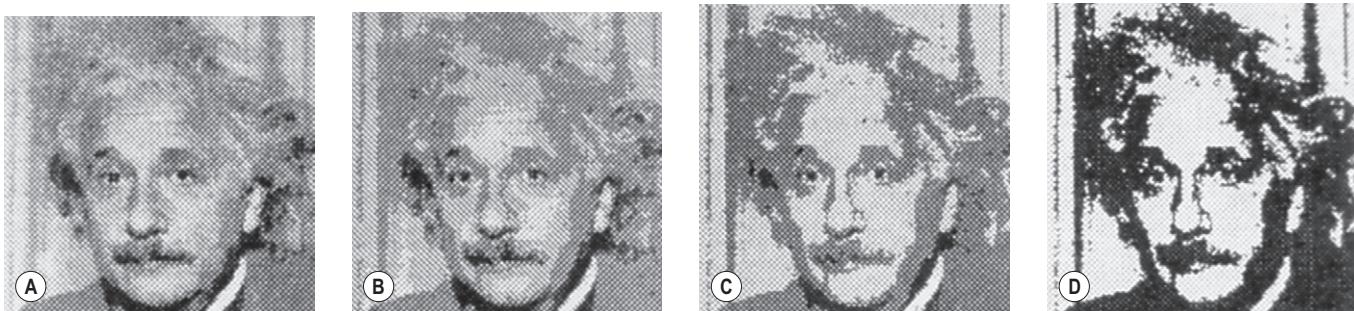

Figure 1.5 A series of computer simulations of the face of Albert Einstein with an extensive gray scale on the left (16 gray scale) and only a 2 gray scale on the right, the latter being similar to a line drawing. (From Lakshminarayanan V et al. Human face recognition using wavelength. In: Vision science and its applications. Santa Fe: Optical Society of America, 1995.)

For example, think of a mime (i.e. a painted face with a few dark lines and spots for eyes and nose) as creating different line drawings of the face. What is astonishing is that, although made of only a few dark lines, the mime can recreate most human expressions. It seems reasonable to imagine that the mime presents faces similar to those seen by the young child or found in a child's drawing. The faces have no texture, no shadowing, and no creases – only a line for a mouth, circle for eyes, and occasionally, a dot for a nose. Is it not then possible that infant astigmatism helps represent faces as line drawings to the infant visual system? Line drawings also save memory storage space, which would be an advantage for the small infant brain.* Figure 1.5 illustrates this point in a different way. The face of Albert Einstein is shown with a complete gray scale on the left and is shown as a line drawing (only black and white) on the right. The line drawing requires much less computing power than a face with texture and would be more compatible with the child's immature processing system.

Line orientation receptors

As noted earlier, in many infants the amount of astigmatism can rise to a level of greater than 2 diopters in the first year of life. The orientation of the distortion is usually horizontal (180 degrees) initially. In the course of the next 2 years, the meridian of distortion rotates to the vertical and the amount of the astigmatism diminishes. This slow rotation of the axis of exaggeration can help activate different groups of brain cells, which become sensitive to features in the retinal image with different tilts. In fact, the discovery of these brain cells with orientation selectively leads to a ground-breaking understanding of the functional architecture in the higher brain. In 1958 Torsten Wiesel and David Hubel, working in their laboratory at the Harvard Medical School, implanted electrodes in the visual cortex of an anesthetized cat to record cortical cell responses to patterns of light, which they projected onto a screen in front of the cat. After 4 hours of intense work, the two scientists put the dark spot slide into the projector, where it jammed. As the edge of the glass slide cast an angled shadow on the retina, the implanted cell in the visual cortex fired a burst of action potentials. Torsten Wiesel described that moment as the "door to all secrets."

The pair went on to prove that cells in the cortex responded only to stimuli of a particular orientation. Similar responding cells were all located in the same part of the cortex. This work opened up the area of how and where the brain encodes specific features of the retinal image. Fittingly, Drs. Hubel and Wiesel were awarded the Nobel Prize for Medicine in 1981.²³

Monitoring other's eye movements

Another function of great survival value to the infant is the ability to follow the eye movements of his or her caretakers. Consider this a near task involving the contrast discrimination of a 12-mm dark iris against a white sclera framed by the palpebral fissure; such a task can be accomplished with a visual acuity of 20/200.

The British psychologist Simon Baron-Cohen, in his book *Mindblindness*,^{*} suggests that a major evolutionary advance has been the human's ability to understand and then interact with others in a social group (e.g. playing social chess). He further suggests that we accomplish this social intelligence primarily by following the eye movements of others, which begins at a young age. For example, an infant of 2 months begins to concentrate on the eyes of adults. Infants have been shown to spend as much time on the eyes as all other features of an observer's face.

By 6 months of age, infants look at the face of an adult who is looking at them two to three times longer than an adult who is looking away. We also know that when infants achieve eye contact, a positive emotion is achieved (i.e. infants smile). By age 14 months, infants start to read the direction that an adult is looking. Infants turn in that direction and then continue to look back at the adult to check that both are looking at the same thing. By age 2, infants typically can read fear and joy from eye and facial expression.

Recognizing movement

Infants are capable of putting up their arms to block a threatening movement. This act tells us that infants appreciate both movement and the implied threat of this particular movement.^{24,5} Admittedly, infants cannot respond if the threat

*This idea was suggested by David Marr in "Early Processing of Visual Information," published in Transactions of the Royal Society of London, Series B 1976; 275:483.

*In his book *Mindblindness: An Essay on Autism and Theory of Mind*, published by MIT Press in 1995, Baron-Cohen ferrets out the key features of "eye following" in the normal child by comparing them with those of the autistic child.

moves too quickly, probably because the immature myelination of the nerves slows the neural circuits. Nevertheless, a definite appreciation of movement and threat exists.

For movement to be registered accurately, the infant retina probably records an object at point A. That image is then physiologically erased (in the brain and/or retina), and the object is now seen at point B. This physiologic erasure is important because, without it, movement would produce a smeared retinal image. Researchers think that the infant probably sees movement as a smoothed series of sharp images, not smears.²⁵ This hypothesis is supported by other experiments demonstrating that the infant can appreciate the on/off quality of a rapidly flickering light at an early age. It seems logical that the movement of an image across the retina (with the inherent erasures) is physiologically related to the rapid on/off registration of a flickering light.

A related reflex, the foveal reflex, is triggered by stimulation of the peripheral retina, activating the eye movement system so that the fovea is directed to the visual stimulus.

Summary – social seeing

Although the visual system of the infant is immature, some infants can recognize and respond to adult facial expressions on the first day of life and follow the mother's glances by 6 weeks of age. Clearly, the infant's top priority is to maintain a social relationship with his or her mother or other caring adults. This idea was described succinctly by the "language expert" Pinker:²⁶ "Most normally developing babies like to schmooze." As infants grow, they learn to see people and objects in the way that their culture demands and communicate in the expected manner; that is, "We don't see things as they are but as we are." Is it possible that the immature eye and visual system actually facilitate socially biased seeing? Perhaps the smaller, simpler retinal images, along with the less sophisticated brain processing, prevent the many other details of life from confusing the key message; that is, social interaction takes top priority.

Even in adulthood there is plasticity of the visual system, e.g. after the implantation of multifocal IOLs (intraocular lenses). These IOLs superimpose blurred near images on a sharply focused distant image. Thus, the patient's brain must filter and suppress the third, fourth and so on blurred images from the scene. This is a time-dependent phenomenon that may take days to months to occur.²⁷

The image of the human adult eye

The image quality of the human adult eye is far superior to that of the human infant, although probably inferior to certain predator birds. Its wide focusing range is smaller than that of certain diving birds, and its fine sensitivity to low light levels is weaker than spiders or animals with a tapetum lucidum. Its ability to repair itself is probably not as efficient as some animals (e.g. newts, which can form a new lens if the original is damaged). Finally, the human eye has the ability to transmit emotional information²⁸ (e.g. excitement by means of pupil dilation, sadness by means of weeping), but with less forcefulness than some fish, who uncover a pigmented bar next to the eye when they are about to attack,²⁹ or the horned lizard, which squirts a jet of blood

from its eye when it is threatened.³⁰ Thus, in reading this chapter, one must appreciate the eye's level of performance in light of its large spectrum of functions.

Tuned to visible light waves

When our retinas receive an image of a spotted puppy in a room, what is really happening in terms of information transfer? Light waves from the ceiling light are cast onto the puppy. The puppy's body reflects and scatters the light waves into our eyes. In a sense, information about the puppy has been encoded into visible light waves. The optical elements of the eye focus the encoded light waves onto our retina as a map of bright and dim colored dots, known as the *retinal image*. Nerve signals report the retinal image to the brain. In the brain the nerve signals are recreated into the impression that a real puppy is in the room.

One might liken the function of the eye to that of a radio, which receives radio waves carrying a Beethoven symphony. The specific station broadcasting the symphony beams it out on a specific radio wavelength. The radio then receives the radio waves, and the speaker reconverts the waves to musical sounds. If the eye is to receive and process visible light, it must be constructed with the ability to be tuned to the wavelengths of visible light. The physicist would substitute the term *resonate* for *tune*. Literally, *resonate* means to resound another time. A simple example of resonance is an opera singer who can make a wine glass hum when the frequency (or wavelength) of the note is the same as the natural frequency of the glass. What is the natural frequency of anything? The answer has to do with composition and size. Organ pipes of different lengths resonate at different frequencies and wavelengths. Changing the length of the antenna on a car radio allows the frequencies of different stations to be received. The best receiver for a specific wavelength (frequency is the reciprocal of wavelengths) is physically the same size as the wavelength, a precise number of wavelengths, or a precise fraction (one-fourth, one-half) of the size of the wavelength. Therefore optical theory demands that the size of the key components of the eye be the size of a wavelength of visible light or some number (*n*) times the size of, or a fraction of the size of, the wavelengths of visible light; in addition, the key components must be made of a resonating material.

Role of the cornea

The human cornea is a unique tissue. First, it is the most powerful focusing element of the eye, roughly twice as powerful as the lens within the eye. It is mechanically strong and transparent. Its strength comes from its collagen fiber layers. Some 200 fiber layers crisscross the cornea in different directions. These fibers are set in a thick, watery jelly called *glycosaminoglycan*. The jelly gives the cornea pliability. For a long time, no one could explain convincingly the transparency of the cornea. No one could understand how nature combined tough, transparent collagen fibers (with their unique index of refraction) with the transparent glycosaminoglycan matrix, which had a different index of refraction, and still maintain clarity. Perhaps an everyday example of this phenomenon will help. When a glass is filled from the hot water tap, the solution looks cloudy. Looking

closely, one can see many fine, clear expanded air bubbles (which have a unique index of refraction) within the water (which has different refractive properties). Conversely, cold water appears clear because its air bubbles are tiny. The normal corneal structure might be considered optically similar to the structure of the cold water (i.e. tiny components with different indices of refraction).

Miller & Benedek³¹ were ultimately able to prove that if the spaces consisting of glycosaminoglycan and the size of the collagen fibers were smaller than one-half a wavelength of visible light, the cornea is clear, even if the fibers were arranged randomly. An orderly arrangement of the fibers also helps maintain corneal transparency.

Another way to explain it is to say that the cornea is basically transparent to visible light because its internal structures are tuned to the size of a fraction of the wavelengths of visible light. Figure 1.6 is an electron micrograph showing the fibers of the human cornea. The black dots are cross sections of collagen fibers imbedded in the glycosaminoglycan matrix. In this specimen (Fig. 1.6A), the fibers are spaced closer than half a wavelength of visible light apart, and the fibers in each of the major layers are arranged in an orderly manner. In an edematous, hazy cornea there are large spaces between collagen fibers (Fig. 1.6B).

This arrangement of corneal fibers serves a number of important functions. First, the arrangement offers maximal strength and resistance to injury from any direction. Second, the arrangement produces a transparent, stable optical element. Third, the spaces between the major layers act as potential highways for white blood cell migration if any injury or infection occurs. Horizontal arrangement of corneal lamellae, which can slide over each other during eye rubbing, facilitates the clinical development of pathological conditions such as keratoconus. The lack of interlamellar adhesion and corneal thinning facilitate a bulging under IOP and gravity. Enzymatic digestion seems to be the causative agent in the thinning, which eventually deforms the anterior surface of the cornea. This conical cornea is irregularly astigmatic and will produce multiple blurred images in the retina. Collagen cross-linking helps connect the adjacent lamellae, inducing greater corneal strength by resisting interlamellae sliding, and thus reduces the progression of keratoconus (Box 1.1).³²

Role of the crystalline lens

Is it easier to see underwater with goggles?* Without goggles, the water practically cancels the focusing power of the cornea,^t leaving objects blurred. The goggles ensure an envelope of air in front of the cornea, restoring its optical power. If water cancels optical power, how can we explain the focusing ability of the crystalline lens, which lies inside the eye and is surrounded by a fluid known as *aqueous humor*? The answer is that the focusing power resides in the unusually high protein content of the lens. The protein concentration

*Because the index of refraction of water is greater than air, objects underwater appear about one-third closer and thus one-third larger than they would in air (i.e. magnification = 1.33x).³³

^tThe cornea is a focusing element for two reasons. First, it has a convex surface. Second, it has a refractive index greater than air. Actually, its refractive index is close to that of water. Thus, when one is underwater, the surrounding water on the outside and the aqueous humor inside the eye combine to neutralize the cornea's focusing power.

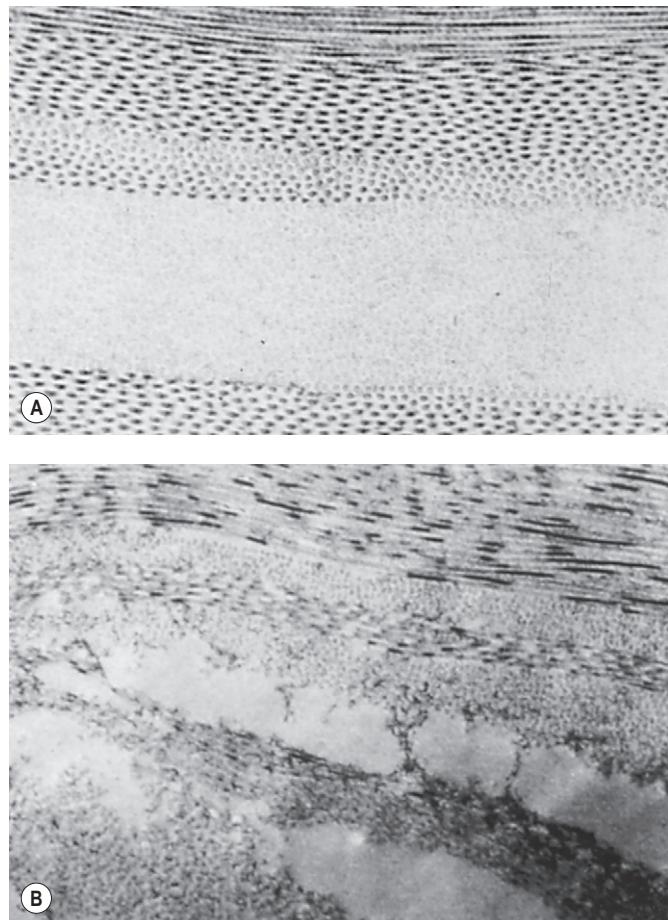

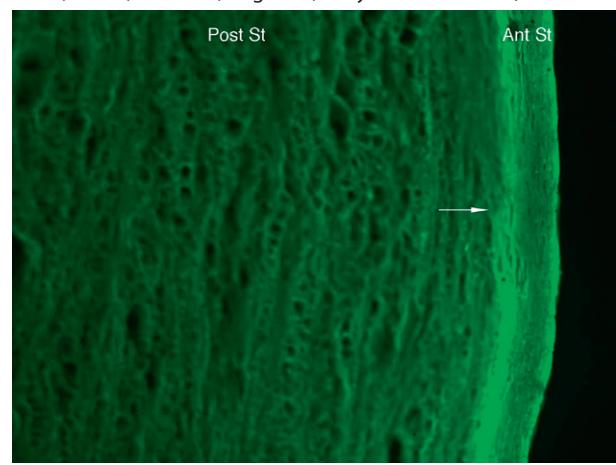

Figure 1.6 (A) Electron micrograph showing the neat pattern of corneal collagen fibers. The black dots are the fibers cut on end. In this photo the spacing between fibers is less than a wavelength of light apart. (B) Large spaces between collagen fibers, as seen in a waterlogged, hazy cornea. (From Miller D, Benedek G. Intraocular light scattering. Springfield, Ill: Charles C Thomas, 1973.)

Box 1.1

An example of immunofluorescent staining for confocal microscopy (40×) of a bovine cornea soaked with a riboflavin (0.01 percent) solution. Prior to staining the specimen was submitted to 30 minutes exposure to UV light (365 nm). Note the connection between lamellae in the anterior stroma (ant st) compared to the laxity of the posterior stroma (post s). (Courtesy Bottos, Schor, Chamon, Regatieri, Dreyfuss and Nader.)

may reach 50 percent or more in certain parts of the lens.* Such a high concentration increases the refractive index above that of water and allows the focusing of light. Now we are ready to appreciate the real secret of the lens.^{31,34}

Normally, a 50 percent protein solution is cloudy, with precipitates floating about like curdled lumps of milk in a cup of coffee. However, the protein molecules of the normal lens do not precipitate. In a manner not fully understood, the large protein molecules known as *crystallins* (large protein molecules ranging in size from 45 to 2000 kD) seem to repel each other, or at least prevent aggregation, to maintain tiny spaces between each other. The protein size and the spaces between them are equivalent to a small fraction of a light wavelength. Spaced as they are, one might say that they are tuned to visible light and allow the rays to pass through unimpeded. On the other hand, if some pathologic process occurs, the protein molecules clump together and the lens loses its clarity. When this happens, light is scattered about as it passes through the lens. The result is a cataract.

Accommodation

If the emmetropic eye is in sharp focus for the distant world, it must refocus (accommodate) to see closer objects.[†] For example, the child's range of accommodation is large, as noted earlier. This allows the child to continue to keep objects in sharp focus from an infinite distance away to objects brought to the tip of the nose. The act of accommodation is fast, taking only about one-third of a second. Our range of accommodation decreases with each passing year, so by the age of 45, most of us are left with about 20 percent of the amplitude of accommodation we started with.

With age, the lens enlarges and becomes denser and more rigid. In so doing, it progressively loses the ability to accommodate. Parenthetically, the cornea of many birds, from pigeons to hawks, can change shape to accommodate.³⁵ The avian cornea does not change flexibility with age; therefore these birds do not become presbyopic. However, there is no "free lunch" in nature. The human lens, sitting within the eye surrounded by protective fluid is far less vulnerable to injury than the cornea.

Role of the retina

After light passes through the cornea, the aqueous humor, the lens, and the vitreous humor, it is focused onto the retinal photoreceptors. The light must pass through a number of retinal layers of nerve fibers, nerve cells, and blood vessels before striking the receptors. These retinal layers (aside from blood vessels) are transparent because of the small size of the elements and the tight packing arrangement.

The bird retina does not have blood vessels. The human retina has retinal blood vessels that cover some of the retinal receptors and produce fine angiosomas. A bird's retina

*The chemical composition of a focusing element such as the crystalline lens determines the refractive index. Water has a refractive index of 1.33. As the protein concentration of the lens rises, the index of refraction approaches 1.42.

[†]The question "How does accommodation 'know' it has achieved the sharpest focus?" seems to be best answered by a sensing system in the brain. However, some have suggested that the system takes advantage of the naturally occurring chromatic aberration of the primate eye to fine-tune focusing.³⁶

obtains much of its oxygen and nutritive supply from a tangle of blood vessels (the pecten), which is covered with black pigment and sits in the vitreous in front of the retina and above the macula (so as to function as a visor). The negative aspect of such a vascular system is vulnerability to a direct blunt or penetrating injury that can lead to a vitreous hemorrhage and sudden blindness. Obviously, this is less probable in the bird because of its lifestyle.

Rhodopsin

The rods and cones are made up of a biologic molecule that absorbs visible light and then traduces that event into an electrical nerve signal. The rhodopsin molecule is an example of Einstein's photoelectric effect.* In fact, only one quanta (the smallest possible amount of light) of visible light[†] is needed to trigger the molecule, that is, snap the molecule into a new shape.[‡]

The internal structure of the molecule allows the wavelengths of visible light to resonate within its electron cloud and within 20 million millionths of a second, inducing the change in the molecule that starts the reaction.

Probably the earliest chemical relative of rhodopsin is to be found in a primitive purple-colored bacteria called *Holobacterium halobium*. Koji Nakanishi, a biochemist at Columbia University, in an article titled "Why 11-cis-Retinal?"³⁷ (a type of rhodopsin) notes that this bacteria has been on the planet for the last 1.3 billion years.^{38,39} Its preference for low oxygen and a salty environment places its origin at a time on earth where there was little or no oxygen in the atmosphere and a high salt concentration in the sea. Although found in primeval bacteria, bacteriorhodopsin is a rather complicated molecule, containing 248 amino acids. It is thought that this bacteria probably used rhodopsin for photosynthesis, rather than light sensing. Time-resolved spectroscopic measurements have determined that this molecule changes shape within one trillionth of a second after light stimulation.⁴⁰ This early form of rhodopsin absorbs light most efficiently in the blue-green part of the spectrum, although it does respond to all colors.⁴¹

To function as the transducer for vision, the photopigment must capture light and then signal the organism's brain that the light has registered. As noted earlier, one molecule needs only one quanta to start the reaction. Even more amazing is the molecule's stability. Although only one quanta of visible light is necessary to trigger it, the molecule will not trigger accidentally. In fact, it has been estimated that spontaneous isomerization of retinal (the light-sensing chromophore portion of rhodopsin) occurs once in a thousand years.⁴⁰ If this were not so, we would see light flashes every time there is a rise in body temperature (a fever). To better understand the rhodopsin mechanism, one may

*Some wavelengths of light are powerful enough to knock electrons of certain molecules out of their orbits, thereby producing an electric current. Einstein was awarded the Nobel Prize for explaining the "photoelectric effect."

[†]In 1942, Selig Hecht and his co-workers in New York first proved that only one quanta of visible light could trigger rhodopsin to start a cascade of biochemical events eventuating in the sensing of light.

[‡]Photoactivation of one molecule of rhodopsin starts an impressive example of biologic amplification, in which hundreds of molecules of the protein transducer each activate a like number of phosphodiesterase molecules, which in turn, hydrolyze a similar number of cyclic guanine monophosphate (cGMP) molecules, which then trigger a neural signal to the brain.⁴²

picture a hair trigger on a pistol that takes only the slightest vibration (but only a special type of vibration) to be activated. As noted, the activating quanta must be of the proper energy level to "kick in" the reaction. That is, the quanta of light must be made of wavelengths of visible light.

Receptor size and spacing

Retinal receptor factors that influence the optical limits of visual acuity occur in the foveal macular area. The fovea itself subtends an arc of about 0.3 degree. It is an elliptical area with a horizontal diameter of 100 µm. The area contains more than 2000 tightly packed cones. The distance between the centers of these tightly packed cones is about 2 µm. The cone diameters themselves measure about 1.5 µm (a dimension comparable to three wavelengths of green light) and are separated by about 0.5 µm.⁴³⁻⁴⁶ Therefore the fine details of the retinal image occupy an elliptical area only about 0.1 mm in maximum width.

A discussion of the diffraction limits of resolution, in a theoretical emmetropic human eye, must involve the anatomic size of the photoreceptors and the pupil. A point or an object is focused on the retina as an Airy disc because of diffraction. The angular size of the Airy disc is determined as follows:

$$\text{Angular size (in radians)} = 1.22 \times \frac{\text{wavelength (mm)}}{\text{pupil diameter (mm)}}$$

Let the wavelength be 0.00056 mm (560 nm; yellow green/light). Then

$$\text{Angular size} = 0.00068 \text{ radians/pupil diameter (mm)}$$

For a pupil of 2.4 mm (optimal balance between diffraction and spherical aberration in the human eye):

$$\text{Angular size} = 0.00028 \text{ radians, or about 1 minute of arc} *$$

Given this angle of 1 minute, the actual size of the Airy disc can be calculated if the distance from the nodal point to the retina is known. The optimal distance depends on the diameter of the photoreceptors. Because these act as light guides, the theoretical limit is 1–2 µm. To obtain the maximum visual information available, Kirschfeld calculated that more than five receptors are required to scan the Airy disc.³¹ Assume that each foveal cone is 1.5 µm in diameter and that there is an optimal space of 0.5 µm between receptors. The following equation describes the situation for three cones and two spaces (5.5 µm).

$$5.5 \mu\text{m} / \tan 1 \text{ minute} = \text{Nodal point to retina distance}$$

Substituting 0.0003 from equation (2) into equation (3) gives equation (4):

$$5.5 \mu\text{m} / 0.0003 = \text{Nodal point to retina distance}$$

From equation (4) the distance from the nodal point to the retina can be rounded off to 18.00 mm, which is close to the distance between the secondary nodal point and the retina in the schematic human eye.

How closely does optical theory agree with reality? The average visual acuity for healthy eyes in the age group

younger than 50 was better than 20/16. In the distribution within the group younger than 40, the top 5 percent had an acuity of close to 20/10.⁴⁷

Another related factor must be kept in mind. The fixating eye is in constant motion, as opposed to a camera on a tripod. Presumably, these movements prevent bleaching or fading within individual photoreceptors. These small movements, called either *tremors*, *drifts*, or *microsaccades*, range in amplitude from seconds to minutes of angular arc. Such movements tend to smear rather than enhance our traditional concept of visual resolution. It can only be presumed that to maintain high resolution within the context of this physiologic nystagmus, the visual system takes quick, short samples of the retinal image during these potentially smearing movements and then recreates an image of higher resolution.⁴⁸⁻⁵⁰

The unique essence of the vertebrate retina is that the structure of the transparent optical components, the rhodopsin molecule, and the size of the foveal cones are all tuned to interact optimally with wavelengths of visible light.^{51,52} It is earth's unique atmosphere and its unique relationship to the sun that have allowed primarily visible light, a tiny band from the enormous electromagnetic spectrum of the sun, to rain down upon us at safe energy levels. Our eyes are a product of an evolutionary process that has tuned to these unique wavelengths at these levels of intensity.^{53,54}

With this basic science background, we can discuss how functions such as visual acuity and contrast sensitivity are monitored in a clinical setting.

Visual acuity testing

The idea that the minimum separation between two point sources of light was a measure of vision dates back to Hooke in 1679, when he noted "tis hardly possible for any animal eye well to distinguish an angle much smaller than that of a minute: and where two objects are not farther distant than a minute, if they are bright objects, they coalesce and appear as one."⁵⁵ In the early nineteenth century, Purkinje and Young used letters of various sizes for judging the extent of the power of distinguishing objects. Finally, in 1863, Professor Hermann Snellen of Utrecht developed his classic test letters. He quantitated the lines by comparison of the visual acuity of a patient with that of his assistant, who had good vision. Thus 20/200 (6/60) vision meant that the patient could see at 20 feet (6 m) what Snellen's assistant could see at 200 feet (60 m).⁵⁵

The essence of correct identification of the letters on the Snellen chart is to see the clear spaces between the black elements of the letter. The spacing between the bars of the "E" should be 1 minute for the 20/20 (6/6) letter. The entire letter is 5 minutes high. To calculate the height of "x" (i.e. a 20/20 or 6/6 letter), use the following equation:

$$\tan 5 \text{ minutes} = x \text{ feet}/20$$

$$0.0015 = x/20 \text{ feet}$$

$$x = 0.36 \text{ inches (9.14 mm)} *$$

Chart luminance

In clinical visual acuity testing, the chart luminance should (1) represent typical real work photopic conditions and (2)

*One minute of arc is the spacing between the bars of a 20/20 symbol. Interestingly, the sizing of the symbol was originally determined empirically.

*The 20/200 (6/6) letter is 10 times larger, or 3.6 inches (9.14 cm).

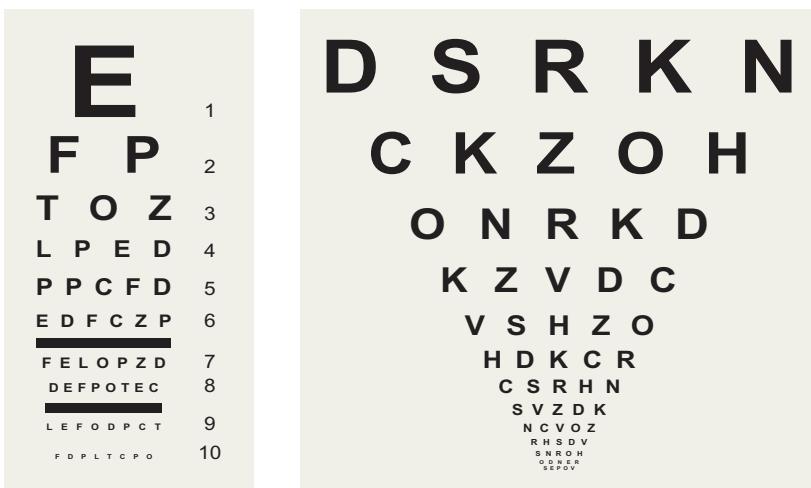

Figure 1.7 The standard Snellen chart and the Bailey-Lovie chart are examples of visual acuity charts.

be set at a level where variation produced by dust accumulation in the projector system, bulb decline, or normal variation in electrical current levels minimally affect visual performance. Thus chart luminance between 80 and 320 cd/m² meet such criteria (160 cd/m² is a favorite level of illumination).

Visual acuity as Log MAR

If one looks at a standard Snellen acuity chart (Fig. 1.7), the lines of symbols progress as follows: 20/400, 20/200, 20/150, 20/120, 20/100, 20/80, 20/70, 20/60, 20/50, 20/40, 20/30, 20/25, 20/20, 20/15, and 20/10. Thus the line-to-line decrease in symbol size varies from 25 percent (20/20 to 20/150) to 20 percent (20/120 to 20/100) to 16.7 percent (20/30 to 20/25).

Would it not be more logical to create a chart of uniform decrements, that is, a chart in which the line-to-line diminution in resolution angle were 0.1 steps? To create such a chart, one must first describe the spaces within a symbol (i.e. spaces between the bars of "E") in terms of "minutes of arc" (MAR) at 20 feet (6 m). Thus the 20/20 line represents a resolution of 1 MAR. If we take the log to the base of 10 of 1 (minute), we get 0. A spacing of 1.25 MAR (the equivalent of 20/30) yields a log value of 0.2, whereas a spacing of 1.99 MAR (the equivalent of 20/40) yields a log MAR of 0.3. See Table 1.1 for a complete listing of equivalents (courtesy of Prof. Dr. Wallace Chamonon).^{56,57}

The Bailey-Lovie acuity chart (Fig. 1.7) uses the log MAR sizing system. Figure 1.8 shows a standardized retroilluminated visual acuity chart commercially available, as used in the EDTRS protocol. Log MAR tests add precision to visual acuity testing. Thus, subtle individual variation may be identified under controlled conditions even in this high-contrast environment by counting the number of letters correctly identifiable by the subject.⁵⁸

Visual acuity chart contrast

Clean printed charts using black characters on a white background usually have a character-to-background luminance contrast ratio between 1/20 and 1/33. For projected charts, the contrast ratio drops to a range of 1/5 to 1/10. Such a decrease in contrast is probably the result of the light scattering produced within the projector and the ambient

Rights were not granted to include this figure in electronic media.

light falling on the screen. Therefore the test should be performed in a dark room or using retroilluminated charts as shown in Figure 1.8.

Contrast sensitivity testing

Visual acuity testing is relatively inexpensive, takes little time to perform, and describes visual function with one notation, e.g. 20/40 (6/12 or 0.5). Best of all, for more than 150 years it has provided an end point for the correction of a patient's refractive error. However, contrast sensitivity testing, a time-consuming test born in the laboratory of the visual physiologist and described by a graph rather than a simple notation, has recently become a popular clinical test. It describes a number of subtle levels of vision, not accounted for by the visual acuity test; thus it more accurately quantifies the loss of vision in cataracts, corneal edema, neuro-ophthalmic diseases, and certain retinal diseases. These assets have been

known for a long time, but the recent enhanced popularity has arisen because of cataract patients. As life span increases, more patients who have cataracts request medical help. Often, their complaints of objects that appear faded or objects that are more difficult to see in bright light are not described accurately by their Snellen acuity scores. Contrast sensitivity tests and glare sensitivity tests can quantitate these complaints. Several validated quality of life assessment questionnaires are also available.⁵⁹ They offer the possibility of evaluating vision-related symptoms in a comparable manner, either over a given time frame (pre vs. post operative period) or among different interventions and patients (presbyopic

LASIK vs. multifocal IOL). A patient happy with his or her vision but with visual acuity worse than 20/20 has been described as a "20/happy" patient. With physical evaluation alone it may not be possible to diagnose such "happiness," but subjective tests such as a quality of life questionnaire may help identify it. This is critically important when highly irregular astigmatism or highly aberrant human optical systems are to be evaluated, e.g. intracorneal ring placement for treating keratoconic patients.

Contrast sensitivity testing is related to visual acuity testing. Contrast sensitivity tests the equivalent of four to eight differently sized Snellen letters in six or more shades of gray.

Definition and units

Contrast

Whereas a black letter on a white background is a scene of high contrast, a child crossing the road at dusk and a car looming up in a fog are scenes of low contrast. Thus contrast may be considered as the difference in the luminance of a target against the background:

$$\text{Contrast} = \frac{(\text{Target luminance} - \text{Background luminance})}{(\text{Target luminance} + \text{Background luminance})}$$

To compute contrast, one uses a photometer to measure the luminance of a target against the background. For example, a background of 100 units of light and a target of 50 units of light yields the following:

$$\text{Contrast} = \frac{(50 - 100)}{(50 + 100)} = \frac{50}{150} = 33\% \text{ percent}$$

Contrast sensitivity

Suppose the contrast of a scene is 33 percent, or one-third, which also represents the patient's threshold (i.e. the patient cannot identify targets of lower contrast). The patient's contrast sensitivity is the reciprocal of the fraction (i.e. 3). A young, healthy subject may have a contrast threshold of 1 percent, or 1/100 (i.e. a contrast sensitivity of 100). Occasionally, subjects have even better contrast thresholds. A subject could have a threshold of 0.003 (0.03 percent, or 1/1000), which converts into a contrast sensitivity of 3000. In the visual psychology literature, the contrast threshold is described in logarithmic terms. Therefore a contrast sensitivity of 10 is 1, a contrast sensitivity of 100 is 2, and a contrast sensitivity of 1000 is 3.

However, the video engineer describes contrast by using a gray scale that may contain more than 100 different levels of gray. A newspaper printer may use the term *halftones* in place of gray scale and may need more than 100 different half tones (densities of black dots) to describe the contrast of a scene.

Targets

Both the visual scientist and the optical engineer use a series of alternating black and white bars as targets. The optical engineer describes the fineness of a target by the number of line pairs per millimeter (a line pair is a dark bar and the white space next to it); the higher the number of line pairs per millimeter, the finer the target. For example, about 100 line pairs per millimeter is equivalent to a space of 1 minute between two black lines, which is almost equivalent to the spacing of the 20/20 (6/6) letter. In experimental testing, 109 line pairs per millimeter is equivalent to 20/15 (6/4.5).

The vision scientist describes the alternating bar pattern in terms of spatial frequency; the units are cycles per degree (cpd). A cycle is a black bar and a white space. To convert Snellen units into cycles per degree, one must divide the Snellen denominator into 600, or 180 if meters are used, for example, 20/20 (6/6) converts to 30 cpd (600/20, or 180/6), and 20/200 (6/60) converts into 3 cpd (600/200, or 180/60).

Sine waves

So far, targets have been described as dark bars of different spatial frequency against a white background. These are also

known as *square waves* or *Foucault gratings*. However, in optics, few images can be described as perfect square waves with perfectly sharp edges. Diffraction tends to make most edges slightly fuzzy, as do spherical aberration and oblique astigmatism. If the light intensity is plotted across a black bar with fuzzy edges against a light background, a sine wave pattern results. Sine wave patterns have great appeal because they can be considered the essential element from which any pattern can be constructed. The mathematician can break down any alternating pattern (be it an electrocardiogram or a trumpet's sound wave) into a unique sum of sine waves, known as a *Fourier transformation*. Joseph Fourier, a French mathematician, initially developed this waveform language to describe heat waves. Fourier's theorem states that a wave may be written as a sum of sine waves that have various spatial frequencies, amplitudes, and phases.

It also is thought that the visual system of the brain may operate by breaking down observed patterns and scenes into sine waves of different frequencies. The brain then adds them again to produce the mental impression of a complete picture. Fourier transformations may be the method the visual system uses to encode and record retinal images. In fact, it has been shown that different cells or "channels" occur in the retina, lateral geniculate body, and cortex and selectively carry different spatial frequencies. So far, six to eight channels have been identified. It also has been shown that all channels respond to contrast. Interestingly, the cortex shows a linear relationship between the amplitude of the neuronal discharge and the logarithm of the grating contrast.⁶⁰ As a result of the preceding reasoning, most contrast sensitivity tests are based on sine wave patterns rather than square wave patterns of different frequency.

Recording contrast sensitivity

Figure 1.9 shows a number of functions, including the contrast sensitivity testing function for a normal subject. The

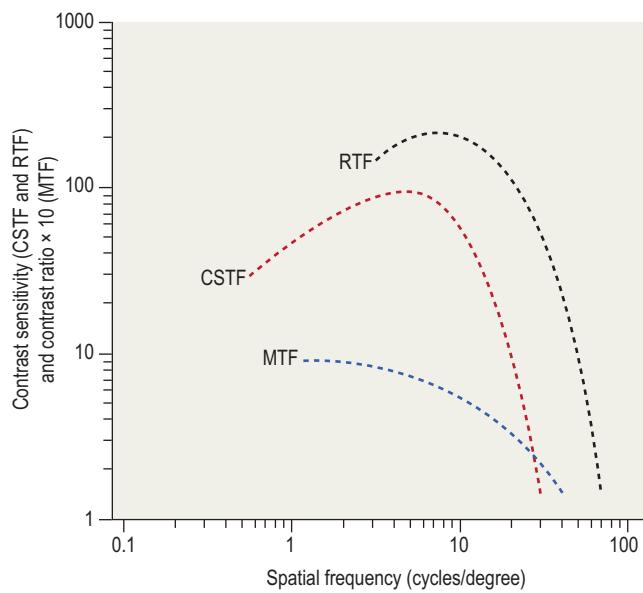

Figure 1.9 The normal human contrast sensitivity function (CSTF) is the sum of the contrast sensitivity of the purely optical contribution (MTF), and the neuroretinal enhancement system (RTF). (Modified from Mainster M. Surv Ophthalmol 1978; 23:135.)

shape of the human contrast function is different from that of almost all good optical systems, which have a high contrast sensitivity for low spatial frequency. The contrast sensitivity gradually diminishes at the higher spatial frequencies, as diffraction and other aberrations make discrimination of finer details more difficult. The contrast sensitivity function for the purely optical portion of the visual system (cornea and lens) is the modulation transfer function. The human contrast sensitivity function is different from the sum of its components because the retina–brain processing system is programmed to enhance the spatial frequencies in the range 2–6 Hz. Receptor fields, on/off systems, and lateral inhibition are the well-known physiologic mechanisms that influence the different spatial frequency channels and are responsible for such enhancement.

In Figure 1.9, the wave labeled “retinal testing function” represents the retinal neural system performance.^{60–62} Normal variations are found in the contrast sensitivity function. For example, contrast sensitivity decreases with age. Two factors appear to be responsible. First, the normal crystalline lens scatters more light with increasing age, which thus blurs the edges of targets and degrades the contrast. Second, the retina–brain processing system itself loses some ability to enhance contrast with increasing age.

The contrast sensitivity also decreases as the illumination decreases. Thus contrast sensitivity for a spatial frequency of 3 cpd drops from 300 to 150 to 10 as the retinal luminance drops from 9 to 0.09 to 0.0009 trolands. (The *troland* is a psychophysical unit; 1 troland is the retinal luminance produced by the image of an object, the luminance of which is 1 lux, for an area of the entrance pupil of 1 mm².)

The contrast sensitivity function also is an accurate method by which to follow certain disease states. For example, the contrast sensitivity of a patient who has a cataract is diminished, as it is in another light-scattering lesion, corneal edema. Because the contrast sensitivity function depends on central nervous system processing, it is not surprising that conditions such as optic neuritis and pituitary

tumors also characteristically have diminished contrast sensitivity functions.

Glare, tissue light scattering, and contrast sensitivity

When a transparent structure loses its clarity, the physicist describes it as a light *scatterer* rather than a light *transmitter*. This concept is foreign to the clinician whose textbooks talk about opaque lenses and corneas. The word *opaqueness* conjures up the image of a cement wall that stops light. Of all the experiments demonstrating that most cataracts scatter light rather than stop light, the most graphic involves the science of holography. If it is true that a cataract splashes or scatters oncoming light, resulting in a poor image focused on the retina, it should theoretically be possible to collect all the scattered light with a special optical element and recreate a sharp image. The essence of such an optical element, one that would take the scattered light of the cataract and rescatter it so that a proper image could be formed, would be a special inverse hologram of the cataract itself. Figure 1.10 shows how such a filter would work. Miller et al⁶³ were able to demonstrate how an extracted cataract (the patient’s visual acuity was worse than 20/200) would be made relatively transparent by registering a special inverse hologram of that specific cataract in front of the cataract.

To follow the progress of conditions such as cataracts or corneal edema, a measure of tissue transparency or tissue backscattering is useful. Although photoelectric devices can be used to quantitate the amount of light scattered by various ocular tissues, a subjective discrimination system is needed to evaluate patient complaints. The Snellen visual acuity test was the traditional index, but it is not sensitive enough. Figure 1.11 shows a scene in a fog taken with a digital camera where the closer objects are sharp (good acuity through less cloudy media) and the more distant objects have poor contrast and resolution, as seen through a very cloudy media (i.e. cataract).

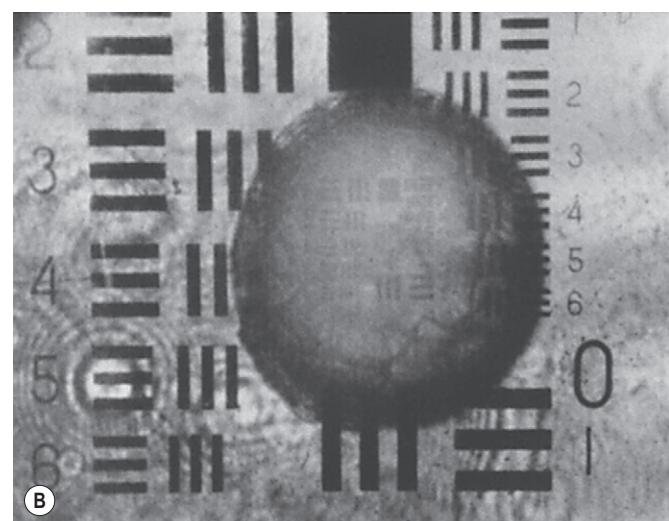

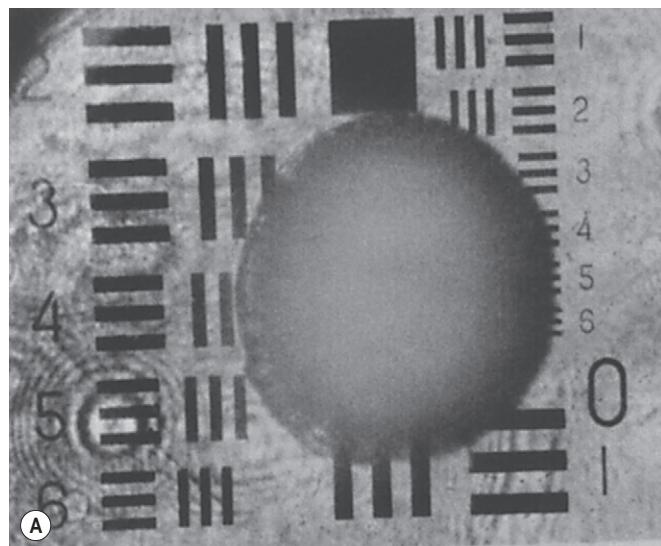

Figure 1.10 Note how the addition of the inverse conjugate hologram in registration with the cataract allows you to see the resolution chart. (From Miller D, Benedek G. Intraocular light scattering, Springfield, Ill: Charles C Thomas, 1973.)

Figure 1.11 A scene in a fog taken with a digital camera where the closer objects are sharp (good acuity through less cloudy media) and the more distant objects have poor contrast and resolution, as seen through a very cloudy media (i.e. cataract).

LeClaire et al⁶⁴ observed that many patients with cataracts showed good visual acuity but had poor contrast sensitivity in the face of a glare source. In fact, this should not come as a surprise because the essence of vision is the discrimination of the light intensity of one object as opposed to another, often with a natural glare source present. Thus a plane is seen against the sky because the retinal image of the plane does not stimulate the photoreceptors to the same degree that the sky does. Terms such as *contrast luminance* and *intensity discrimination* are used to describe differences in brightness between an object and its background.

How then can ocular light scattering, glare, and contrast sensitivity be linked together to give the clinician a useful index? An industrialist scientist named Holliday set the stage to solve this puzzle.⁶⁵ In 1926, Holliday developed the concept of glare and glare testing to measure the degrading effect of stray light. In the 1960s, Wolfe, a visual physiologist working in Boston, realized that glare testing could be a useful way to describe the increase in light scattering seen in different clinical conditions.^{66,67} How does increased light scattering produce a decrease in the contrast of the retinal image in the presence of a glare source? **Figure 1.12** shows how corneal edema splashes light from a naked light bulb onto the foveal image, reducing the contrast of the image of the target. **Figure 1.13** illustrates the way a patient with a cataract or corneal edema would see a scene in the presence

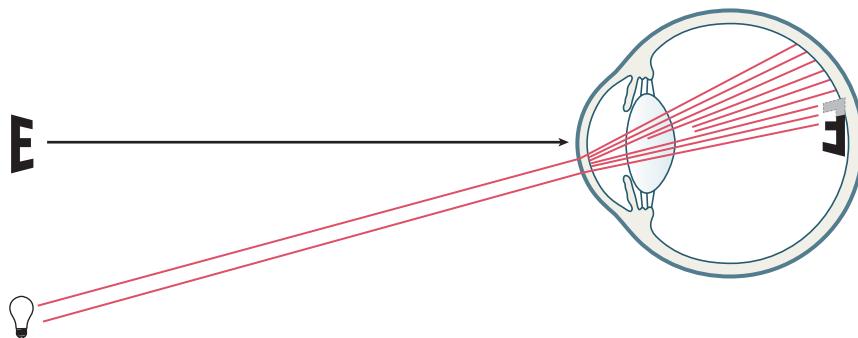

Figure 1.12 Corneal edema scatters the light from the peripheral light source onto the fovea, decreasing the contrast of the foveal image. (From Miller D, Benedek G. Intraocular light scattering, Springfield, Ill: Charles C Thomas, 1973.)

Figure 1.13 Photograph of the way the scene would appear to a normal patient (**A**) and a patient with corneal edema (**B**) in the face of glare. (From Miller D, Benedek G. Intraocular light scattering, Springfield, Ill: Charles C Thomas, 1973.)

of a glare source. In the mid-1970s, Nadler observed that many of his cataract patients complained of annoying glare. His observations rekindled interest in glare testing and led to the first clinical glare tester – the Miller–Nadler glare tester.⁶³

Clinical conditions affecting glare and contrast sensitivity

Optical conditions

This section describes how contact lenses, cataracts, opacified posterior capsules, displaced intraocular lenses (IOLs), and multifocal IOLs affect glare sensitivity and contrast. With the exception of IOLs, these conditions primarily diminish contrast sensitivity because of increased light scattering.

Corneal conditions

Corneal edema

Studies tracing the progression of corneal decompensation have shown that the stroma increases in thickness before the epithelium changes.⁶⁸ The stroma may increase in thickness by up to 30 percent before the epithelium becomes edematous. Studies have shown that an increase in stromal thickness above 30 percent need not influence Snellen visual acuity results if there is no epithelial edema.⁶⁹ Unlike Snellen visual acuity, both contrast sensitivity and glare sensitivity are compromised as soon as the stroma thickens. Mild edema affects only the middle and high frequencies of a contrast sensitivity test, sparing the low frequencies. With further edema, the sparing of the low frequencies disappears and contrast sensitivity is decreased throughout the spatial frequency spectrum.⁶³ Glare sensitivity measurements also detect early epithelial edema. A mildly edematous epithelium is roughly equivalent to an increase of 10 percent in stromal thickness, whereas moderate to significant epithelial edema has a profound effect on glare and contrast sensitivity.

Contact lens wear

The wearing of contact lenses may reduce contrast sensitivity in a number of subtle ways. Patients with significant corneal astigmatism who wear thin soft contact lenses experience blur that affects their contrast sensitivity. Aging of the plastic material itself or surface-deposit accumulations can affect soft lens hydration and ultimately influence acuity, glare, and contrast sensitivity. Most important, contact-lens-induced epithelial edema produces increased glare disability and reduced contrast sensitivity.⁶³

Keratoconus

Patients with keratoconus demonstrate attenuation of contrast sensitivity with relative sparing of low spatial frequencies despite normal Snellen visual acuity. However, once scarring develops in the keratoconic cornea, all frequencies become attenuated. In addition, glare sensitivity acutely increases as soon as scarring develops. Thus contrast sensitivity testing at a number of spatial frequencies, with or without a glare source, may be an excellent way of following the progression of keratoconus.⁶³

Nephrotic cystinosis

In a study of patients with infantile-onset cystinosis, contrast sensitivities were reduced at all frequencies, although the loss at high frequencies was the greatest. Of 12

subjects, 10 showed glare disability, compared with a control population.⁷⁰

Penetrating keratoplasty

Contrast sensitivity or glare testing may also be useful in detecting the earliest signs of graft rejection. In such cases, the earliest corneal damage is corneal edema. Although visual acuity may remain normal, contrast and glare performance start to slip. As the edema progresses to involve the epithelium, the degradation of these visual functions is accentuated. Similarly, reversal of graft rejection may be followed by an improvement in the contrast sensitivity function.⁶³

Refractive surgery

Some patients who have undergone radial keratotomy or photorefractive keratoplasty with postoperative corneal haze have been reported to experience increased glare sensitivity.^{71,72} The extent of the problem and the number of patients complaining of heightened glare sensitivity varies from study to study and depends on the time elapsed since the surgery and the method by which the glare was assessed. Modern refractive surgery approaches the haze problem decreasing the healing process intensity either by the use of LASIK (using mechanical or laser microkeratome) or mitomicin-C and PRK. Both techniques are effective and have their own indications. Glare due to haze is nowadays less frequent than glare due to postoperative spherical aberration.

Harper & Halliday⁷³ reported on four unilaterally aphakic patients and found significant contrast sensitivity losses in the eyes with epikeratoplasty when compared with the normal fellow eye.

Cataracts and opacified posterior capsules

Figure 1.12 demonstrates the way that an edematous cornea or cataract scatters stray light onto the fovea and degrades contrast sensitivity, thereby heightening glare disability. Thus measurements of contrast sensitivity are usually better correlated with patient complaints than with a visual acuity measurement. The addition of a glare source to a contrast sensitivity test causes a dramatic decrease in the contrast function. Of the various cataract types, the posterior subcapsular cataract degrades the glare and contrast function the most. It should be noted that the presence of a glare light diminishes both visual acuity and contrast sensitivity in cataract patients. In the presence of a glare light, the contrast sensitivity function gradually diminishes as a simulated cataract increases in severity, whereas the visual acuity function holds steady until an 80 percent simulated cataract produces a dramatic drop in visual acuity.

Progressive opacification of the posterior capsule after an extracapsular cataract extraction produces a progressive increase in glare disability.⁷⁴ A neodymium:yttrium-aluminum-garnet (Nd:YAG) laser capsulotomy in such cases improves the visual function. The improvement of contrast and glare sensitivity after Nd:YAG laser treatment depends on the ratio of the area of the clear opening to the area of the remaining opaque capsule. Thus a photopic pupil of 4 mm would require a 4-mm capsulotomy for best results in daylight. However, if the pupil dilates to 6 mm at night, an oncoming headlight would induce an annoying glare unless the capsulotomy were enlarged to 6 mm in diameter. Thus the smallest capsulotomy is not necessarily the best from an optical point of view.

Modulation transfer function

Optical engineers generally evaluate optical systems by means of a system similar to contrast sensitivity, called the *modulation transfer function* (MTF). The MTF is the ratio of image-to-object contrast as a function of spatial frequency, where the object is either a bar graph or a sinusoidal grating. It gives more information than the parameter of resolving power. For example, two systems may have the same resolving power, but one might be unable to form useful images of low-contrast objects, which the other could readily form. A smaller pupillary aperture introduces diffraction interference, which makes it difficult to resolve fine detail (higher spatial frequencies). Thus the spatial frequency cutoff occurs sooner with the small aperture system. In an MTF plot, the vertical axis is akin to contrast sensitivity (see Figure 1.9). Because it represents the ratio of contrast of image against contrast of object, its values decrease from 1.0 to 0. The MTF is conceptually similar to the manner in which electronic engineers evaluate an amplifier. The performance of an amplifier is described by the output/input ratio, or the gain, for different sound frequencies. The MTF concept also may be useful in the comparison of the performance of the eye with that of optical and electronic instruments. Campbell & Green⁷⁵ plotted the MTF of the human eye for various pupillary diameters and found that a smaller pupil system has a better contrast ratio than a larger pupil system. This probably reflects the opposing factors of a somewhat better performance with greater illumination and the degrading effect of spherical aberration with a larger pupil. As noted earlier, a pupil size in the range 2.0–2.8 mm gives the maximum MTF for high spatial frequencies.

Depth of focus

How can an insect or a small animal like a rat see objects clearly from 10 m to 10 cm without an accommodating mechanism? How does a pinhole allow a patient with presbyopia to read the newspaper without a reading correction? The answer is that both situations rely on an optical system with an increased depth of focus.

Recall that an image can be thought of as being made up of an array of points. Thus the finite size of the pixels, the photographic grains, or the photoreceptor clusters ultimately determine the fineness of details of the recorded image. This means that a blur of a focused point is tolerated if it is no

bigger than the size of the receptor. Because a point of light is focused as an Airy disc, a cluster or two to five cones is considered the "limiting grain size." Let us review two important definitions:

Depth of focus: *the amount of blur in diopters or millimeters from the retina that will be tolerated or go unnoticed*

Depth of field: *the distance range, in object space, that an object can move toward or away from a fixed focus optical system and still be considered in focus*

Figure 1.14 is a schematic of the eye. For simplicity, we used a reduced eye, with a biconvex lens representing the cornea and lens. Let:

- () = the object that can move from infinity to a near point N
- ρ = pupillary diameter
- f = focal length of the model eye
- x = distance from the retina that near point remains in focus
- c = limiting photoreceptor cluster size (i.e. limiting grain size or pixel size)
- N = refractive index of the model eye
- $D_1 = n/f$ (i.e. dioptric power of eye when viewing a finite object)
- $D_2 = n/(f+x)$ (i.e. dioptric power of eye when viewing near object at N)

(In this case, the eye can be considered to have lengthened (theoretically) by a distance x .)

Depth of focus is as follows:

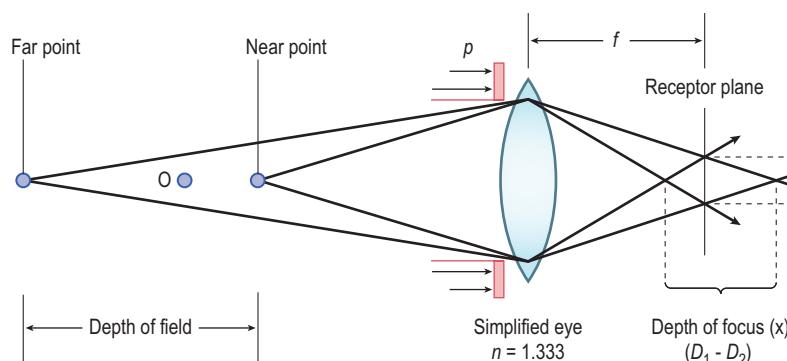

$$D_1 - D_2 = \frac{n}{f} - \frac{n}{f+x} = nx(f+x) - nf/f(f+x) = nx/f(f+x)$$

(but by similar triangles). Thus

$$D_1 - D_2 = nc/f\rho$$

This equation tells us that the depth of focus in diopters ($D_1 - D_2$) is proportional to the index of refraction (n) and the limiting photoreceptor of grain size c . The depth of focus is also inversely proportional to the pupil size (ρ) or the focal length of the system (f).

For example, determine the depth of focus for a reduced human eye under the following conditions. Let:

$$D_1 = \frac{n}{f}$$

$$D_2 = \frac{n}{f+x}$$

$$D_1 - D_2 = \frac{n}{f} - \frac{n}{f+x}$$

$$D_1 - D_2 = \frac{nc}{fp}$$

Figure 1.14 A schematic representation of a single refracting surface model eye where ρ = pupillary diameter, f = focal length distance from the retina where image of near object falls, c = limiting photoreceptor cluster size (i.e. similar to grain or pixel size), n = refractive index, $D_1 = n/f$ dioptric power of eye when viewing infinite object, $D_2 = n/(f+x)$ (i.e. dioptric power of an eye when viewing near object). Thus depth of focus = $D_1 - D_2 = n/f - n/(f+x)$. Ultimately, we find $D_1 - D_2 = nc/f\rho$.

- Pupil (ρ) = 3 mm, or 0.003 m
- Focal length (f) = 22.2 mm, or 0.0222 m
- Limiting cone cluster (c) = 5 cones (Assume each cone is 1.5 μm in diameter and spacing between cones is 0.5 μm . The total cluster of 5 cones + 4 spaces = 9.5 μm , or 0.0000095 m.)
- Index of refraction (n) = 1.333

$$\text{Depth of focus } (D_1 - D_2) = 1.33 \times 0.0000095 / 0.0222 \times 0.003 \\ = 0.189$$

Our calculation of 0.189 for the reduced (hypothetical) eye with a pupil of 3 mm is about half of the 0.40 diopter (Fig. 1.15A), which is the average value from four (real) human studies.^{75–78} Thus we may conclude that the normal eye has a modest depth of focus.

Interestingly, Figure 1.15B represents a study in which artificial pupils (placed in front of the cornea) between 1 and 2 mm were used. Within this range of apertures, a depth of focus between 2 and 4 diopters was obtained.³¹

Do we ever see the equivalent of pupillary apertures of between 1 and 2 mm in human patients? Yes, we do in cases of trauma, disease, or use of strong miotics. Figure 1.16 demonstrates four examples of 1- to 2-mm clear areas within a corneal opacity. Actually, the patient shown in the upper left had an acuity of 20/20. Figure 1.17 shows four examples of 1- to 2-mm clear areas within traumatic cataracts or 1- to 2-mm spaces between traumatic cataracts and iris tears. In Figure 1.18, we can see the equivalent of a reduced pupillary aperture produced by a ptosis or a conscious reduction of the palpebral fissure as a result of squinting. It is comforting to know that in cases of trauma, disease, or significant refractive error, the human eye can call on a 2- to 3-diopter depth of focus mechanism.

The clinical diagnosis of "corneal visual acuity" has been proposed, e.g. the "Holladay Diagnostic Summary," first presented in the EyeSys corneal topography system. It predicts decreased visual acuity areas of the cornea that have irregular surfaces, assuming that there is a transparent media behind the corneal epithelium.

Optical aberrations

The famous nineteenth century German physiologist Herman von Helmholtz, in Volume 1 of his *Treatise on Physiologic Optics*,⁷⁹ wrote that the optical aberrations of the human eye are "of a kind that is not permissible in well constructed instruments." The implication is that the optical design of the human eye would receive low marks if evaluated by someone from the optical industry. If we are to simply compare the optical quality of the living human eye with that of our best cameras and telescopes under ordinary static daylight conditions, then Helmholtz was correct. The optical imperfections noted by Helmholtz are discussed in the following sections.

Light scattering

Fingerprints on spectacle lenses scatter light, making small letters difficult to read. Raindrops or windshield wiper smears on the car windshield make the reading of street signs difficult. In a similar way, small bubbles from the warm water tap give a haze to a glass of water and make it difficult to see the details at the bottom of the glass. These are all

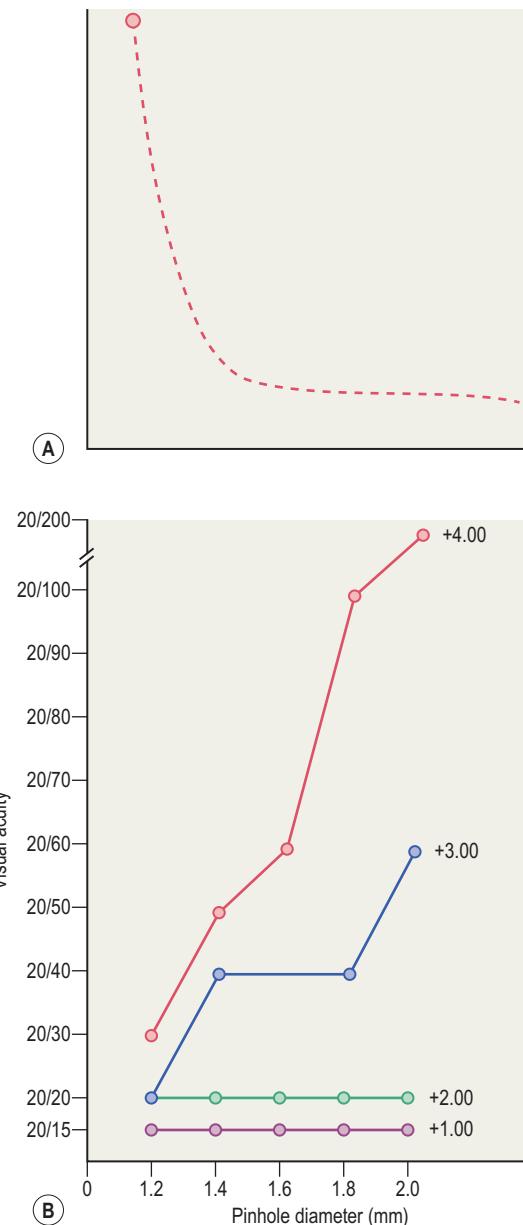

Figure 1.15 (A) An averaged depth of focus versus pupil size function representing four different studies.^{24,62,80,81} (B) Plot of visual acuity versus pinhole diameters (between 1 and 2 mm) using different blurring lenses (i.e. +1 diopter, +2 diopters, +3 diopters, and +4 diopters). Thus, for example, the subject could achieve a visual acuity of 20/40 through a 1.8-mm pinhole, but vision would be blurred by a 3-diopter lens. (Modified from Miller D. Optics and refraction: a user friendly guide. St Louis: Gower Medical, 1991.)

examples of light scattering, which can obscure the details of any object.

As noted earlier, the cornea is clear, but technically speaking, it is not perfectly transparent. Its composition of fine collagen fibers, loaded into a watery matrix of glycosaminoglycans and populated by fine cells that swim in the matrix, scatter a small percentage (10 percent of incident light) and create a slight haze. This is unquestionably a flaw, as opposed to the glass optical systems of cameras and telescopes. However, the "imperfect" corneal structure allows for healing. Thus we can appreciate that a

Holladay diagnostic summary maps (Holladay JT. J Cataract Refract Surg 1997; 23(2):209–21). The patient's refractive error was a -4.00 D, prior to a Lasik treatment 4 months earlier. Presently, the visual acuity is 20/15 in daylight (3mm pupil) and 20/25 in dim light (5 mm pupil). The upper maps include refractive power maps on standard and auto scales. The bottom left shows a profile difference map which demonstrates the patient's corneal shape compared to 'normal' cornea. The bottom right represents a distortion map which displays the optical quality of the cornea. Note that the 20/16 central (3 mm pupil) visual acuity predicted by the distortion map was achieved by the patient.

Box 1.3

The picture represents the cornea of a 51-year-old female patient who had an Acufocus Presbyopic inlay implanted 45 days earlier. Unaided near visual acuity changed from J9 to J2 after surgery. Distance vision changed from 20/20 to 20/25. (Courtesy of the Refractive Surgery Section – Department of Ophthalmology – Paulista School of Medicine, Sao Paulo, Brazil.)

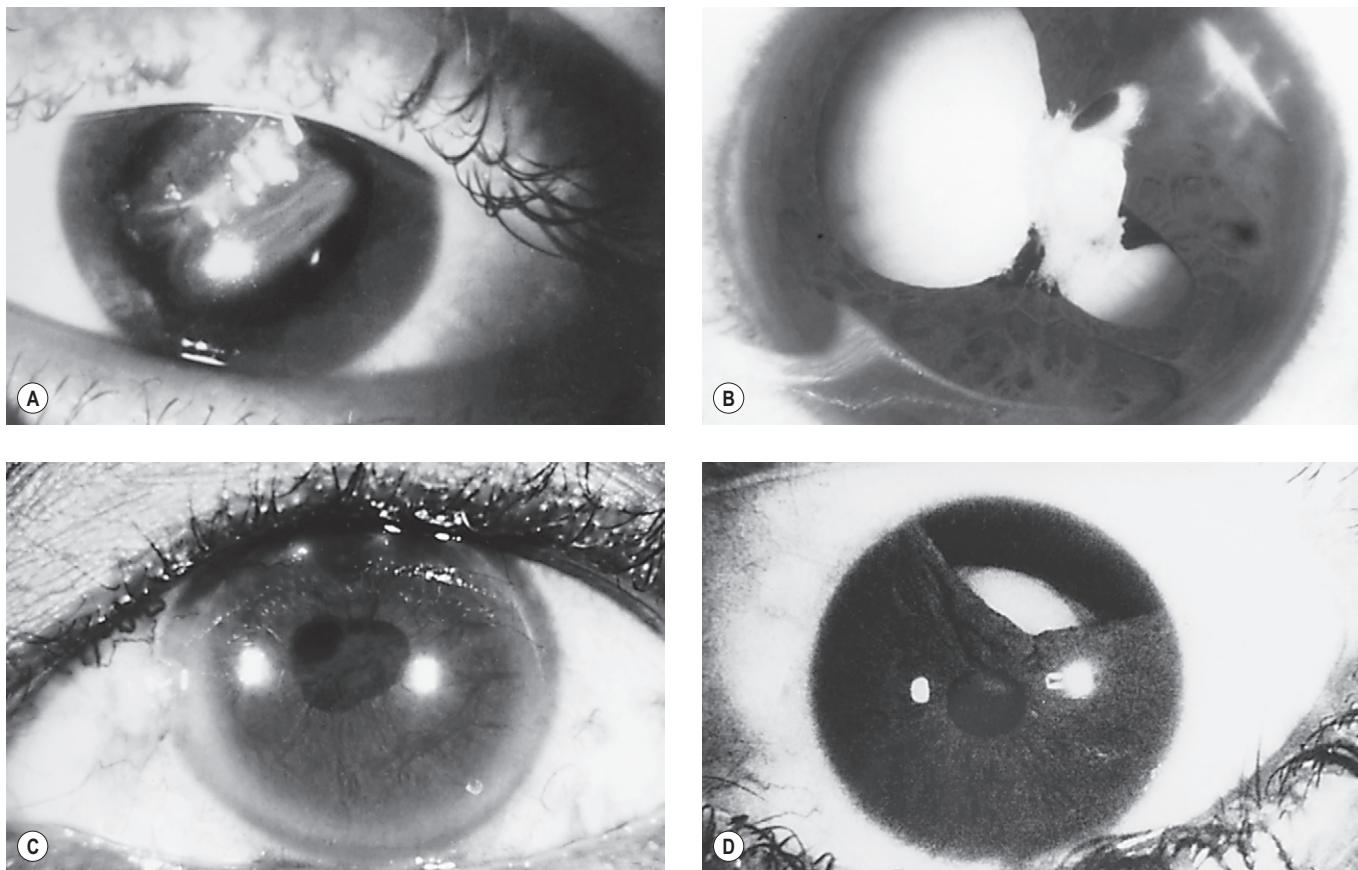

Figure 1.17 Four examples of 1- to 2-mm clear area within traumatic cataracts or 1- to 2-mm spaces between traumatic cataracts and iris tears.

Figure 1.18 The equivalent of a reduced aperture produced by a ptosis.

10 percent level of light scatter is a fair price to pay for a self-healing system.

The lens of the eye is made up of tens of thousands of fine fibers (each a bag of clear protein solution) packed closely together. The living lens continually adds outside fibers and packs old cells in its nucleus throughout life, ultimately increasing its volume by a factor of 3 in the older eye. The refractive index of the fibers differs from that of the

thin spaces between the fibers. Thus the young lens scatters about 20 percent of the incident light. Is there a practical advantage to the fiber structure of the lens? There are many ways that the lens may be injured, including inflammation from diseases inside the eye, blunt blows from fists or rocks, periods of malnutrition, poisoning, and osmotic upset from systemic disease. In all of these situations, the part of the lens being laid down at the time of the injury or disease loses transparency. This hazy section may also be lumpy in thickness. However, in a short time, new transparent layers cover and compress the hazy ones, smoothing and reducing the blurring effect of the injury. Again, we now understand that a small level of light scattering resulting from this fiber layering system is a fair price to pay for a self-repairing lens system.

Natural defenses against light scattering

The reader may have been led astray in thinking that the eye has no defense against normal light scattering. In fact, it does. For example, the birefringent capacity of the collagen fibers in the cornea, in combination with the birefringence of the fovea, may cancel out some annoying glare caused by light scattering through a process known as *destructive interference*, somewhat akin to the way polarizing sunglasses cancel annoying glare.

The retina has three defenses against the image-degrading effects of scattered light. To appreciate one of the defenses, one first must recognize that not all colors (wavelengths) are

scattered equally. The fine components of eye tissue scatter blue light 16 times more than red light. This light produces lipofuscin-induced cell toxicity in *in vitro* experiments. It has also been proposed as a pathological mechanism for cataract formation and retinal damage.⁸² Yellow filter spectacles reduce chromatic aberration and sharpen the retinal image by reducing the number of wavelengths striking the retina. However, a yellow filter makes the sky look gray rather than blue. This effect, although unnatural, enhances the contrast of objects seen against the sky. There is presently insufficient evidence to prove or disprove the claim that a yellow IOL will prevent or slow down macular degeneration.

Therefore a defense that can reduce blue scattered light would be disproportionately helpful. Sprinkled throughout the ultrasensitive fovea and its immediate surround is yellow pigment. The yellow pigment is efficient at absorbing the scattered blue light, thus preventing much of it from degrading the retinal image.³¹

The second defense used by the retina involves the positioning of the rods and cones. Each rod or cone functions as a light guide. To enter the guide, light must enter at a specific angle. Interestingly, normally focused light enters a photoreceptor at a different angle than does scattered light.⁸³ The photoreceptors of the retina are directed so that they primarily receive focused light, but not scattered light (Fig. 1.19). Stiles and Crawford established the fact that the human visual system has reduced sensitivity to light rays that enter near the edge of the pupil compared to those entering centrally. This effect, referred to as the psychophysical Stiles-Crawford effect, is the result of the orientation of photoreceptors, which preferentially guide the central rays to the retina more efficiently than the peripheral rays.⁸⁴

The dark brown pigment of the retinal pigment epithelium and the choroid absorbs any stray light that has passed through the retina and prevents such light from backscatter, which would reverberate among the neighboring photoreceptors. None of these defenses is perfect, but all work to reduce the annoyance of scattered light.

The brow and eyelid may also be thought of as blocking annoying glare sources such as the overhead sun. Interestingly, the Asian lid has a double fold and serves as a more effective thicker visor than the Caucasian lid, thereby more effectively blocking the glaring effect of the sun overhead.

Chromatic aberrations

A rainbow is produced by millions of tiny round droplets of water vapor that hover over the earth during or after a rain. Each water droplet functions as a tiny, powerful round lens. Such a powerful lens bends each wavelength of color differently. A rainbow is caused by the chromatic aberration of the water droplets. Thus, like Newton's prism, the tiny droplets break up white light into the colors of the rainbow. The phenomenon of strong lenses producing colored fringes around a focused image is known as *chromatic aberration*.^{85,86} The optical components of the eye (cornea and lens), like the fine water droplets, also produce chromatic aberration. The total chromatic aberration of the photopic human eye is about 3 diopters. However, we do not see colored fringes around objects because significant colored fringes of red and blue are less likely to be seen as a result of the cones' relative insensitivity to the colors at the ends of the spectrum. Also,

the visual processing in the retina and brain can sharpen the edges of the retinal image and "erase" the colored blur. Although we rarely consciously sense the chromatic aberration of the eye, some researchers believe that the retina may make use of the faint colored fringes around images to help accommodation reach a precise end point.^{36,87}

Spherical aberration

A major distortion produced by many high-powered optical systems such as the cornea or lens is called *spherical aberration*. Figure 1.19 shows the results of this aberration. The rays at the edge of the lens are bent more than those going through the center of the lens, creating a smeared focus. The cornea (a strong optical element) is subject to spherical aberration. Figure 1.20 shows that the cornea sits at the front of the eye like a small, strongly curved dome. The steeper the dome (the shorter its radius of curvature), the more spherical aberration created. We have known since the time of the French mathematician Descartes that spherical aberration can be controlled by flattening the curvature of the edge of a lens, thereby weakening the focusing power of the lens periphery. Descartes described such a surface as *aspheric*. Most cameras today use lenses with aspheric surfaces.

The average cornea is also somewhat aspheric. It becomes slightly flatter at its periphery, allowing it to more smoothly merge with the sclera. However, there are some real-world considerations that make it advantageous to keep the cornea steeply curved. In the event of a direct blow to the eye by a blunt object, presumably the steep protruding cornea can

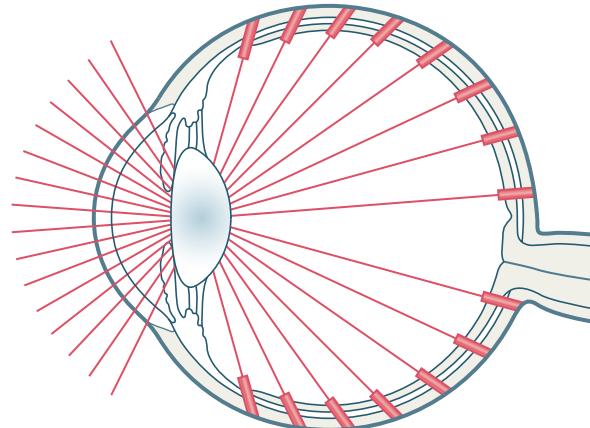

Figure 1.19 The orientation of the retinal photoreceptors in the normal human eye. Note that they are directed to the second nodal point of the eye.

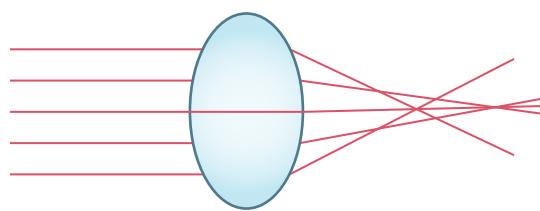

Figure 1.20 An illustration of the smearing of sharp focus created by spherical aberration. Note that the peripheral rays are bent more than the paraxial rays of light.

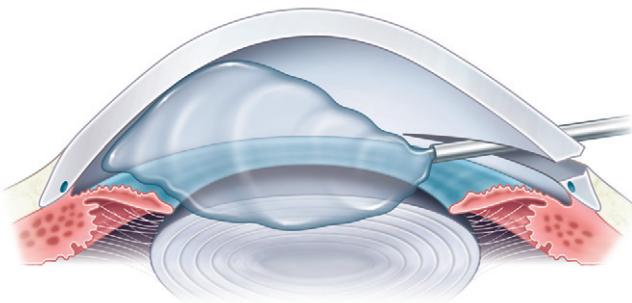

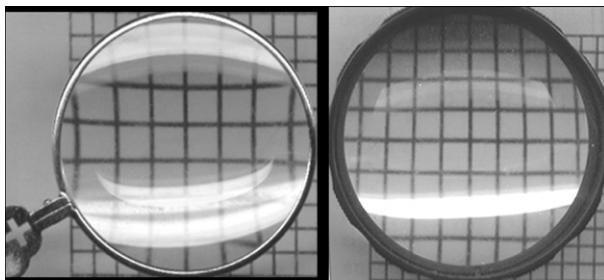

Figure 1.21 Three-dimensional drawing of the cornea sitting atop the eye as a small dome, vaulting over the internal structures. The viscoelastic material injected into the anterior chamber should remind the reader that the vitreous humor (similar properties) serves as a second damping element in the event of blunt trauma.

Box 1.4

A practical example is the comparison between the optical properties of the +20D trial frame lens and the aspheric indirect binocular ophthalmoscope (IBO) +20D lens. Both lenses focus light coming from infinity to a focal point of 5 centimeters behind the lens. However, when analyzing the quality of the entire image, one can observe a deformity in the periphery of the image formed by the trial frame lens, which is not present with the aspheric lens. The higher the power of a lens, the more the distortion produced by spherical aberration. The figure on the right demonstrates the spherical aberration (i.e. peripheral distortion) produced by a typical +20D spectacle lens. The figure on the left demonstrates the reduced spherical aberration produced by an aspheric +20D indirect ophthalmoscopy lens.

absorb the blow, much like a spring. The steeper the cornea, the more it vaults over the rest of the eye and the greater the spring effect (Fig. 1.21). Such a spring-dampening effect protects the deeper eye structures. How then does the eye satisfy both needs? In daylight, with the pupil being constricted, the iris tissue essentially blocks many of the light rays coming through the corneal periphery and effectively cancels most of the spherical aberration. Thus spherical aberration from the cornea has an important degrading effect only when illumination is dim and the pupil is large. Night myopia can develop in these situations and is more of a problem when the corneal asphericity is greater. Such greater asphericity is often found after corneal refractive surgery.

Happily, in dim light, the human eye switches to the rod retinal system in which seeing fine details takes a lower priority than simply seeing large shapes.

The crystalline lens is also a powerful optical element and therefore is also vulnerable to spherical aberration. Although

an aspheric surface corrects the aberration in cameras and telescopes, nature has chosen a different approach for the crystalline lens. Recall that refraction, or the bending of light, can be controlled by either the curvature of the lens surface or the index of refraction of the composition of the lens. The high index of refraction of the crystalline lens is the result of a high concentration of protein. The lens has a lower refractive index near its edge than at its center. Therefore the lens periphery has a weaker focusing action and self-corrects spherical aberration, much as an aspheric surface.²⁹

However, even with the aforementioned correction factors, the total spherical aberration of the human eye varies from 0.25 to 2.00 diopters. The corneal shape is the most important factor in the induction of spherical aberration.⁸⁸

Abolition of spherical aberration not only sharpens focus but can be thought of as concentrating the light at the focus. Concentrating light energy at a focus makes it easier to see a dimly lit object. Therefore cameras, or creatures with an optical system of minimal spherical aberration, function well in low illumination.

Some intraocular lenses are aspheric. However, the degree of IOL asphericity must compensate for the patient's individual corneal asphericity in order to yield the sharpest retinal image of a distant object. On the other hand, the presence of some spherical aberration may blur a distant object but allow an object at an intermediate distance (1–2 meters) to be in focus. As yet, there is no IOL that produces completely sharp images for both distant and intermediate objects.

Light absorption

The lens of a typical 20-year-old absorbs about 30 percent of incident blue light. At age 60, the typical lens absorbs about 60 percent of incident blue light.⁸⁹ This increase in lens absorption of blue light results in both a decrease in subtle color discrimination and a decrease in chromatic aberration.

Summary – a compromise of eye function

The human eye (which is similar to the monkey eye) is a fairly good resolving optical instrument.^{20,90,91} Admittedly, the eyes of certain birds are even better optical instruments, reaching the outer limits of the constraints of the laws of physics. One must appreciate that the evolution of better and better optics had to be balanced against other useful functions, such as glare prevention, injury prevention, injury repair, and use of the eyes for non-verbal communication.

The aging eye

The components of human eyes usually last a lifetime. This was reinforced to me years ago when our eye team did a visual screening of residents in a housing project for older adults. On average, most residents were older than 80 years. The number of residents with 20/40 vision in at least one eye was more than 90 percent.⁹² This finding should not minimize the disability of people with cataracts (which affect 9.4 million people older than age 65 in the United States).⁹³ However, it is important to recognize that a high percentage of people live their entire lives with good vision

– thanks to a number of positive compensations that help the aging eye. For example, the human macula is particularly vulnerable to damage from ultraviolet and blue light. Fortunately, a yellow pigment effectively absorbs or scatters away most of these harmful wavelengths, thus diminishing the potential damage to the macula.⁹⁴

One of the more remarkable aspects of the aging eye is that the eye lens continually acquires new layers of fibers, becoming both progressively thicker and steeper. These changes would normally lead to an increase in lens focusing power and a tendency toward nearsightedness in older eyes. In fact, this does not happen universally because the index of refraction of the cortex of the lens decreases in a perfectly compensatory fashion,⁹⁵ so the lens power often stays constant.

Evolution of ocular components

Human eyes are fascinating examples of a potpourri of components seen all along the evolutionary trail. Indeed, human eyes contain components previously developed for other uses. For example, our retinal rhodopsin may have come from an ancient bacterium, which may have used the rhodopsin for photosynthesis. Our rounded corneal curvature originally comes from primitive fish. As noted earlier, when a person is under water, the corneal refractive power is canceled by the surrounding water. However, rounded shape helps decrease water resistance because the eye is then more streamlined. Finally, and most difficult to explain, many of the special crystalline proteins that have been identified in animal eye lenses are similar to metabolic enzymes found elsewhere in the body. For example, lactic dehydrogenase- β is similar to E-crystalline found in the lens; arginosuccinate lyase is similar to γ -crystalline found in the lens.⁹⁶ Non-lenticular enzymes have been adapted to also function as special lens proteins, a process known as *gene sharing*. The term *gene sharing* simply names the phenomenon without giving us an idea of which function came first or what evolutionary pressures forced the new use of the molecules. In summary, one might think of this entire process of nature as reaching into its dusty attic to find new uses for old creations as the ultimate in recycling efficiency.

Non-optical brain mechanisms that enhance the retinal image

There is a group of visual phenomena in which the retinal image is enhanced or made complete by the brain.⁹⁷ They represent ways of improving the retinal image in non-optical ways. One might think of these brain-processing effects as examples of methods of going beyond the limits of the laws of optics to bring out visual information.⁹⁸

Contrast enhancement

The visual brain has the ability to sharpen the contrast of elements in the retinal image. Figure 1.22 presents two faces with the same degree of grayness. In the right figure, the face is seen against a black background, whereas in the left figure, it is seen against a white background. The gray face on the black background looks lighter (enhancing its contrast), whereas the gray face looks darker on the white background. This effect is reduced when the edges of the faces are fuzzy.

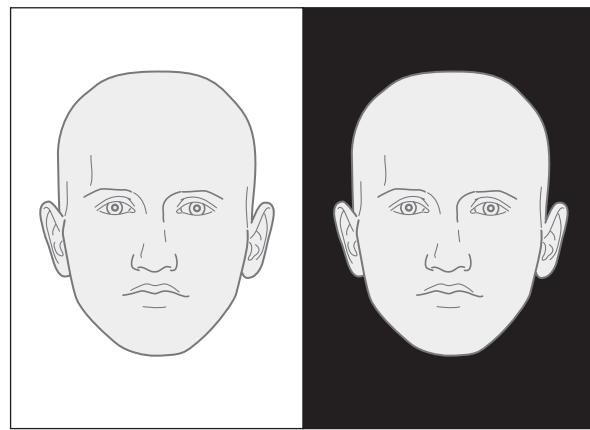

Figure 1.22 Right: Gray face is seen against a black background. Left: Same gray face is seen against a white background. A contrast enhancement function makes the gray face look lighter on the black and darker on the white side. (Illusion created by R. Miller, F. Miller, and D. Miller.)

One might speculate that a sharper edge on an object brings out a stronger contrast enhancement response.

Computer graphics professionals (the Joint Photographic Experts Group) have taken advantage of the knowledge of the physiology of human vision and released an image data compression format named after the group, i.e. JPEG. The JPEG compression process first separates the image into luminance and color signals. This step doesn't reduce the inherent quality of the image. The JPEG process then performs a variety of arithmetic procedures which separate out and remove small differences (in luminance and color) between adjacent pixels which would not be noticed by the human visual system. This process involves dividing the picture up into 8×8 -pixel blocks, and analyzing details contained in each block. The high-frequency (fine details) information is then discarded. Such a process eliminates a great deal of data. The final process results in a very high compression ratio (i.e. often a 95 percent reduction in file size). As expected, such a trade-off results in a loss of high-frequency information (i.e. sharp transitions become blurred). Fortunately, our visual system accepts the slightly reduced image contrast.⁹⁹

Edge sharpening

If an ametrope looks in the distance at a framed picture, the details within the picture will be fuzzy, yet the edges of the frame will be seen as a distinct boundary against the wall. The visual system places a priority on sharpening the edge of the retinal image, even though the details within remain hazy. One might suppose that in the case of the picture on the wall, recognizing the edges of the frame tells one that the fuzzy blob on the wall is a picture rather than a swarm of insects.

There is a second way that the brain processes the edge of a retinal image. If two objects of similar brightness are placed next to each other, they normally appear to merge into one object. However, if the connecting edge of one of these similar objects is slightly darker than the connecting edge of the other, the entire side with the darker edge appears darker than the lighter one. The greater contrast at the edge has spread across the whole panel.

Box 1.5

Figure A is an example of the “completing the picture” illusion. Because of our previous visual experience, we assume that the partially covered words represent “THE EYE.” Wrong!

(A) Because of our previous visual experience, we assume the line covered words will spell “THE EYE.” On removal of the cover, we see we were wrong. If there is a discontinuity in an object, we almost always assume that the object is partially covered. We simple create a full impression of the covered object in our mind. In Figure B, we are made to think that one geographic form covers the other, although the artist simply fitted the outline of one triangle next to the other.

(B) A group of triangles with some seeming to cover the others. In fact, the edges of the shapes simply abut each other. These illusions illustrate the ability of our visual processing system to fill in all sorts of blanks and incongruities within the retinal image to create a coherent story.

Suppose that the object of regard is not covered but that the observer has a brain lesion that has produced a small scotoma in the visual field. When such a patient is presented with a circle or square in which part of the figure resides inside the scotoma, after a brief period, the patient reports that the gap has filled in and the figure looks whole. The same phenomenon takes place if part of an image falls on the physiologic blind spot. It suggests that the visual system, faced with a gap in the information, hypothesizes (gambles) that the region surrounding the scotoma has the needed data and places that data within the scotoma to produce a complete scene.¹⁰⁰

This phenomenon, known as the Craik-Cornsweet-O’Brien illusion, is seen in Figure 1.23. If a pencil is placed between the two vertical rectangles (occluding the boundary), it becomes clear that they are actually the same brightness.

Vernier acuity

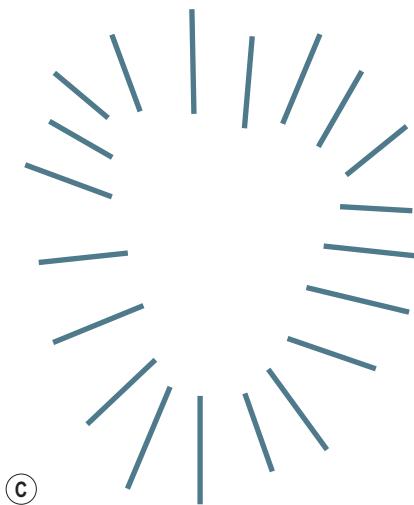

Earlier in this chapter, it was noted that a normal-sighted human being (with 20/20 visual acuity) can detect a separation between two objects as small as 1 minute of angular

There is another series of illusions known as *gap figures*.¹⁰¹ Figure C shows an example of a gap illusion. The defect (gap) is strongly highlighted by the radiating lines as a footprint might appear highlighted to a skilled guide.

(C) A gap figure (modified from an Ehrenstein illusion). Note that the radiating lines seem to create the outline of a foot. A related phenomenon is presented in Conan Doyle’s story *The Adventure of Silver Blaze*, in which Sherlock Holmes identifies the murderer when he concludes that the watchdog must have known the murderer because no barking was heard on the night of the murder. As in the gap figure, the gap in the expected pattern of the dog’s behavior takes on a heightened importance. Hearst appropriately called this phenomenon “getting something for nothing.”¹⁰²

Vision suppression is present in pediatric patients with strabismus in order to avoid diplopia. Vitreous floaters (mostly seen in bright environments) are another example of the nervous system suppressing annoying visual effects. The floaters are structures which have a different index of refraction than the surrounding vitreous and so can cast a shadow onto the retina. Floaters can be called a time domain phenomenon. They are often seen in post op refractive surgery patients, and usually disappear in 3 to 6 months.

Finally, mention should be made of a related temporal blocking of a visual scene, that is, our failure to notice the fleeting disappearance of an image during a blink, a twitch, a flicker, or a saccade.

subtense. Interestingly, it was said that Ted Williams, the great outfielder of the Boston Red Sox, had a visual acuity of 20/10 (could detect a half minute of angular separation). However, there is a visual task (Vernier acuity), which has a threshold of about 5 seconds of arc (1/12th of a minute of arc). Indeed, as seen in Fig. 1.24 most normal-sighted people can line up dots or notice a discrepancy in the alignment of dots or lines as small as 5 seconds of arc or less. We know that the brain is involved in the processing because the experiment can be redesigned so that one eye is

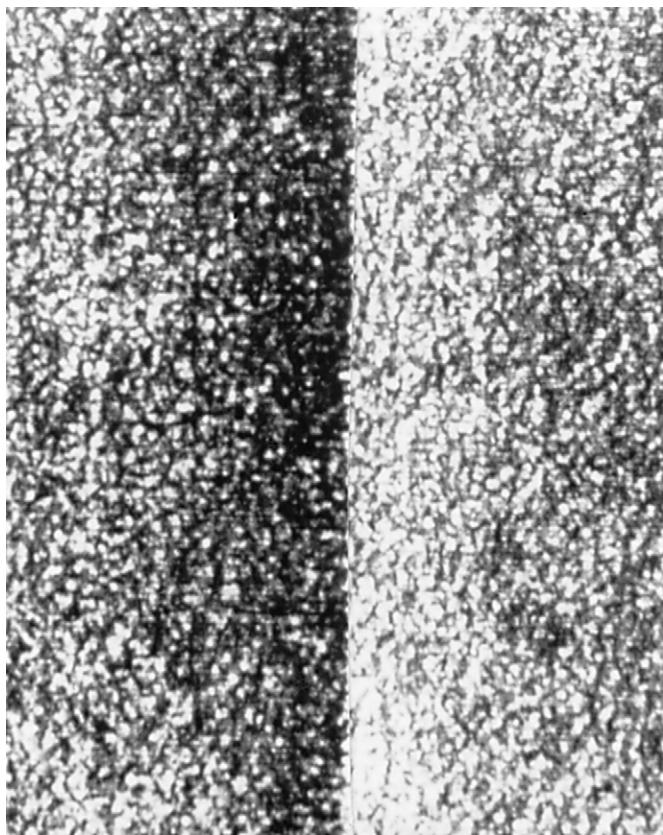

Figure 1.23 The Craik-Cornsweet-O'Brien illusion. The perceived difference in the darkness of the vertical panels disappears if one places a pencil or finger along the border between panels. The effect persists even if the panel details are blurred.

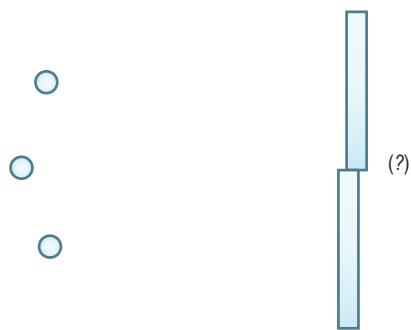

Figure 1.24 Two typical targets for measuring vernier acuity. The subject either notes misalignment of the vertical lines or of the three dots.

presented with the top and bottom dots (which are in alignment), while the other eye is allowed to see only the middle dot. Subjects show similar thresholds whether the experiment is done this way or done monocularly. Clearly, the brain must be where the ultimate processing occurs in these experiments. Because a threshold of less than 5 seconds is well beyond the optical diffraction limit of the eye, Vernier acuity represents a special example of sophisticated brain processing. The challenge is to try to conceptualize some important task necessary for the survival of our *Homo sapiens* ancestors that required such precision. Incidentally, we also know that the macaque monkey demonstrates a high level

Figure 1.25 Note the deer hidden in the bush. By almost closing one's eyes, the distraction of the high grass is canceled and the animal is easier to see. (From: Osborne C, Tanner O, eds. Animal defenses. New York: Time-Life Films, 1978.)

of Vernier acuity. In fact, the adult monkey averages a threshold of about 13 seconds of arc.¹⁰³ Thus it is possible that monkeys and early humans used Vernier acuity to detect the presence of an animal or an enemy hiding behind a stalk or a tree by noting a misalignment between the edge of the tree or stalk and the protruding body of the enemy. If that possible scenario was true, normal Vernier acuity might save a life. Once again, brain enhancement of the retinal image brings out details well beyond the limits of the best optical resolution.

Removing distractions

In Figure 1.25, a deer is hidden in the high grass. Almost completely closing the eyes creates a blurring of the overlying fine grass, making the animal more vividly seen. A similar effect can be achieved through a heavy rain. Again, almost closing the eyes allows figures to be seen more easily through the rain. This is an example of erasing the distractions that have a high spatial frequency.

Refractive errors

Thus far, when pertinent, this chapter has covered the physiologic optics of the average, emmetropic eye. However, the average refractive error in certain populations is not emmetropia. For example, in many Asian groups the incidence of myopia may be between 80 and 90 percent.

Therefore, for a broader review of physiologic optics, this last section covers some of the essential epidemiologic aspects of the refractive errors other than emmetropia.

Prevalence

Studies that tabulate the distribution of refractive errors often are taken from data on young army recruits,^{81,104} which show the incidence of myopia to be about 10 percent. However, this group of healthy young men is not representative of the general population. Stenstrom's study in Uppsala, Sweden, consisted of clinic patients, colleagues, nurses, and cadet officers, which is a group more reflective of the general population.⁸¹ His study showed that about 20 percent of the population has low myopia (less than

2 diopters), 7 percent has moderate myopia (2–6 diopters), and another 2.5 percent has high myopia (greater than 6 diopters). The great majority of this population (just less than 70 percent) clustered between emmetropia and 2 diopters of hyperopia; the rest were high hyperopes and aphakes.

The spectacle-wearing population of a typical Western country provides a different focus on emmetropes. Bennett¹⁰⁵ surveyed the distribution of spectacles dispensed in England. His study of refractions carried out by the average eye clinician showed that about 20 percent are myopic refractions and 75 percent of all refractions require prescriptions from -0.5 to +8.00 diopters. Subtraction of Stenstrom's estimate of the percentage of high hyperopes shows that about 65 percent of all refraction prescriptions are for presbyopia. Interestingly, Indians from the Amazon rainforest have an extremely low incidence of myopia. From an overall sample of 486 people, 259 indigenous people and 78 Brazilians between 12 and 59 years of age, only 2.7 percent of eyes showed myopia of -1.00 D or more and 1.6 percent had bilateral myopia of -1.00 D or more.¹⁰⁶

Myopia

Pathologic myopia

Curtin¹⁰⁷ estimates that 2–3 percent of the population has pathologic myopia (a condition in which there is a significant enlargement of the eyeball with a lengthening of the posterior segment). This group falls into Stenstrom's group of patients with myopia of greater than 6 diopters. The term *pathologic* is used because these patients show significant choroidal and retinal degenerative changes, a high incidence of retinal detachment, glaucoma, and increased occurrence of staphyloma development. At present, high myopia (greater than 6 diopters) is regarded as hereditary, either autosomal dominant, autosomal recessive, or X-linked recessive. Some high myopia might be inherited in a complex fashion. So far, eight loci for high myopia have been reported, including MYP1 (Xq28), MYP2 (18p11.31), MYP3 (12q21-q23), MYP4 (7q36), MYP5 (17q21-q22), MYP11 (4q22-q27), MYP12 (2q37.1), and MYP13 (Xq23-q25). Different genetic loci have been mapped in different populations, but none of the responsible genes has yet been identified.^{108–110}

Physiologic, or school, myopia

As noted by Stenstrom,¹¹¹ most patients have myopia that is less than 2 diopters; this type of myopia is called *physiologic*, or *school, myopia*. The word *physiologic* implies that this form of myopia is a normal, physiologic response to a stress. In fact, substantial evidence exists that increased time spent reading from early teenage to the mid-twenties is that stress.^{4,108}

However, near work is not the sole cause of physiologic myopia. Racial and ethnicity studies show that myopia is more prevalent among Asian and Jewish persons and less prevalent among African-Americans.⁵⁰ The results of a study in Taiwan showed the incidence of myopia to be about 12 percent in children 6 years of age or younger, 55 percent in children 12 years of age or younger, 75 percent in children 15 years of age or younger, and 84 percent in those older than 18 years of age.¹¹² Thus it appears that many if not most

cases of physiologic myopia result from a combination of an inherited predisposition and excessive close work during the student years.

Astigmatism

About 50 percent of term infants in their first years of life show astigmatism of more than 2 diopters.^{113–115} This may arise from the influence of the recti muscles that pull on the delicate infant sclera, because the astigmatism seems to change in different gaze directions. Howland et al¹¹⁴ suggested that the high astigmatism helps the infant bracket the position of best focus while learning to accommodate. By adulthood, this high incidence of astigmatism has disappeared. Studies show that about 15 percent of the adult population has astigmatism greater than 1 diopter and only 2 percent have astigmatism greater than 3 diopters. It is possible that much of the high astigmatism in this last group is related to some form of intraocular surgery (e.g. corneal transplants, cataract surgery, repair of corneal lacerations).

Presbyopia

Although presbyopia is age related, its age of onset varies around the world. For example, presbyopia develops earlier in people who live closer to the equator.^{80,116} Specifically, the age of onset of presbyopia was noted to be 37 years in India, 39 years in Puerto Rico, 41 years in Israel, 42 years in Japan, 45 years in England, and 46 years in Norway. Further studies show the important variable to be ambient temperature rather than latitude. Thus the higher the ambient temperature, the earlier the onset of presbyopia.

On the other hand, life expectancy is lower in developing countries where the ambient temperatures are usually high. Thus, although presbyopia starts at a young age in the developing world, fewer persons with presbyopia are found in the general population. For example, in Haiti the prevalence rate of presbyopia is about 16 percent for the normal population, whereas in the United States it is 31 percent.¹¹⁷ The lower rate of presbyopia in Haiti is paradoxical. The reason is probably that the average life span in Haiti is much shorter than in Western countries. Seen in perspective, presbyopia constitutes about 65 percent of all those who wear glasses in developed Western countries. Thus it is of little surprise that the first spectacles produced sometime in the fourteenth century were created for persons with presbyopia.

Components of ametropia

The overall refractive state of the eye is determined by four components:

- Corneal power (mean, 43 diopters)
- Anterior chamber depth (mean, 3.4 mm)
- Crystalline lens power (mean, 21 diopters)
- Axial length (mean, 24 mm)

Figure 1.26 shows the distribution of total refraction and the four components just mentioned for 194 eyes.¹¹⁸ The most striking conclusion drawn from Figure 1.26 is that, although each of the individual optical components may be considered randomly distributed, the overall refractive status does not show a normal distribution of refractive errors, but rather a skew in the region of emmetropia. It seems that the

Figure 1.26 Curves of distribution of refraction and its components in 194 eyes. (Adapted from Sorsby A, Sheridan M, Leary GA: BMJ 1960; 1394; and Sorsby A et al: Med Res Counc Special Rep Serv Rep 1959; 293.)

various components cooperate to achieve a higher-than-expected incidence of refractive state between 0 and +2 diopters.

This cooperation of components to produce a higher-than-expected incidence of emmetropia and low hyperopia has been called *emmetropization*.¹¹⁸ The process of emmetropization seems to be fully effective during the infantile growth of the eye. As noted earlier, the average sagittal diameter of the eye is approximately 18 mm at birth. By the age of 3 years, the axial length increases to about 23 mm. Such elongation of the eye theoretically yields a state of myopia of about 15 diopters. However, during this period, the data show that almost 75 percent of these young eyes are hyperopic.¹¹⁹ Between 3 and 14 years of age, the elongation increases, on average, an additional millimeter. Again, this should theoretically produce another 3 diopters of myopia. However, at 14 years of age, the average refractive state shows a strong clustering in the emmetropic neighborhood. Because the cornea and anterior chamber depth change little during these periods of eye growth, it appears that the power of the crystalline lens must change to maintain emmetropia. It seems possible that the process is coordinated by the retina-brain complex, which might tune each component to ensure a sharp image. However, studies of infant monkeys who were raised in the dark or who have had their optic nerve sectioned suggest that emmetropization is largely programmed on a genetic basis.¹²⁰ The experiments further showed that procedures that result in significant degradation

of the retinal image, such as the suturing of the lids together or induction of a corneal opacity during the early growth period, influence the axial growth process. Surprisingly, these types of opacification significantly increase the axial length and produce states of myopia of up to 12 diopters. Such excessive image degradation seems to override the emmetropization process and result in high levels of axial myopia.

In conclusion, it appears that a genetic bias underscores the refractive state of the eye. However, this genetic program can be tuned by environmental and intrinsic (i.e. intraocular) factors. Koretz et al,¹²¹ Laties & Stone,¹²² and Stone et al^{8,111,121,123-126} have provided further insights into the biophysical and biochemical controls of emmetropization and their failure.

Optical Aberrations and Wavefront Sensing

Ricardo N. Sepulveda & Ron Krueger

Introduction

Myopia, hyperopia and cylinder are refractive errors known as second-order aberrations. These aberrations result in the inability of the eye to focus images appropriately on the retina. In myopia, light rays entering the eye focus anterior to the retina. This is most often seen in an elongated eye. In contrast, hyperopia occurs in a short eye where light rays tend to focus behind the retina. Astigmatism results from an irregular-shaped cornea or early cataractous lens, which causes the light rays to focus at multiple points along the pathway to the retina. With regular astigmatism, the rays focus into a line oriented in the same axis of the cylinder, and yet another oriented 90° away. These basic optical errors related to the eye are what we have been correcting for the past 200 years with the aid of spectacles, contact lenses and even refractive surgery (Fig. 2.1).

With the advent of wavefront technology, we have discovered a new way of conceptualizing how light rays behave when entering the eye. This technology allows us to visualize in two-dimensional images, the complex profile of refracted light as it passes through the cornea and the crystalline lens. We are able to now detect higher-order aberrations such as coma, trefoil and spherical aberrations. Laser technology for refractive surgery has evolved significantly over the past years. It now permits us to correct higher-order aberrations by performing a "customized" ablation of the cornea according to the data provided by wavefront sensors, improving the visual performance significantly. What is also exciting is how wavefront technology may be applied to customize contact lenses and even intraocular lenses.

This chapter intends to provide the reader with a basic understanding of optical aberrations, wavefront sensing technology and the benefit of correcting higher-order aberrations in the human eye.

Optical aberrations

In a perfect optical system, such as one free of aberrations, emerging image-forming rays are planar and converge onto

a single point. In reality, however, we have learned that this is not true for our optical system, the human eye. In this section, we will review basic concepts of wavefront optics and explain the different types of optical aberrations.

Wavefront optics

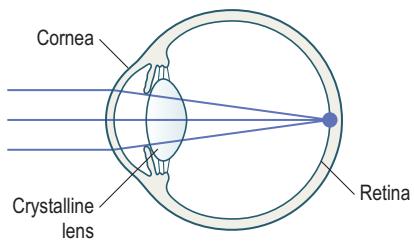

In geometric optics, we study the relationships between refractive error and pupil size, which have an impact on the blur of an image. By reducing the pupil size of an eye with a given refractive error, the blur of an image improves by increasing the depth of focus. This can be understood by looking through a pin-hole, in which images appear to be sharper, but at the same time we decrease light and image resolution by inducing diffraction.

In physical optics, we describe light as energy which is transmitted in the form of a wave. The properties of a wave are wavelength, frequency, and velocity. In air, the speed of light remains relatively constant. When the light passes through a higher index of refraction, its properties change and aberrations are formed. This can be explained by the following equation:¹

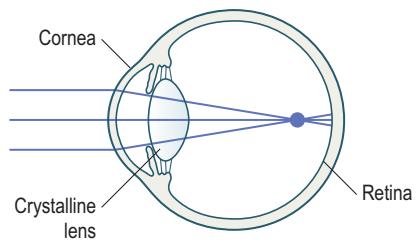

$$F = Vn/\lambda$$

where F = frequency, V = velocity, n = index of refraction, λ = wavelength.

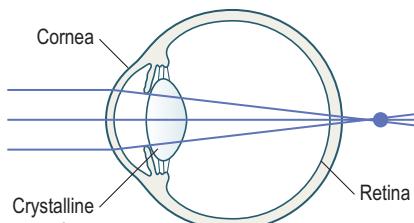

The waves of light are joined at a single point in time by what is called a wavefront and always travel perpendicular to it. When the light waves emerge from a point source, the wavefront takes on a spherical shape. As the light waves move on, the wavefront becomes progressively more flat or planar. When light waves pass through an aberration-free optical system, they emerge from it perpendicular to the wavefront, forming a spherical shape which is either converging or diverging as if coming from a single point. When the wavefront is interrupted by an optical media with an irregular surface, the emerging wavefront is not planar, the light waves are irregular and unparallel to the wavefront. The distorted shape that a wavefront takes after emerging from an irregular optical media is called a wavefront aberration (Fig. 2.2).¹

**A Emmetropia**

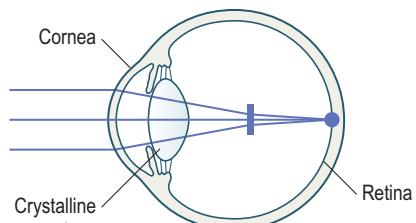

In emmetropia, light rays focus on the retina

**B Myopia**

In myopia, light rays focus anterior to the retina

**C Hyperopia**

In hyperopia, light rays focus behind the retina

**D Astigmatism**

In astigmatism, images focus on two different planes

Figure 2.1 Refractive states. **(A)** In emmetropia, light rays focus on the retina. **(B)** In myopia, light rays focus anterior to the retina. **(C)** In hyperopia, light rays focus behind the retina. **(D)** In astigmatism, variations in the surface of the cornea and lens cause light rays to focus at two different points. When one focal line is located anterior to the retina and the other on the retina, it is termed *myopic astigmatism*. When one focal line is located on the retina and the other behind it, it is termed *hyperopic astigmatism*.

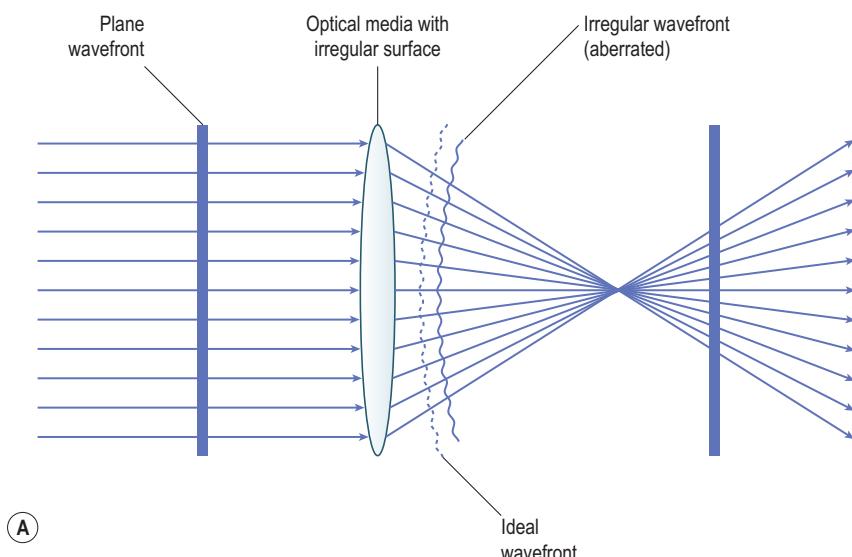

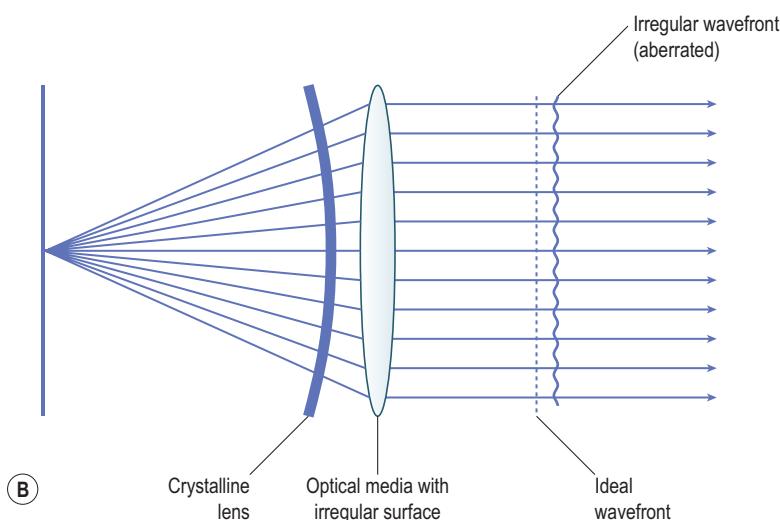

**A****B**

Figure 2.2 Wavefront aberrations. **(A)** The aberrated wavefront for light coming from an object at distance. The light emerging does not converge on a single point, but rather multiple different points. **(B)** Light diverging from a single point source forms an aberrated wavefront as it emerges from an irregular optical media unable to form a parallel beam of light.

Box 2.1 Optical limitations to vision

- Pupil size
- Nyquist sampling limit
- Diffraction
- Stiles-Crawford effect

Optical limitations to vision

We cannot discuss the limitations that a human eye's optics impose on the image quality without introducing the concepts of point spread function (PSF) and modulation transfer function (MTF). To further understand this, we must think of the eye as a camera. Where the cornea, crystalline lens and vitreous are the optical lenses of a camera, the pupil is the aperture, and the retina is the photographic film on which the images will be imprinted (Box 2.1).

PSF is the intensity with which an optical system distributes an image from a point source onto the retina. The point source is influenced by the pupil size. The larger the pupil, the more irregular the shape of the point source imaged on the retina (Fig. 2.3).²⁻⁴

MTF is the ability of the eye's optics to focus a sharp image on the retina with high contrast. As light passes through optical structures of the eye, it undergoes a process of "degradation" which can be measured by MTF. If we present an optical system with patterns of light and dark bars and measure their luminance, we are measuring the "modulation" or contrast of the light.⁵⁻⁷

$$M = \frac{(\text{Maximum Luminance} - \text{Minimum Luminance})}{(\text{Maximum Luminance} + \text{Minimum Luminance})}$$

MTF involves spatial frequency and measures the sine waves (Fourier transformation) of the light source in cycles per degree (c/deg), which is similar to sound frequency being measured in Hertz (cycles per second). MTF is defined as the modulation of the image, M_i , divided by the modulation of the stimulus (the object), M_o , giving rise to the following equation:⁵⁻⁷

$$\text{MTF}(v) = M_i/M_o$$

Low spatial frequency corresponds to large angular spacing between white bars (wide grating) and high spatial frequency corresponds to fine grating (Fig. 2.4). The spatial frequency of the images entering the eye can be influenced by the pupil size – the wider the pupil, the higher the spatial frequency of an object that can be perceived by the eye. However, the highest spatial frequency that can be detected by the visual system is also limited by the number of photoreceptors densely packed in the fovea also known as the Nyquist Sampling Limit. The Nyquist Sampling Limit states that spatial frequencies are only detected when they are less than one half the sampling frequency. The human eye cannot detect sampling frequencies higher than 60 c/deg, because the cones on the fovea provide a sampling rate of about 120 c/deg (Fig. 2.5).⁸⁻¹¹ Our brain compensates for much of this retinal undersampling, making us interpret images as being sharp.¹¹

Diffraction is a phenomenon which occurs when light waves are bent as they enter an aperture – in the case of the

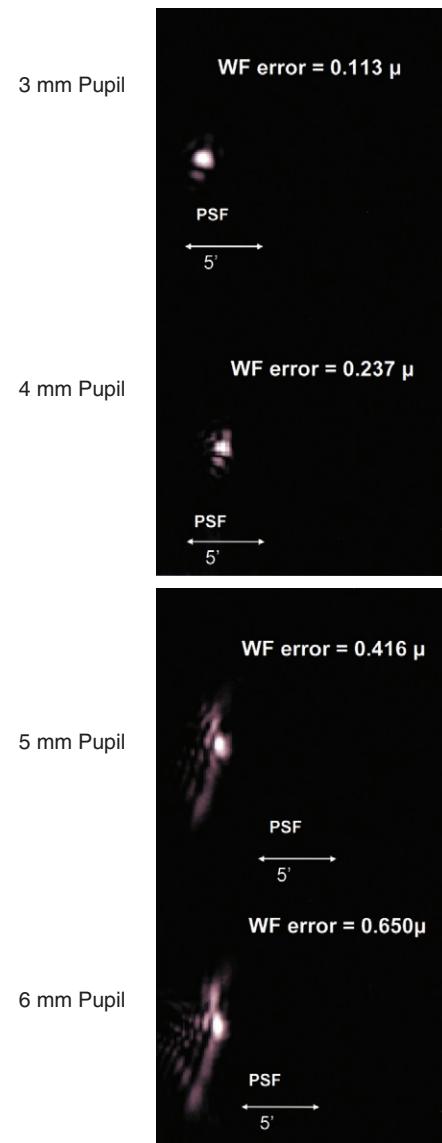

Figure 2.3 Point spread function and pupil size. Point spread function is the intensity with which an optical system focuses an image from a point source on the retina. Note how the blurring of the point source increases as the size of the pupil increases. (Modified from Azar D. *Refractive surgery*, 2nd edn. New York: Mosby. Copyright Elsevier 2006)

human eye, the pupil. In 1896, the German physicist, Arnold Sommerfeld, defined diffraction as "any deviation of light rays from a rectilinear path which cannot be interpreted as a reflection or refraction".¹² Diffraction is important in image quality because it sets limits to the resolution of an image.¹³ When a wavefront propagates without interruption, the array of point sources combine and interfere to form a new wavefront of similar shape as the previous one. When the same wavefront is interrupted by an aperture, the waves from the array of point sources combine and form a different shape. As the aperture's diameter increases, light is diffracted less.^{14,15} This principle was described by Huygens & Fresnel.¹⁶

The Stiles–Crawford effect¹⁷ is another factor which influences image quality. This is the effect of light entering the cones transversely from the pupil margin, which is perceived

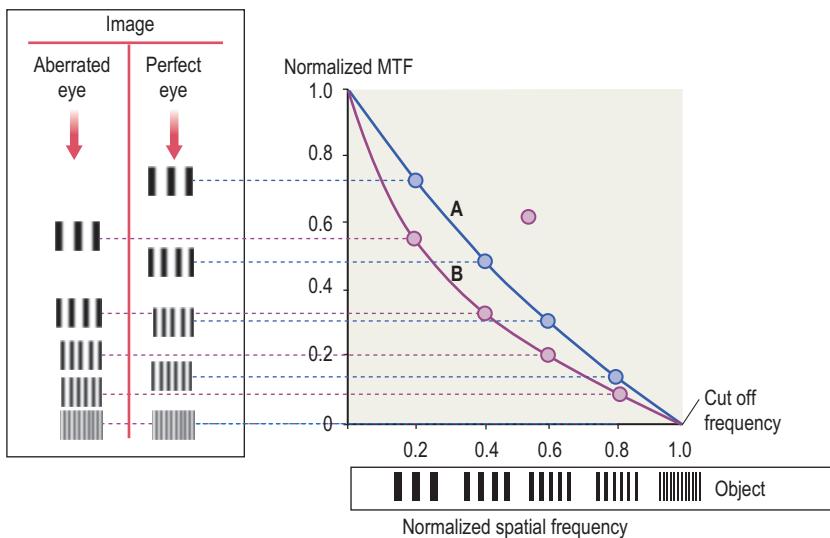

Figure 2.4 Modulation transfer function. MTF is the ratio of image to object contrast as determined by the spatial frequency of a sinusoidal grating. Curve A (blue) represents the MTF of an aberration-free optical system and curve B (purple) that of an aberrated optical system. Notice how image contrast is less at all spatial frequencies for the aberration-free optical system when compared to the aberrated optical system when looking at the images to the left. (From Azar D. *Refractive surgery*, 2nd edn. New York: Mosby. Copyright Elsevier 2006)

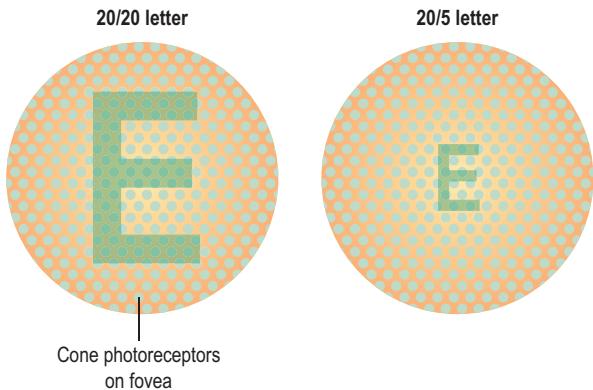

Figure 2.5 Nyquist sampling limit. The spatial frequency is limited by the number of cone photoreceptors densely packed in the fovea. A 20/20 letter is sampled by more photoreceptors than a 20/5 letter (>60 c/deg) where the image is undersampled and uncorrectly detected.

half as bright as the light entering the center of the pupil. In simpler terms, light that passes through the edge of the pupil contributes less to image quality than light entering the center of the pupil.¹⁷

Aberrations

Aberrations are dictated by the performance of any given optical system. They occur when light from one point of an object after transmission through the system does not converge into (or does not diverge from) a single point causing image blur. There are two classes of aberrations: chromatic and monochromatic. Theoretically, correcting both chromatic and monochromatic aberrations increases the contrast of images focused on the retina (contrast sensitivity).

Chromatic aberrations

Chromatic aberration is also known as "achromatism". It is defined as the inability of a lens to focus all colors of light on a single point. A rainbow is formed by droplets of water which bend color wavelengths differently producing chromatic aberration. Chromatic aberration arises because the

Box 2.2 Monochromatic aberrations

- Piston
- Tilt
- Defocus
- Spherical aberration
- Coma
- Astigmatism

index of refraction of the media is not the same for all wavelengths. It can be longitudinal or transverse. In longitudinal chromatic aberrations, the wavelengths focus at a different distance from the lens.¹⁸ The index of refraction of a medium is higher for shorter wavelengths. This explains why the cornea focuses blue light (455–492 nm) in front of the retina when the eye is corrected for green light (492–577 nm). Transverse chromatic aberrations occur when wavelengths focus at different positions of a focal plane, such as seen when a pupil is de-centered.

Monochromatic aberrations

Monochromatic aberrations are defects of an image caused by the nature of a lens. An irregular-shaped cornea or an aging crystalline lens (e.g. cataract) produce monochromatic aberrations (Box 2.2).

Piston and tilt are not considered true optical aberrations, as they do not represent a curvature of wavefront. Piston and tilt are monochromatic aberrations which are not visually significant. Defocus and astigmatism are the lowest-order true optical aberrations.

Helmholtz¹⁹ theorized the existence of these aberrations by observing a point source of light with his own eyes. He proposed that the human eye perceived aberrations which were not seen through conventional lenses. Liang & Williams²⁰ later would develop a technique to objectively measure the wavefront aberrations of the eye up to 10 radial orders using a Shack-Hartmann device.²¹ The wavefront aberrations captured by the device are then transmitted to a computer which uses Zernike polynomials to calculate and

represent them as a two-dimensional image. It is the correction of these monochromatic aberrations by spectacles, contact lenses, intraocular lenses and refractive surgery, which have been proved to result in improvement of visual performance.²²

Measuring optical aberrations

The interest in measuring wavefront aberrations in ophthalmology grew as refractive surgery became more and more popular in the last 20 years. Coma and spherical aberrations are secondary effects of standard laser corneal ablations. In normal eyes, wavefront aberrations are not a significant source of image quality degradation. In post-refractive surgery eyes, the induction and worsening of pre-existing higher-order aberrations worsens as pupil size increases. The effect of "starbursts" and "glare" are the product of induced higher-order aberrations, which become more problematic for patients while functioning under poor light conditions. Modern technological advances in the field have enabled us to detect these aberrations and create "customized" corneal ablations to reduce them.

Aberrometry and wavefront sensing devices

The term "aberrometry" is used to describe the science of the detection and analysis of wavefront aberrations. To interpret optical aberrations, we must become familiar with the concept of optical path length (OPL). Earlier in this chapter, we learned how waves of light are slowed down as they travel through the higher index of refraction present in the ocular media compared to air for the same length. This results in higher oscillations of the waves within the eye. Thus, OPL is defined by the number of oscillations of these light waves from a point source of light, traveling through a media of x index of refraction at any given length.^{23,24} To measure aberrations in any optical system, we compare the OPL of a light ray passing through any point (x,y) present at the plane of the pupil with the chief ray passing through the center of the pupil $(0,0)$. This results in what is then called the optical path difference (OPD),²⁵ and its variation across the pupil is represented in a two-dimensional map.²⁴ Thus, optical aberrations represent differences in OPL which are influenced by the integrity of the optical media (i.e. tear film quality,²⁶ corneal defects and irregularities (i.e. keratoconus),²⁷ opacifications in the crystalline lens,²⁸ vitreous abnormalities, and decentering or tilting of any ocular component).

Christopher Scheiner, a German astronomer from the 1600s, set the platform for modern aberrometry and wavefront sensing devices with the invention of the Scheiner Disk. He reasoned that an optically imperfect eye would form two separate images on the retina when looking at a distant light source through a disk containing two pinholes (Fig. 2.6).

In 1895, Tscherning²⁹ developed an instrument to measure aberrations of the eye consisting of a grid with 1-mm squares on a +5 diopter lens. He called his instrument an "aberroscope", and it worked by placing the instrument in front of an individual's eye while viewing a light source. The individual would then interpret the shadows and draw them

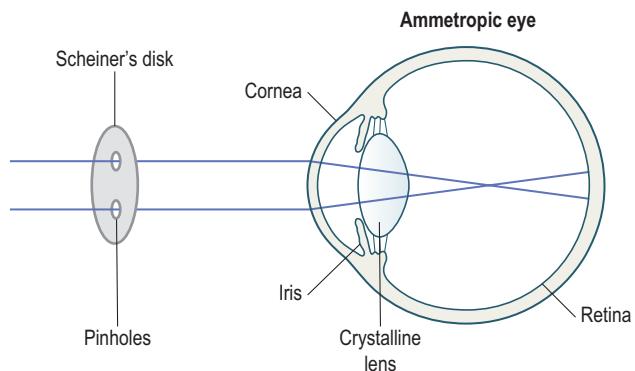

Figure 2.6 Scheiner's disk. An ammetropic eye forms two separate retinal images when viewing a distant light source through a disk with two pinholes.

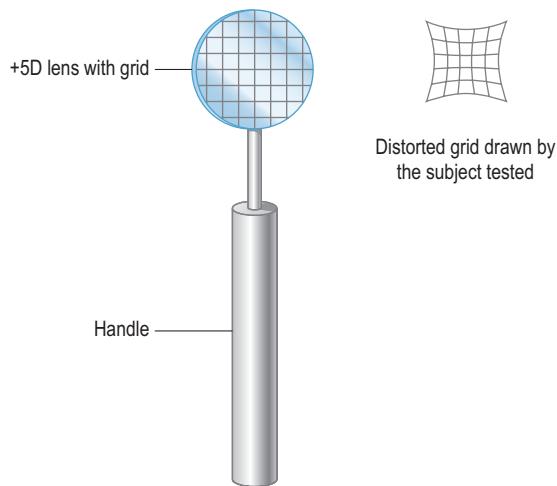

Figure 2.7 Tscherning aberroscope. This aberroscope used a +5 diopter lens with a grid composed of 1-mm squares. The subject views a distant light source through the grid and draws the distortions on paper.

(Fig. 2.7). This, of course, provided a subjective way of measuring aberrations, but is nonetheless a bright idea. In 1900, Hartmann developed a device, based on the principle of Scheiner's Disk, which constructed wavefront aberrations based on ray-tracing.³⁰ In the late 1970s Howland et al developed a different aberroscope and discovered that higher-order aberrations, specifically coma, were the principal aberrations present in normal eyes at every pupil diameter. They were also the first to introduce Zernike polynomials to measure wavefront aberrations.^{30,31}

In the field of astrophysics, wavefront technology emerged from the need to perfect telescopic devices used to view distant stars, planets, and galaxies. The Hubble telescope uses the Shack-Hartmann wavefront sensor and adaptive optics in the form of deformable mirrors to compensate for monochromatic aberrations induced by the atmosphere as light enters the earth and increasing image resolution. In 1978, Josef Bille was the first to develop this type of wavefront technology for the eye at the University of Heidelberg, Germany. A Shack-Hartmann sensor device works by detecting aberrated light waves reflected by the retina emerging from the eye on an array of tiny lenses (lenslets) (Fig. 2.8).³²

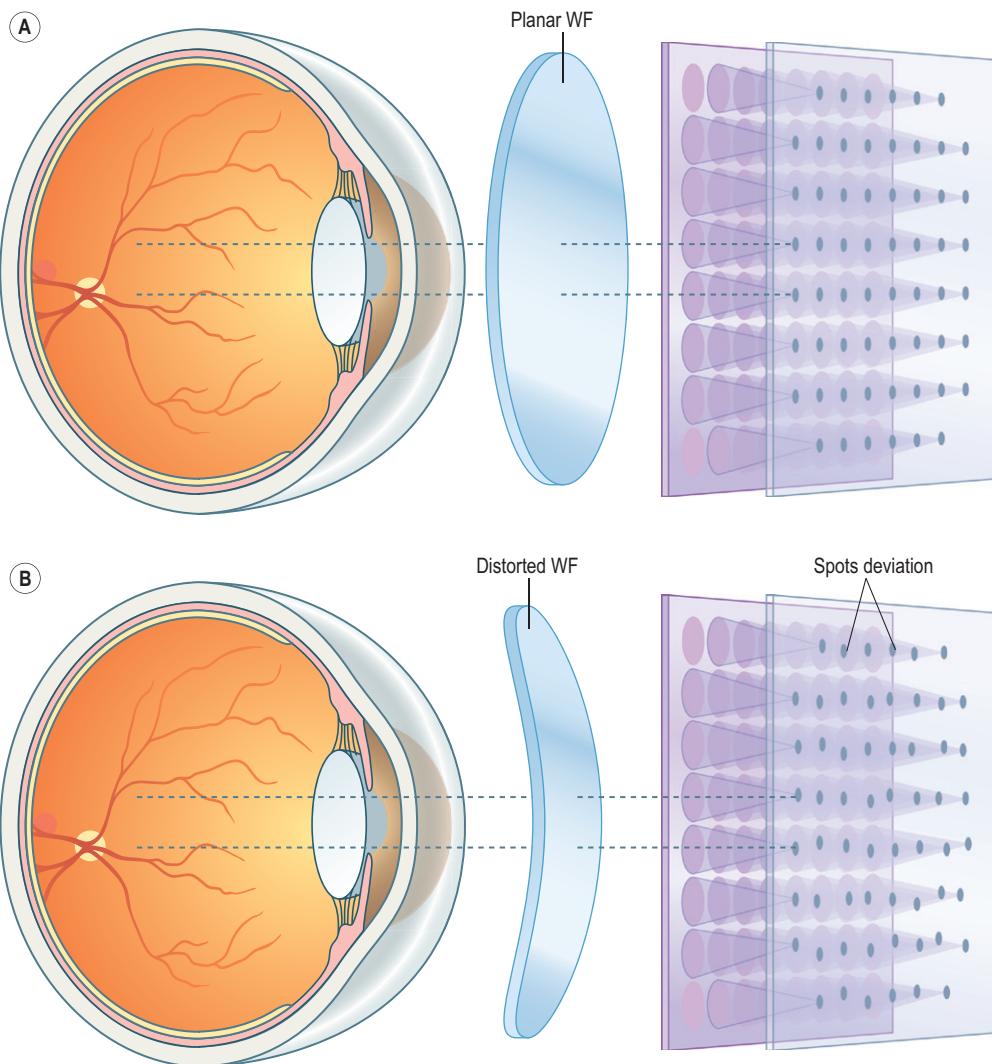

Figure 2.8 The Shack–Hartmann sensor. Light is reflected on the retina from a point source and the emerging wave from the eye is transmitted through an array of lenslets which focus the wavefront on a CCD device and processed in a computer to produce a two-dimensional image. In an aberration free eye (**A**) a planar wave emerges from the eye showing no distortion of the spots focused by the array of lenslets. In an aberrated eye (**B**), the wavefront emerging from the eye is distorted and the focused spots are deviated. (From Azar D. *Refractive surgery*, 2nd edn. New York: Mosby. Copyright Elsevier 2006)

This technology has also been employed by scientists from the University of Rochester to experimentally image the cone photoreceptors of the fovea in real time.¹

In the eye, the cornea and the crystalline lens act much as the earth's atmosphere in inducing monochromatic aberrations. Because these structures have a circular form, the aberrations may be mathematically described by a series of polynomials called Zernike polynomials, named after Frits Zernike. Zernike polynomials are the preferred method of representing wavefront aberrations for various reasons.^{33–36} They are mathematically stable, they are based on circular geometry, and they are continuously orthogonal over a unit circle.^{33,37,38} They are reported as a single- or double-indexing scheme, or as a system of coordinates.³⁹ Figure 2.9 shows the first five radial orders of the Zernike pyramid used to describe the eye's wave aberrations.

Lower-order aberrations are simple refractive errors such as defocus and astigmatism, which can be corrected by conventional refraction. Third-order aberrations and higher are

termed higher-order aberrations. Each Zernike mode has a value expressed as the root mean square in microns (RMS) or as a standard deviation across the pupil⁴⁰ and serves as a means of quantifying the severity of the aberrations present in an eye.

There are multiple wavefront sensing devices commercially available thanks to the increase in demand of customized laser refractive surgery in the past years. Companies like Alcon, Visx, Bausch and Lomb, Meditec, Schwind and Topcon use the Shack–Hartmann device as a basis for wavefront analyses. Only WaveLight utilizes a device named after Tscherning (Tscherning Aberrometer) in their systems. The Tscherning device detects wavefront patterns by shining a laser through a grid into the eye and analyzing the pattern imprinted on the retina (Fig. 2.10). A modification of this method using a rapidly placed, sequential pattern of rays is utilized by Tracey. These two methods are a form of "ray tracing" and the former was introduced by Theo Seiler (Fig. 2.11).^{41,42} Emory University has developed an aberrometer

(Ingoing Adjustable Aberrometer) which measures light rays manually focused on the retina by the subject being tested. Nidek (Nidek OPD) uses a mechanism to measure aberrations called Slit Skiascopy,⁴³ in which a slit of light scans the eye along different axes. Photodetectors then determine the timing and scan rate of the light reflected to construct the wavefront.

Wavefront sensing devices not only measure aberrations but also function as refractometers, giving us an idea of the patient's spherocylindrical refractive error. The refraction provided by these devices is not entirely accurate and should be complemented by a proper manifest and cycloplegic refraction⁴⁴ before transferring these numbers to the laser device.

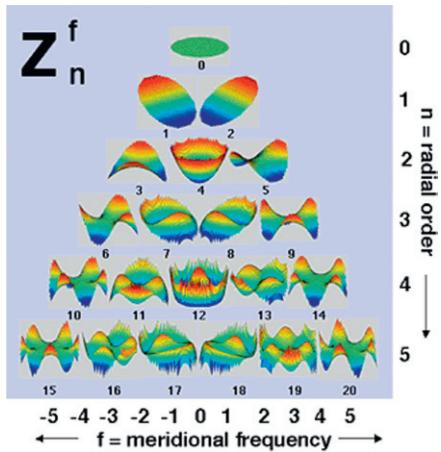

Figure 2.9 Zernike pyramid. The Zernike functions up to the fifth radial order are represented. n represents the radial order and f the meridional frequency. Lower-order aberrations are those of the 2nd radial order (astigmatism and defocus). 3rd radial order and higher are considered higher-order aberrations. Clinically significant HOAs such as coma and trefoil are of the 3rd radial order, and spherical aberrations are of the 4th radial order.

Wavefront sensing devices

See Box 2.3.

Correcting higher-order aberrations

The main focus of laser refractive surgery nowadays is to not only correct refractive errors such as defocus and astigmatism, but to create customized ablations which compensate for induced higher-order aberrations (HOA) such as spherical aberration (optimized ablation) and also correct pre-existing aberrations (customized ablation). It has been proven by experimental correction of ocular aberrations with adaptive optics that the image quality improves by increasing contrast sensitivity.⁴⁵

Visual disturbances associated with HOA

Because an aberrated eye generally has multiple kinds of aberrations present, it is difficult to pinpoint exactly which aberration causes a certain kind of symptom. We know that

- Poor image contrast
- Poor night vision

in general, patients with significant higher-order aberrations, such as a side effect of conventional refractive surgery, complain of glare, starbursts, haloes, ghost-images, poor contrast and poor night vision (see Box 2.4). Fortunately, these symptoms do not happen frequently, and they tend to occur under conditions of dim illumination because of the resulting pupil dilatation. The extent to which these limit a person's ability to function normally, however, may vary from mild to severe.

Visual performance after correcting HOA

We are yet to develop an ideal system to clinically assess visual performance pre-operatively and post-operatively in patients undergoing refractive surgery. The Snellen acuity chart is the standard clinical form of assessing visual acuity and is far from perfect. A dim illuminated chart and "crowding" phenomenon limit the test's ability to accurately estimate visual acuity.⁴⁶ Furthermore, studies have shown poor reliability with up to 13% of subjects tested showing discrepancies of two lines or more.⁴⁷ The ideal method for testing visual acuity would be one that clearly defines the quality of

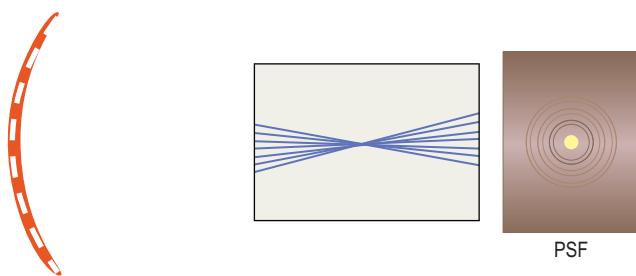

visual perception and the quality of the retinal image. The task of assessing visual perception is challenging because of the complex neural and cognitive processing involved. Retinal image quality can be assessed using aberrometers.

Most of the results highlighting the benefit of customized corneal ablations use the Snellen acuity chart, root mean square (RMS) wavefront values and contrast sensitivity. Data on the benefit of HOA correction varies between the different excimer laser platforms used for customized corneal ablations. Studies have shown stability of contrast sensitivity under mesopic conditions and less induction of HOA after customized LASIK when compared to conventional LASIK.^{48,49} But wavefront guided treatments require greater corneal tissue ablation than conventional LASIK, thus putting the cornea at risk for biomechanical instability (i.e. keratectasia).⁵⁰ The studies suggest, however, that spherical aberrations are reduced almost 50% in custom treatments vs only 12% in conventional treatments. Thus, it is safe to conclude, that under the right conditions, customized treatments are superior to conventional treatments when using laser vision correction. Later in this chapter, the clinical application of HOA correction will be discussed in more detail.

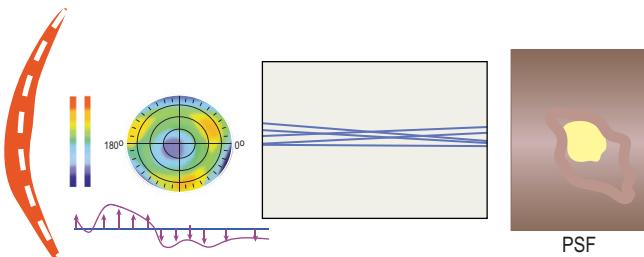

Factors which limit the benefit of HOA correction

Customized corneal ablations are intended to correct the overall aberrations of the eye. The treatment not only reduces the aberrations induced by the cornea, but it is also designed to shape the cornea in a way to compensate for other aberrations that may be induced by the tear film quality, pupil or the crystalline lens. The tear film contributes to up to 70%

Optical system with NO optical aberrations

to the corneal refractive power.⁵¹ Dry eyes, for example, have greater coma and spherical aberrations compared to non-dry eyes.⁵²

Diffraction caused by the pupil causes a great impact on the quality of the retinal image, and is directly proportional to the pupil size. These changes in image quality may be assessed by measuring PSF and optical transfer function (OTF). Figure 2.12 shows how pupil size affects the PSF at different pupil diameters in a typical eye compared to a diffraction-limited eye (free of aberrations). We can observe how at smaller pupil sizes, diffraction is the main source of poor image quality. But as the pupil diameter increases, aberrations degrade the image more than diffraction. As previously discussed in this chapter, pupil diameter also affects MTF. Figure 2.13 displays the ratio of image contrast to object contrast as a function of the spatial frequency of a sinusoidal grating.

Accommodation also plays a role in correcting HOAs. In young subjects accommodating on near targets, MTF decreases because of the miosis which occurs during accommodation,^{53–57} and also because aberrations also increase during accommodation. As the patient ages, the correction of aberrations becomes less efficient because the initial correction plan is based on the patient's accommodative status at the time of examination.

It is well known and documented in the literature that ocular aberrations change as the eye ages.⁵⁷ Age-related corneal and crystalline lens changes alter the aberrated status of the eye.⁵⁸ In young subjects, the cornea usually has "with-the-rule" astigmatism, with the vertical meridian being steeper. In older subjects, the steepening of the cornea shifts horizontally, causing "against-the-rule" astigmatism. The

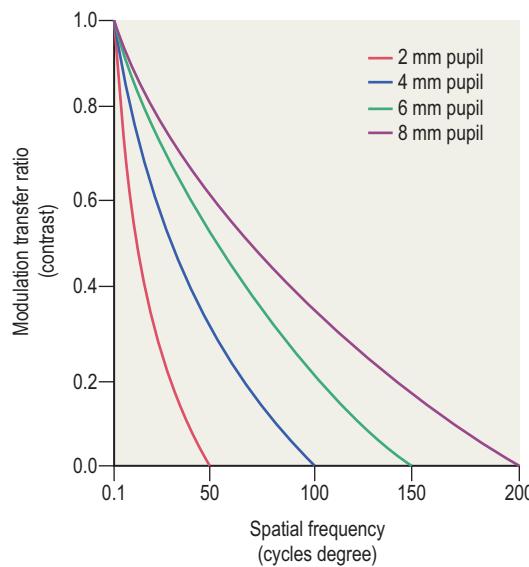

Figure 2.13 Pupil diameter and MTF. This graph represents the importance of pupil diameter and MTF in an aberration free optical system. As pupil diameter increases the MTF ratio (contrast) increases as a function of spatial frequency.

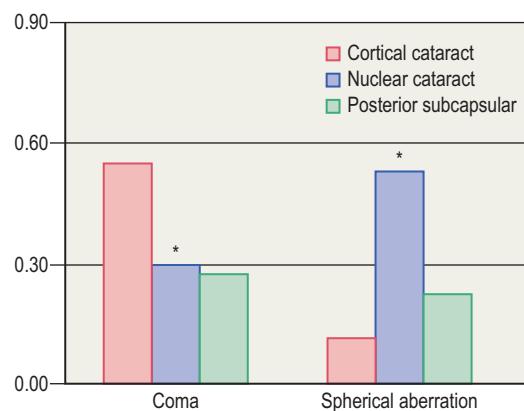

Figure 2.14 Higher-order aberrations in the aging crystalline lens. Wavefront analyses of patients with cortical, nuclear and posterior subcapsular cataracts measured at pupil diameters of 6.0 mm (Data from Rocha KM, Nose W, Bottos K, et al., Higher-order aberrations of age-related cataract. J Cataract Refract Surg 2007; 33(8): 1442–6. ²⁸).

formation of cataracts in the crystalline lens and its change in radius of curvature as it ages, also produce aberrations in the eye, with coma being predominant.^{28,59} In Figure 2.14, we can appreciate the aberrations caused by different types of cataracts. The group concluded that coma aberrations predominated in cortical cataracts, and spherical aberrations predominated in nuclear cataracts.²⁸ Interestingly, in a study by Lee et al⁵⁹ the amount of spherical aberrations present was found to be inversely proportional to the degree of nuclear sclerosis. This discordance may be caused by the different aberrometers used and difference in pupil sizes used to collect the data. Thus, this topic remains controversial. It is helpful to keep in mind that even though we correct HOAs in a patient at a certain age, these will change with time due to changes in the internal optics of the eye.

Clinical applications of wavefront aberration correction

In the previous sections of this chapter, we have attempted to provide the reader with a basic science knowledge of wavefront optics and how the correction of HOAs could potentially improve image quality overall. With an increasing market and demand for super sharp vision (i.e. "super-vision"), scientists have worked hard at making this technology clinically available in many different forms. We will review the different types of wavefront guided corneal ablations and the future of HOA correction with spectacles, contact lenses and intraocular lenses.

Corneal ablations

There are several laser platforms utilized for corneal ablations. These range from the simple conventional treatments to the more sophisticated topographical guided and wavefront customized ablations. Differences in these treatment modalities lie in the type of beam delivery, spot size, treatment zone, and amount of tissue ablated for each diopter of refractive error treated. For the purpose of this chapter, we will only discuss the wavefront customized corneal ablations.

There are two types of wavefront customized ablations: wavefront guided ablations (WGA) and wavefront optimized ablations (WOA). Let us first discuss the differences between these two.

Both types of treatment aim to correct for HOAs in the eye. In WGA, the treatment is aimed to correct the pre-operative HOAs, while in WOA, the treatment attempts to reduce HOAs generated during surgery. The WOA profile corrects expected HOAs for an average eye, and those that are anticipated as a result of the surgery. This means that an eye with higher than normal HOAs, will end up with near equally high HOAs after treatment.^{60,61} Wavefront guided ablations may be better at correcting high pre-operative HOAs because new post-treatment HOAs may be less than HOAs present pre-treatment. Studies comparing the two profiles have concluded that WGA may be the preferred method in eyes with RMS errors $>0.3\text{ }\mu\text{m}$. Padmanabhan et al⁶¹ found that WGA induced fewer HOAs and had better contrast sensitivity after surgery. Another study found higher total RMS errors in patients after WOA than in those after WGA.⁶² After statistical analyses, however these differences were not statistically significant. With new programs available, there is the possibility of combining both treatment algorithms to make a better ablation profile (Allegretto Wave, WaveLight Laser Technologie AG).⁶⁰ Such programs are currently undergoing FDA trials and awaiting approval.

Excimer lasers used to treat wavefront-customized ablations typically use a small-diameter and circular flying spot laser. The cornea is ablated by delivering multiple pulses, and the energy used by each spot is generally Gaussian in order to obtain smooth surfaces. Because these ablation profiles can be used to treat very irregular corneas, many technical aspects must be addressed. In order to achieve adequate outcomes, the surgeon should obtain reliable wavefront analysis, compensate for cyclotorsion during treatment,

ensure proper functioning of eye tracker, and calculate enough residual stromal bed to prevent ectasia.

Correcting HOA with spectacles, contact lenses and intraocular lenses

What happens to those individuals who are poor candidates for customized refractive surgery? These patients are obligated to correct their refractive errors with spectacles or contact lenses, or undergo corneal cross-linking with riboflavin and ultraviolet light prior to refractive surgery. Since there are inherent problems with how these devices are adequately aligned and synchronized to the eye, it has been challenging to apply wavefront technology to them. We will discuss HOA correction with intraocular lenses in the latter part of this section.

For wavefront-customized spectacles to work, they would have to be stable enough to not decentre with head movements, and they would have to be designed in such a way that the aberrations would be corrected in all fields of gaze and at different pupil sizes. Ophthonix, Inc. (Vista, CA), has designed a lens available for commercial use, which consists of a three-layer structure with a refractive index of 1.6. The middle layer consists of a patented photopolymer in between two coated lenses. The lens corrects HOAs from the 2nd to 6th order using wavefront guided technology. The company's aberrometer measures both lower- and higher-order aberrations using the "Talbot" effect.⁶³ Thibos & Miller, from the University of Indiana, are working on developing an electronic spectacle device which may potentially compensate for HOA. It consists of using transparent liquid-crystals embedded on glass providing it with the capability of varying its refractive index.⁶⁴ This would potentially provide patients with the advantage of electronically adjusting the spectacle according to their visual demands.

The use of customized contact lenses that would correct HOAs has also been proposed.²⁵ As we know, there are rigid gas permeable (RGP) and soft contact lenses. In a clinical setting, RGP lenses are helpful in correcting refractive errors in highly irregular corneas. The smooth contour of their anterior and posterior curvatures, coupled with the tear film formed within the interface, provide a new refracting surface for the eye. These lenses are designed to move freely, reaching up to 1mm of decentration from the referent visual axis of the eye with every blink.⁶⁵ Needless to say, a wavefront-customized RGP would have to sit on the eye in a stable manner such that its movement relative to the visual axis would be minimal. This property makes RGP lenses difficult for correcting HOAs such as coma and trefoil. These aberrations are present in higher magnitude in the general population⁶⁶ and are also the most sensitive to rotational misalignment. Soft contact lenses, on the other hand, are much more stable and less likely to undergo misalignment relative to the visual axis. This is especially true for prism-ballasted lenses, currently available for the correction of spherical and cylindrical errors (e.g. toric lenses). These lenses rotate less than 5° with every blink, which is ideal for HOA correction because coma, trefoil, and astigmatism are tolerant to mis-rotations of up to 60°.⁶⁷

The most common surgical procedure in ophthalmology in patients over 60 years of age is cataract surgery with

removal of the natural crystalline lens and implantation of an intraocular lens (IOL) in the remaining capsular bag. Since nearly 3 million cataract surgeries are performed in the US each year, one can infer that a significant amount of research is currently being focused on designing customized intraocular lenses. Studies have shown that implanted monofocal spherical IOLs induce positive spherical aberrations.^{68,69} To compensate for positive spherical aberration, aspheric IOLs were designed and are commercially available, such as the Tecnis-Z9000 (Pfizer, New York, NY) and SN60WF (Alcon, Fort Worth, TX). These lenses are designed with a prolate anterior surface, hence the term *aspheric*, and have the same radius of curvature at every point on the surface. Clinical studies have shown that implanted aspheric IOLs markedly increase the MTF with a resultant improvement in image contrast in comparison to monofocal spherical IOLs.⁷⁰ Also commercially available are toric IOLs such as the STAAR toric IOL (STAAR Surgical, Monrovia, CA) and the Acrysof SA60TT (Alcon, Fort Worth, TX), which correct corneal astigmatism. The benefit of both aspheric and toric IOLs depends largely on their centration and stability within the capsular bag. In the future, we may encounter light adjustable IOLs, which once implanted in the eye, may be altered to compensate for residual refractive errors and even HOAs by irradiating the optic with blue light to polymerize monomers and set up a diffusion gradient to alter the lens shape (Calhoun Vision, Pasadena, CA).

In conclusion, the "Quest for Super-Vision", as described by leading investigators in the field of wavefront technology, holds a promising and exciting future. In the last decade, large contributions to the field have been made and continue to flourish. The clinician must be aware of these rapid changes to provide patients with state-of-the-art technology to improve their quality of vision and life. Currently there is no perfect way to treat HOAs. Customized corneal ablations, however, offer the most stable form of HOA correction, and the industry is working diligently at perfecting customized soft contact lenses and intraocular lenses.

Accommodation

Adrian Glasser

Introduction

"There is no other portion of physiological optics where one finds so many differing and contradictory ideas as concerns the accommodation of the eye where only recently in the most recent time have we actually made observations where previously everything was left to the play of hypotheses"

H Von Helmholtz (1909)

It is primarily due to Helmholtz¹ that we owe our current understanding of the accommodative mechanism of the human eye (Fig. 3.1). His insight came from his own work and from pioneers before him. Thomas Young² was instrumental in demonstrating that accommodation occurs, not through changes in corneal curvature or axial length as those before him believed,³ but through changes in the curvature of the lens. Young's painstaking anatomical investigations were insufficient for him to rule out the possibility that the crystalline lens received direct innervation from a branch of the ciliary nerves to allow it to contract as a muscle. It was only after the work of Crampton,⁴ who first described the ciliary muscle from his investigation of bird eyes, that a mechanistic description of how the ciliary muscle might alter lens curvatures was proposed by Müller.⁵ Understanding of human accommodation was mired by confusion from numerous investigations of the eyes of birds and other vertebrates, studied for their comparatively large size to gain insight into the human accommodative mechanism (Box 3.1). However, these species are now known to accommodate through mechanisms quite different from humans.^{6–8} Current understanding of accommodation stems from the work of many early investigators including Brücke,⁹ Cramer,¹⁰ Hess,¹¹ Müller,⁵ Helmholtz and Gullstrand.¹ This path was made tortuous by the diversity of accommodative mechanisms of the various vertebrates studied. Possibly the most ancient of accommodative mechanisms is that of the sauropsidae (lizards, birds and turtles). Although these eyes differ from the primate eye, these species share many unusual ocular characteristics among themselves including striated intraocular muscles, bony plates or ossicles in the sclera, attachment of the ciliary processes to the lens equator, the absence of a circumlental space, a lens annular pad, and in some species at least, corneal accommodation and iris-mediated lenticular accommodation.

The wide diversity of avian visual habitats (aerial, aquatic, terrestrial), eye shapes (tubular, globose and flattened), and feeding behaviors in all likelihood dictates their accommodative needs. Corneal accommodation, of considerable value to terrestrial birds, is of no value to aquatic birds where the corneal optical power is neutralized under water. The evolutionarily divergent accommodative mechanisms, or the absence of accommodation in other vertebrates is, by reasonable conjecture, determined by feeding behaviors. Herbivorous animals (sheep, horses, cows, etc.), those which forage and dig for food primarily using olfactory cues (pigs), or those with nocturnal eyes and relatively poor visual abilities (mice, rats, rabbits) have little need for accommodation. Carnivores have better-developed ciliary muscles than these other species, but still have relatively little accommodative ability; the raccoon is the only non-primate terrestrial mammal with substantial accommodative amplitude.¹² Cats are suggested^{13–15} and raccoons¹² and fish shown to translate the lens forward without lenticular thickening.^{16–18} Other adaptations in the lens, iris, or retina allow other lower vertebrates functional near and distance vision, although these cannot be classified as true accommodation since they rely on static optical adaptations.

Among the vertebrates that do accommodate, amplitudes vary considerably. Diving birds have among the largest amplitudes with cormorant having ~50 D¹¹ and diving ducks suggested to have 70–80D.¹⁹ Among the mammals, vervet and cynomolgus monkeys have approximately 20 D,^{20–22} young rhesus as much as 40 D²³ and raccoons about 20 D.¹² Humans, for only a few short childhood years, may have a maximum of about 10–15D measured subjectively²⁴ or about 7–8 D measured objectively,²⁵ but find much less accommodation adequate for most visual tasks. Although accommodative amplitude gradually declines until completely lost by about age 50 years, to most individuals the deficit appears to be of sudden onset when the accommodative amplitude is diminished to a few diopters as presbyopia develops. Although presbyopes may read at intermediate distances, this is almost certainly due to depth of field (see below) resulting from pupil constriction rather than active accommodation. The word presbyopia (Greek, *presby* meaning an aged person and *opsis* meaning vision) possibly derives from Aristotle's use of the term *presbytas* to describe "those who see well at distance, but poorly at

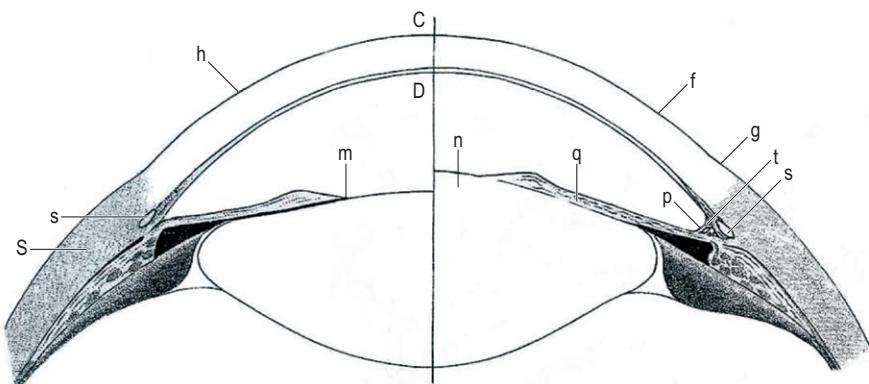

Figure 3.1 Diagram showing the mechanism of accommodation of the human eye as described by Helmholtz. The left half depicts the eye in the unaccommodated state and the right half depicts the eye in the accommodative state. Helmholtz described an increase in lens thickness, an increase in the anterior surface curvature, an anterior movement of the anterior lens surface, but no posterior movement of the posterior lens surface. Key: S, sclera; s, Schlemm's canal; h, cornea; F, side for far vision; m, unaccommodated lens; n, accommodated lens; q, iris; p, trabecular meshwork; f, clear cornea; g, limbus; N, side for near vision; C-D, optical axis. (From Helmholtz von HH. Helmholtz's Treatise on Physiological Optics. Translation edited by Southall JPC in 1924 (original German in 1909). New York: Dover, 1962: vol. 1, ch. 12.)

Box 3.1 Accommodative mechanism

- Accommodation is a dioptric change in optical power of the eye due to ciliary muscle contraction
- Accommodation occurs largely in accordance with the mechanism originally proposed by Helmholtz
- Ciliary muscle contraction moves the apex of the ciliary body towards the axis of the eye and releases resting zonular tension around the lens equator
- When zonular tension is released, the elastic lens capsule molds the young lens into a more spherical and accommodated form
- During accommodation, lens diameter decreases, lens thickness increases, the anterior lens surface moves anteriorly, the posterior lens surface moves posteriorly and the lens anterior and posterior surface curvatures increase, the thickness of the nucleus increases, but without a change in thickness of the cortex
- The increase in curvature of the lens anterior and posterior surfaces results in an increase in optical power of the lens
- The physical changes in the lens and eye result in an increase in optical power of the eye to focus on near objects

near".²⁶ Historically the term was used to describe the condition where the near point has receded too far from the eye due to a diminution in the range of accommodation.²⁷ Despite the wealth of studies of accommodation on vertebrates, only primates are shown to systematically lose the ability to accommodate with increasing age. It may be no coincidence that although absolute life spans differ considerably, the relative age course of the progression of presbyopia is similar in humans and monkeys (Fig. 3.2).

Accommodation

Accommodation is a dynamic, optical change in the dioptric power of the eye allowing the point of focus of the eye to be changed from distant to near objects. In primates this is

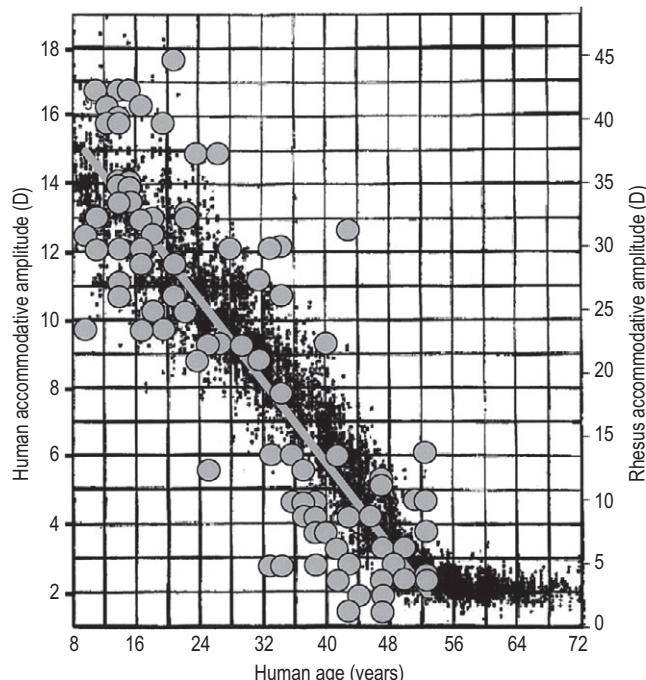

Figure 3.2 Progression of presbyopia in humans (Duane, 1912, small solid black symbols) as measured subjectively using a push-up test, and in rhesus monkeys (Bito et al., 1982, larger gray symbols and solid line) as measured objectively with a Hartinger coincidence refractometer following topical application of the cholinergic agonist pilocarpine. The horizontal axis is in human years and the rhesus data are scaled to human years such that 25 rhesus years is equivalent to 52 human years. The vertical axis is scaled such that the mean amplitudes of 14 D in humans is equivalent to 37 D in rhesus. In humans and rhesus monkeys, presbyopia progresses at the same rate relative to the absolute age span of each species. (From Bito LZ et al. Invest Ophthalmol Vis Sci 1982; 23:23; and Duane A. J Am Med Assoc 1912; 59:1010. Reproduced with permission from Association for Research in Vision and Ophthalmology.)

mediated through a contraction of the ciliary muscle, release of resting zonular tension around the lens equator, a decrease in lens diameter and a “rounding up” of the crystalline lens through the force exerted on the lens by the lens capsule. The increased optical power of the lens is achieved through increased anterior and posterior surface curvatures and increased thickness. In an unaccommodated, emmetropic eye (an eye without refractive error) distant objects at or beyond what is considered optical infinity for the eye (6 m or 20 ft) are focused on the retina. When an object is brought closer to the eye, the eye must accommodate to maintain a clearly focused image on the retina. Myopic eyes, typically too long for the optical power of the lens and cornea combined, are unable to attain a sharply focused image for objects at optical infinity unless optical compensation is provided such as through negative powered spectacle lenses. Myopes can focus clearly on objects closer to the eye than optical infinity without accommodation (i.e. objects at their far point). Young hyperopes are only able to focus clearly on objects at optical infinity through an accommodative increase in the optical power of the eye provided their accommodative amplitude exceeds the amount of hyperopia.

Optics of the eye

Light from the environment enters the eye at the cornea and, in an emmetropic eye, is brought to a focus on the retina through the combined optical power of the cornea and the lens (see Chapter 1). When light from an object is focused on the retina, a clear, sharp image is perceived. This enables the performance of near visual tasks such as reading. If the image is not focused on the retina, these tasks become difficult or impossible to perform without optical compensation to bring the image to focus on the retina.

The optical elements of the eye, cornea, the aqueous humor, the crystalline lens and the vitreous humor all contribute to the optical power of the eye (see Chapters 1 & 2). Specific details for schematic eyes are given in Bennett & Rabbets.²⁸ In the adult human eye an average, normal cornea has a radius of curvature of about +7.8 mm, a thickness of about 0.25 mm near the optical axis and the cornea provides about 70 percent of the optical refracting power of the eye. Light passes from an air environment, with a refractive index of approximately 1.00, through the tear film and into the cornea. The cornea is composed largely of fluid and proteins and therefore has a refractive index greater than air of about 1.376. The optical power of the cornea is due to a combination of the positive radius of curvature and the higher corneal refractive index than the surrounding air. Light then passes through the cornea and into the aqueous humor. Since the refractive index of the aqueous humor is close to that of the cornea (about 1.336) there is relatively little optical effect at the posterior cornea/aqueous interface. Light then enters the anterior surface of the crystalline lens. The surface of the crystalline lens has a refractive index slightly higher than that of the aqueous humor (about 1.386). The lens anterior surface has a radius of curvature of about +11.00 mm which adds to the optical power of the eye. The crystalline lens has a gradient refractive index that progressively increases from about 1.362 at the surface of the

cortex to about 1.406 at the center of the nucleus of the lens. The gradient refractive index of the lens adds additional optical power to the lens because the gradient results in refraction of light throughout the lens. This results in light taking a curved path rather than a straight path through the lens. For simplified optical calculations, the more complex gradient refractive index of the lens is often substituted with a single equivalent refractive index value.

The extent to which the gradient refractive index adds additional optical power to the lens is evident when it is realized that for an equivalent refractive index lens to have the same shape and optical power as a gradient refractive index lens, the equivalent refractive index value must be greater than the highest refractive index value at the center of the gradient refractive index lens. The posterior surface of the crystalline lens has a radius of curvature of about -6.50 mm. Although the posterior lens surface has a negative radius of curvature, it is still a convex surface which adds optical power to the eye, and relatively more so than does the anterior lens surface since the lens posterior surface is more steeply curved than the lens anterior surface. The lens anterior and posterior surface curvatures (as well as the lens gradient refractive index) are important to the optical power of the eye and it is these surfaces that become more steeply curved to allow the accommodative increase in optical power of the lens to occur. Historically it was suggested that the posterior lens surface does not move¹ and that the posterior lens surface curvature does not change appreciably with accommodation.^{1,29,30} However, it is now known that the posterior lens surface does undergo an increase in curvature and moves posteriorly during accommodation as the lens thickness increases.³¹⁻³⁸ Gullstrand suggested that the lens equivalent refractive index must change during accommodation.³⁹ Since the lens shape, axial thickness and equatorial diameter change during accommodation, this dictates that the form of the gradient refractive index of the lens must also change during accommodation.^{40,41} Although the form of the lens gradient refractive index changes as the lens changes shape during accommodation, this does not require a change in the equivalent refractive index of the lens during accommodation, at least to the extent that resolution limits of currently available technology permit this to be discerned.⁴²

The optical requirements for accommodation

The optical power of the crystalline lens increases (i.e. the lens focal length decreases) during accommodation. As a consequence, the eye changes focus from distance to near so the image of a near object is brought to focus on the retina. The dioptric change in power of the eye defines accommodation and accommodation is measured in units of diopters (D). A diopter is a reciprocal meter and is a measure of the vergence of light. Light rays from a point object diverge and are by convention designated to have negative vergence. Light rays converging towards a point image are designated to have positive vergence (see Chapter 1). An object at optical infinity subtends zero vergence at the cornea. The optical interfaces of the eye (the cornea and lens) add positive vergence to draw light rays towards a focus on the retina (Fig. 3.3). When an object is moved from infinity to a point

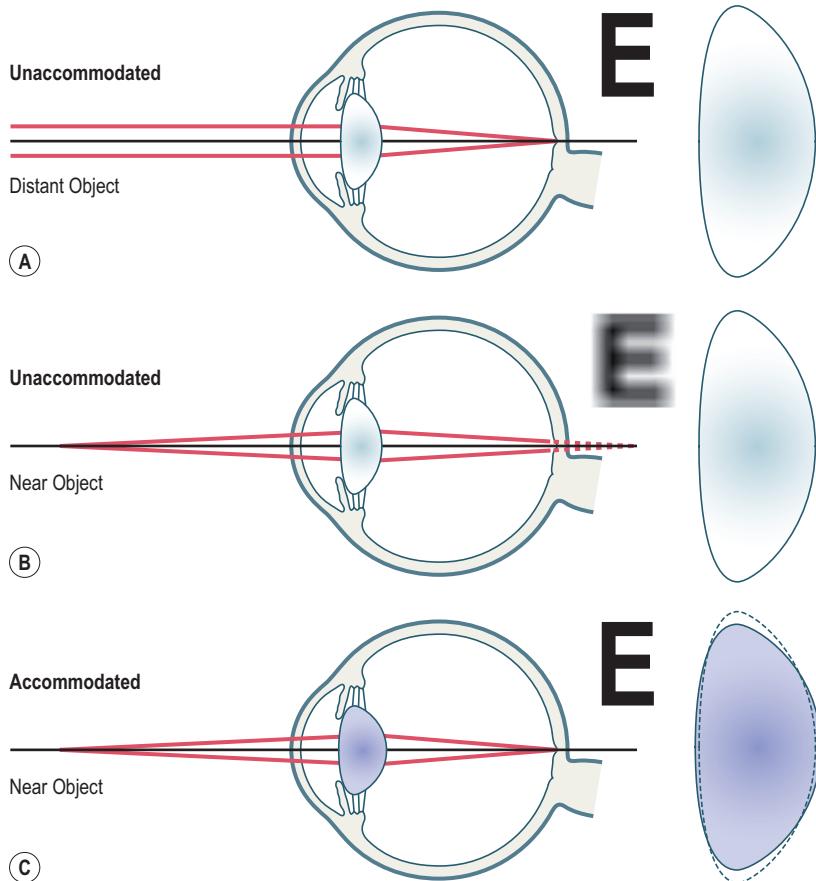

Figure 3.3 The accommodative optical changes in the eye occur through an increase in optical power of the crystalline lens. **(A)** The unaccommodated emmetropic eye is focused on a distant object with the lens in an unaccommodated state. **(B)** A near object subtends divergent rays and in the unaccommodated eye the image would be formed behind the retina and is therefore out of focus when the lens remains unaccommodated. **(C)** In the accommodated eye, the in focus image of the near object is formed on the retina when the lens is in an accommodated state.

closer to the eye, the near object subtends divergent rays on the cornea. To focus on the near object, the optical power of the eye must increase to add positive vergence to the now divergent rays to bring the refracted rays to a focus on the retina. When an emmetropic eye is focused on a distant object the eye is considered unaccommodated. If the eye accommodates from an object at optical infinity to an object 1.0 m in front of the eye, this represents 1.0 D of accommodation. If the eye accommodates from infinity to 0.5 m in front of the eye, this is 2 D of accommodation; from infinity to 0.1 m is 10 D, and so on. The accommodative response is therefore the increase in optical power that the eye undergoes to change focus from an object at optical infinity to the near object.

Depth of field

Clinically, the nearest point of clear vision is typically measured subjectively in an eye corrected for distance vision. This is done by moving a near reading chart towards the eyes while the subject is asked to report when they can no longer sustain clear vision on the near target or when the near target first becomes blurred. Although the reciprocal of this near reading distance expressed in meters is clinically referred to as the accommodative amplitude, this is technically inaccurate. The push-up test is a subjective measure of the difference between the far point and the near point expressed in units of diopters. However, this is not a measure of the true dioptric change in power of the eye because of the depth of field of the eye.

Depth of field is defined as the range over which an object can be moved towards or away from the eye in object space without a perceptible change in the blur or focus of the image. The depth of field of an eye depends on many factors. For example, depth of field is dependent on pupil size. A large pupil results in a wide and steep cone of light converging towards the retina. A small error in image focus with respect to the position of the retina therefore results in a large change in image blur. A large pupil results in a relatively small depth of field. A small pupil results in a narrow and flat cone of light converging towards the retina. Small errors in image focus with respect to the position of the retina result in relatively small changes in image focus. A small pupil therefore results in a relatively larger depth of field.

The depth of field of an eye is dependent on the level of illumination because of the effect that illumination has on pupil diameter. For a brightly illuminated object, pupil size will decrease resulting in an increase in depth of field. The presence of optical aberrations such as astigmatism, coma and spherical aberration also act to increase the depth of field of an eye. The presence of ocular aberrations results in an image that is not in sharp focus on the retina. Therefore, small movements of the object in object space would not perceptibly alter the focus of the image on the retina in an eye with aberrations. With accommodation and with increasing age the pupil size decreases. An effort to focus at near therefore increases the depth of field of the eye due to pupil constriction. When the nearest point of clear vision is assessed using subjective methods, such as the push-up or push-down method, the depth of field of the eye results in

an overestimation of the dioptic change in optical power of the eye. When the near point of clear vision is measured using a subjective push-up method, this overestimates the objectively measured accommodative response amplitude by about 1–2 D.^{43–46} Subjective testing of this nature in complete presbyopes might lead one to believe that about 1 D of accommodation is present, but this is not a true change in optical power of the eye and is therefore called pseudoaccommodation.

Visual acuity

In addition to the depth of field of the eye, acuity or contrast sensitivity of the eye also affect the subjective measurement of the near point of clear vision. The subjective push-up measurement relies heavily on the subject perceiving when the object can no longer be seen in sharp focus. As a near reading target is brought closer to the eye, the subject must decide at what point an object is no longer in acceptable focus. As mentioned, the level of illumination of the target can affect the depth of field of the eye, but illumination also affects the contrast and the brightness of the image. If the target is viewed in dim illumination, it is more difficult to detect when it is in clear and sharp focus. A brightly illuminated reading target will be seen more clearly. The increased illumination provides higher contrast on the target and so smaller changes in focus or blur of the target are more easily detected. While increasing the level of illumination will help to improve the contrast sensitivity and acuity, this will also decrease the pupil size and will thereby increase the depth of field of the eye and so result in a nearer point of perceived clear vision. Further, in cases of cataract or other opacities of the ocular optical media, the image of a near object is not seen clearly and so small changes in the focus of the image are less readily detected. With increasing age the optical clarity of the lens decreases and the prevalence of cataract increases. Retinal disease can also affect visual acuity. Elderly patients often have reduced visual acuity and/or reduced contrast sensitivity, although not solely due to decreased optical performance.⁴⁷ If the near point of clear vision is measured using the subjective push-up test in presbyopes or in patients with cataracts or retinal disease, this will overestimate the true objectively measured accommodative amplitude.^{44,46,48}

The anatomy of the accommodative apparatus

The accommodative apparatus of the eye consists of the ciliary body, the ciliary muscle, the choroid, the anterior and posterior zonular fibers, the lens capsule and the crystalline lens (Fig. 3.4). Theoretical suggestions for a role for the vitreous in accommodation^{49–52} and empirical evidence against a need for the vitreous in accommodation^{53–55} exist. The ciliary muscle is located within the ciliary body beneath the anterior sclera. The ciliary muscle is comprised of three muscle fiber groups oriented longitudinally, radially (obliquely) and circularly. The anterior zonular fibers span the circumlental space extending from the ciliary processes to insert all around the lens equator. These zonular fibers

constitute the suspensory elements of the crystalline lens. Posterior zonular fibers extend between the tips of the ciliary processes and the pars plana of the posterior ciliary body near the ora serrata. The crystalline lens consists of a central nucleus and a surrounding cortex. This lens is surrounded by the collagenous elastic lens capsule.

The ciliary body

The ciliary body is a triangular-shaped region bounded on its outer surface by the anterior sclera and on its inner surface by the pigmented epithelium. It lies between the scleral spur anteriorly and the retina posteriorly. The anterior ciliary body begins at the scleral spur at the angle of the anterior chamber. The base of the iris inserts into the anterior ciliary body. Posterior to the iris, the ciliary processes are found at the anterior-innermost point of the ciliary body and form the corrugated pars plicata of the ciliary body. Posterior to the pars plicata the smooth surface of the ciliary body is called the pars plana. The vitreal surface of the pars plana is spanned by longitudinally oriented posterior zonular fibers.^{56–58} The most posterior aspect of the ciliary body joins to the ora serrata of the retina. The outer surface of the ciliary body beneath the anterior sclera is the suprachoroidal lamina or supraciliaris, formed by a thin layer of collagen fibers, fibroblasts and melanocytes.⁵⁹ Ultrastructural differences exist between the ciliary non-pigmented epithelial cells at the tips of the processes and those in the valleys, the former being adapted for fluid secretion and the latter for mechanical anchoring of the zonule.⁶⁰ The length of the ciliary body from the tips of the ciliary processes to the ora serrata is longest temporally and shortest nasally.⁶¹

The ciliary muscle

The ciliary muscle occupies a triangular-shaped region within the ciliary body beneath the anterior sclera (Fig. 3.5). It has an anterior origin at the scleral spur in close proximity to Schlemm's canal.^{61,62} Anterior ciliary muscle tendons insert into the scleral spur and the trabecular meshwork, which serve as a fixed anterior anchor against which the ciliary muscle contracts.⁵⁹ Posterior to the scleral spur, the outer surface of the ciliary muscle is attached only loosely to the inner surface of the anterior sclera. The posterior attachment of the ciliary muscle is to the stroma of the choroid. The anterior and inner surfaces of the ciliary muscle are bounded anteriorly by the stroma of the pars plicata and posteriorly by the pars plana of the ciliary body. The ciliary muscle fiber bundles beneath the sclera are oriented such that a contraction of the ciliary muscle results in a forward and inward redistribution of the mass of the ciliary body and a narrowing of the ciliary ring diameter due to sliding ciliary muscle movement along the inner surface of the sphere formed by the anterior sclera. This causes the anterior choroid to be pulled forward. The ciliary muscle is a smooth muscle, with a dominant parasympathetic innervation causing contraction mediated by M3 muscarinic receptors and a sympathetic innervation causing relaxation mediated by β_2 -adrenergic receptors. The ciliary muscle is atypical for smooth muscles, in its speed of contraction, the large size of its motor neurons, the distance between the muscle and the

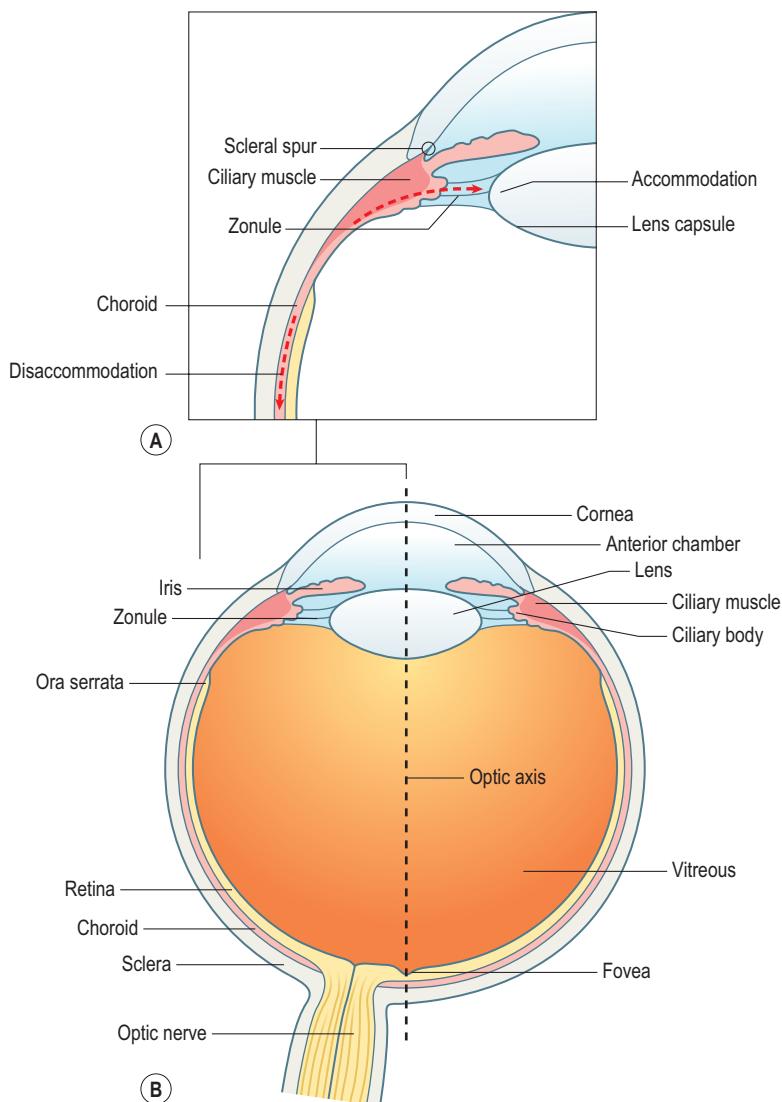

Figure 3.4 Schematic representation of a sagittal section of the anatomy of the accommodative apparatus at the ciliary region of the eye (**A**), in relation to a mid-sagittal section of the eye as a whole (**B**). The schematic shows that the lens capsule, zonule, ciliary muscle and choroid constitute a single elastic ‘sling’ anchored at the posterior scleral canal where the optic nerve leaves the globe, and anteriorly at the scleral spur. The action of accommodation results in a movement of the ciliary body forward and towards the axis of the eye against the elasticity of the posterior attachment of the ciliary muscle and the posterior zonular fibers. With a cessation of an accommodative effort, the ciliary muscle is returned to its unaccommodated configuration through the elasticity of choroid and posterior zonular fibers.

motor neurons, and the unusual ultrastructure of the ciliary muscle cells which in some ways resemble skeletal muscles (indeed, in birds it is a striated skeletal muscle).

There are also regional differences in ultrastructure and histochemistry of the primate ciliary muscle, suggesting that the longitudinal portion may be acting like a fast skeletal muscle to “set” or “brace” the system rapidly, for the contraction of the inner portion to be most effective.⁶³ The ciliary muscle is comprised of three muscle fiber groups identified by their relative positions and orientations, forming a morphologically and functionally integrated three-dimensional structure.⁵⁹ The major group of muscle fibers is the peripheral meridional or longitudinal fibers or Brücke’s muscle.⁹ They extend longitudinally between the scleral spur and the choroid adjacent to the sclera. Located inward to the longitudinal fibers are the reticular or radial fibers. These constitute a relatively smaller proportion of the ciliary muscle. The radial fibers are branching V- or Y-shaped fibers. These radial fibers are attached anteriorly to the scleral spur and the peripheral wall of the anterior ciliary body at the insertion of the iris. They attach posteriorly to the elastic tendons of the choroid. Beneath the radial fibers and positioned more

anteriorly in the ciliary body and closest to the lens are the equatorial or circular fibers or Müller’s muscle. These constitute the smallest proportion of the ciliary muscle.

The division of the ciliary muscle into three muscle fiber groups is somewhat artificial. In reality, there is a gradual transition from the outermost longitudinal muscle fibers to the radial fibers to the innermost circular muscle fibers with some intermingling of the different fiber types. A contraction of the ciliary muscle results in a contraction of all three muscle fiber groups together. With a contraction of the ciliary muscle there is a gradual rearrangement of the muscle bundles, with an increase in thickness of the circular portion and a decrease in thickness of the radial and longitudinal portions.⁵⁹ A contraction of the entire ciliary muscle as a whole pulls the anterior choroid forward, moves that apex of the ciliary processes towards the lens equator and serves the primary function of releasing resting zonular tension at the lens equator to allow accommodation to occur.

The zonular fibers

The zonular fibers are a complex meshwork of fibrils. Fibrils 70–80 nm in diameter⁶⁴ are grouped into fiber bundles

estimated to be between 4–6 to 40–50 micrometers in diameter.^{64,65} The zonule is composed of the non-collagenous carbohydrate-protein mucopolysaccharide and glycoprotein complexes that are secreted by the ciliary epithelium. The zonular fibers are elastin-based elastic fibers and are thought

to be much more elastic than the lens capsule. Their primary function is to stabilize the lens and allow accommodation to occur. Since the zonule is not a continuous tissue, but is composed of fibers, it also allows fluid flow from the posterior chamber behind the iris through to the vitreous chamber (see Chapter 11).

The attachment of the zonular fibers to the lens capsule is superficial with few fibers penetrating into the capsule to form a mechanical (possibly similar to Velcro) or chemical union.⁶⁸ From scanning electron microscopy this anterior zonule crossing the circumlental space and extending to the lens is alternatively described as:

- (i) consisting of three fiber strands running to the anterior, equatorial and posterior lens surfaces,⁶⁶ or
- (ii) fibers that insert along a circular line on the anterior and posterior surface of the lens with some fibers inserting directly on the equator,^{64,65,67} or
- (iii) a zonular fork with two main fiber groups extending to the lens anterior and posterior surfaces with finer bundles seemingly of relative unimportance running to the lens equator,⁵⁷ or
- (iv) successive sagittal lines of insertion from lens anterior to posterior surface and two coronal lines of insertion, one where the fibers insert onto the capsule around the anterior surface and another where the fibers insert onto the capsule around the posterior surface.⁶⁹

Although no systematic crossing of anterior zonular fiber was observed by McCulloch,⁶⁹ crossing of anterior zonular fibers has been observed in other preparations^{54,64,65} and was documented in early diagrams from histology of this tissue (Fig. 3.6). From histological preparations, when an appropriate plane of section is obtained, a continuous line of zonular insertion into the entire lens equator is seen.⁶⁹ Unfixed, dissected human eye specimens show a continuous meshwork of fibers uniformly covering the entire lens equator, and show crossing of zonular fibers.⁵⁴

Observations of the ciliary region during accommodation show that the posterior ciliary body slides forward against the curvature of the anterior sclera, moving the posterior insertion of the posterior zonular fibers forward. However, contraction of the ciliary muscle stretches the posterior

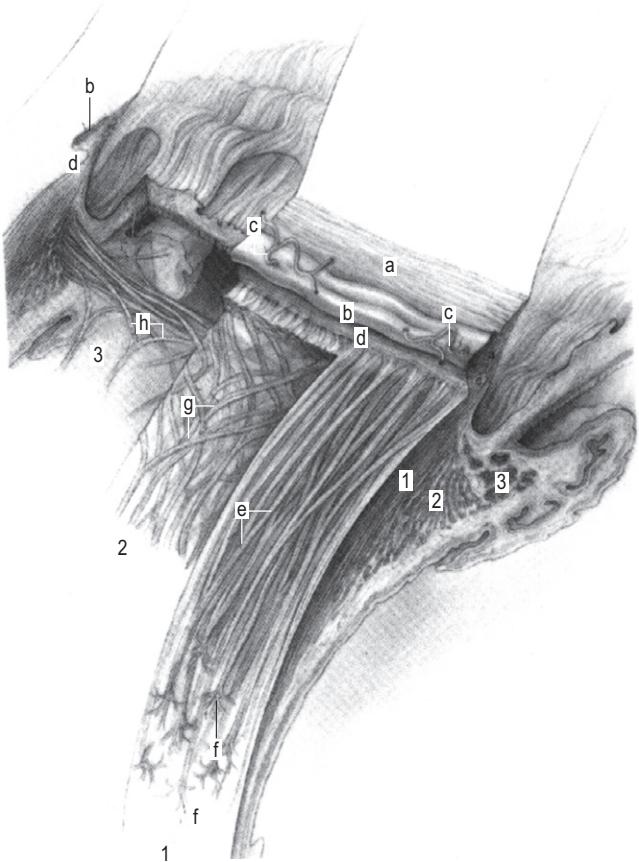

Figure 3.5 Drawing of the ciliary muscle showing a sequential dissection following removal of the outer layers of the globe to reveal the orientation of the underlying ciliary muscle fibers. After removal of the overlying sclera (right) first the meridional or longitudinal fibers, then the reticular or radial fibers and finally the equatorial or circular fibers (left) of the ciliary muscle are revealed. (Reproduced with permission from Hogan MJ, Alvarado JA, Weddell JE. Histology of the human eye. An atlas and textbook. Philadelphia: WB Saunders, 1971.)

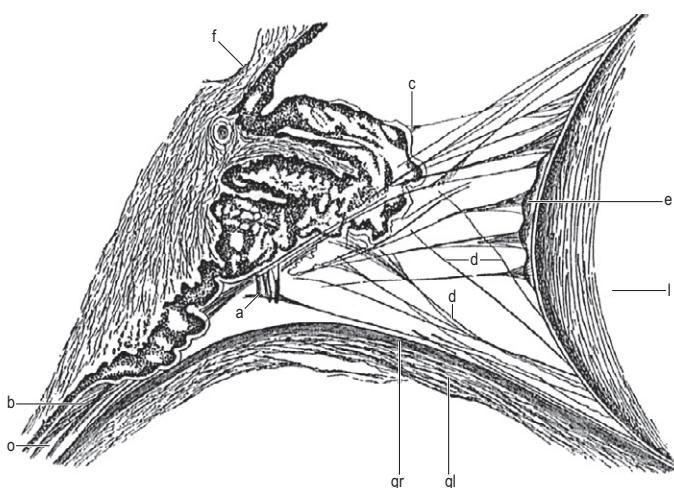

Figure 3.6 Due to the delicate nature of the zonule and the difficulties in observing it, descriptions of the insertion of the anterior zonule onto the lens equator differ. Early anatomists with relatively crude methods produced remarkably accurate diagrams of the structure of the anterior zonule showing crossing of zonular fibers, fiber bundles of varying thickness and insertion into a thickened region of the capsule at the lens equator. Some clumping of zonular bundles is evident in this depiction which is not seen in unfixed specimens. (From Helmholtz von HH. Treatise on Physiological Optics. Translation edited by Southall JPC in 1924 (original German in 1909). New York: Dover, 1962: vol. 1, ch. 12.)

attachment of the ciliary muscle due to a forward and inward movement of the tips of the ciliary muscle and ciliary processes. This suggests that the posterior zonular fibers may similarly assist in pulling the ciliary muscle back to the unaccommodated configuration after cessation of an accommodative effort.

The lens capsule

The crystalline lens is surrounded by the lens capsule (Fig. 3.6). This is a thin, transparent, elastic membrane secreted by the lens epithelial cells largely composed of collagen type IV.⁷⁰ Fincham was the first to attribute the accommodative change in shape of the lens to the forces exerted on the young lens by the lens capsule.⁷¹ Fincham studied the capsule in histological section and found it to be of relatively uniform thickness in non-accommodating mammals. However, in primates Fincham found it to be thickest at the mid-peripheral anterior surface, thinner towards the lens equatorial region with a posterior peripheral thickening, but thinnest at the region of the posterior pole of the lens³¹ (Fig. 3.7). Several aspects of Fincham's idealized description of

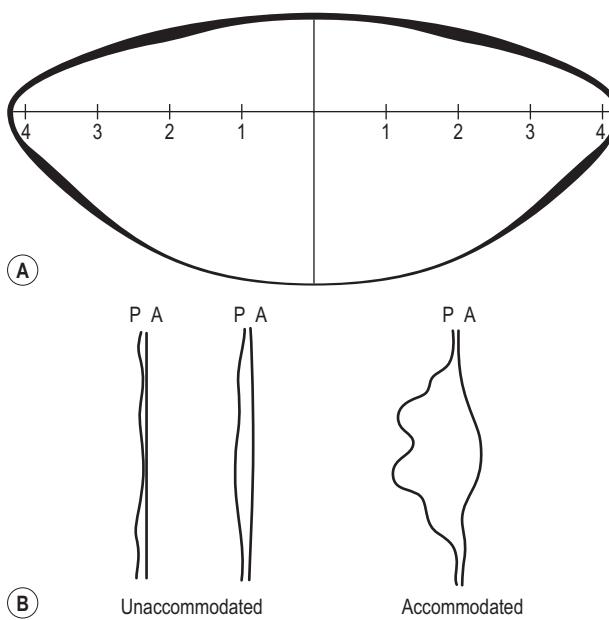

Figure 3.7 (A) Fincham's idealized depiction of the regional variations in thickness of the human lens capsule showing the anterior mid peripheral thickening. The equatorial region of the capsule, to which the zonular fibers insert show regional thinning. This idealized depiction is supported by more recent results, although with some age-related regional variations. (B) Appearance of the anterior (A) and posterior (P) capsule in the eye of a patient in whom the lens was displaced and lost from the eye after ocular injury. When the patient focused with the contralateral eye on a distant object (left) the capsule was relatively taught. When the patient focused on a near object, (middle) capsule became more flaccid. After contraction of the ciliary muscle (right) with eserine, the capsule became completely flaccid. Observation by Graves of the behavior of the empty capsule in this aphakic patient eye served as the basis for Fincham's recognition of the role of the capsular tension holding the lens in a flattened and unaccommodated state when the ciliary muscle is relaxed and the capsule rounding the lens into a more spherical and accommodated form when the ciliary muscle contracts. (From Fincham EF. The mechanism of accommodation. Br J Ophthalmol 1937; Monograph VIII:7–80.)

the capsule have been largely confirmed in a more recent study, although with some age-related changes in thickness.⁷⁰ The capsule is about 11–15 µm thick at the anterior pole. There is an anterior, mid-peripheral thickening of the capsule that is about 13.5–16 µm thick. This is located more central to the region of zonular insertion into the capsule around the lens equator. The equatorial region of the capsule, to which the anterior zonular fibers insert, is about 7 µm thick at the lens equator and does not appear to change systematically with age. The posterior capsule thickness decreases to a minimum at the posterior pole of about 4 µm, without a posterior mid-peripheral thickening⁷⁰ (Fig. 3.8).

The crystalline lens

The lens consists largely of lens fiber cells composing the nucleus and cortex. On the anterior lens surface beneath the capsule is a layer of lens epithelial cells. The embryonic nucleus remains present at the center of the lens throughout life as the cortex grows progressively around it by the addition of an increasing number of layers of lens fiber cells. The deeper layers of lens epithelial cells on the lens anterior surface differentiate to become lens fiber cells. The proliferation of lens epithelial cells and their differentiation into lens fiber cells continues throughout life. Because the lens is contained within the capsule, lens epithelial cells do not slough off as do epithelial cells in other organ systems such as those lining the skin and gut. Therefore, the lens continues to grow throughout life. After adolescence the human lens undergoes a linear increase in mass with increasing age.⁷² In vivo, with increasing age, lens thickness increases^{73,74} with a resulting increase in the anterior surface and posterior surface curvatures.⁷⁵ Although lens thickness and surface curvatures change systematically with increasing age, this occurs without a systematic age-related change in lens diameter.^{74,76,77}

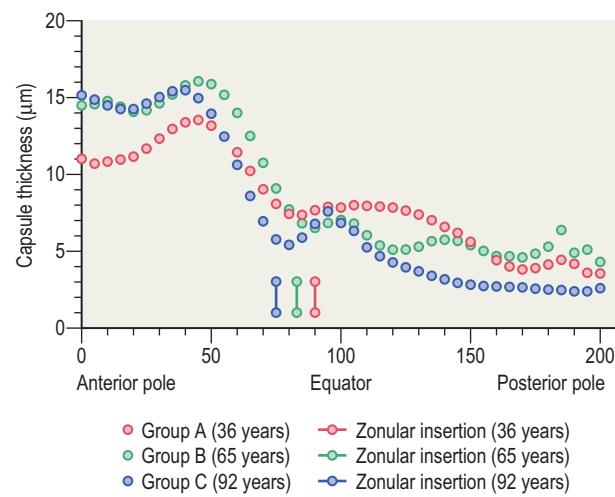

Figure 3.8 Average regional thickness of human capsules from lenses of three different age groups. Symbols connected by vertical lines depict the most anterior positions of the capsules to which the zonular fibers insert. Note regional thinning of the capsule at and posterior to this region is more pronounced in the older lenses. A pronounced anterior mid peripheral thickening of the capsule is evident in all age groups. (From Barraquer RI, Michael R, Abreu R, et al. Invest Ophthalmol Vis Sci 2006;47:2053–60. Reproduced with permission from The Association for Research in Vision and Ophthalmology.)

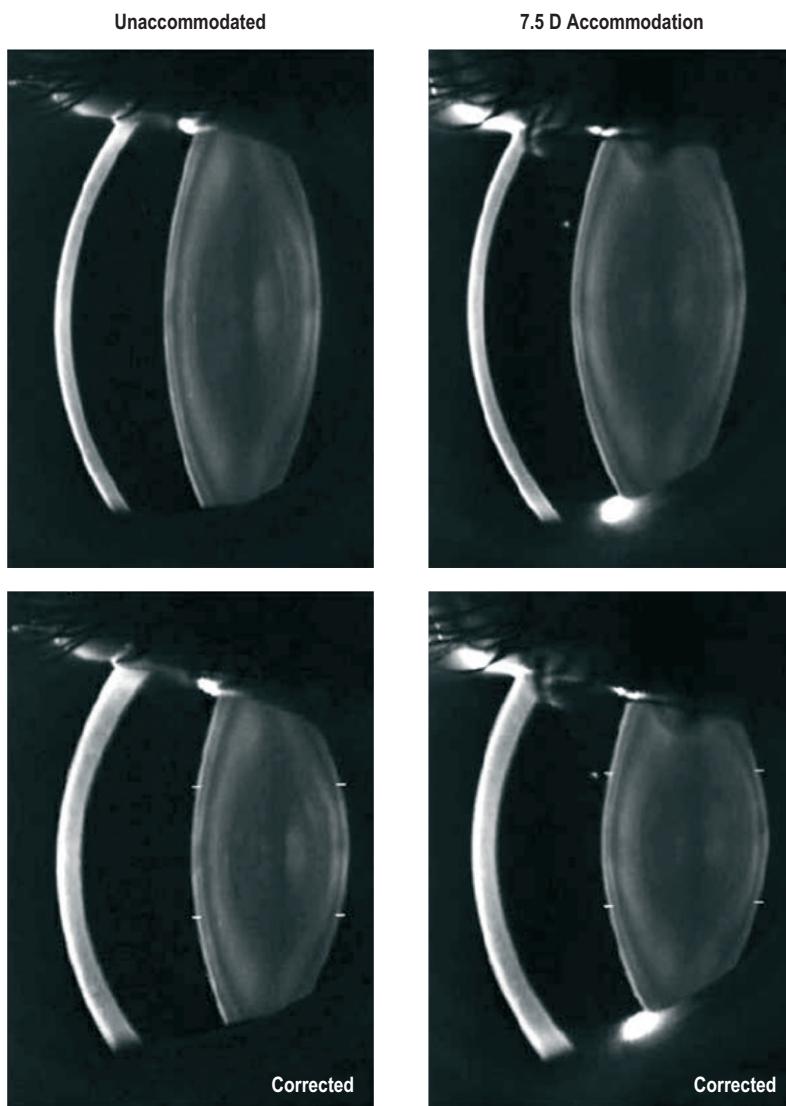

Figure 3.9 Scheimpflug slit-lamp images of a dilated human eye focused at distance (top left) and to a 7.5 D accommodative stimulus (top right). Each optical interface posterior of the anterior corneal surface is progressively distorted by the optical effects due to the preceding optical interfaces. Optical correction of this distortion applied to the images in the unaccommodated (lower left) and accommodated (lower right) eye shows the true dimensions and dimensional changes in anterior chamber depth, lens thickness and lens surface curvatures during accommodation. (From Dubbelman M, van der Heijde GL, Weeber HA. Vision Res 2005; 45:117–32. Reproduced with permission from Elsevier Science Ltd.)

The crystalline lens has a gradient refractive index, with a refractive index of 1.385 near the poles and a higher refractive index of 1.406 at the center of the nucleus. The lens is not optically homogeneous and when viewed through a slit-lamp, several optical zones of discontinuity are observed which allow visual differentiation of the lens nucleus from the surrounding lens cortex (Fig. 3.9). The unaccommodated young adult human lens is roughly 9.0 mm in diameter and 3.6 mm thick. The lens thickness increases by approximately 0.5 mm with 8 D of accommodation.³³

The mechanism of accommodation

Current understanding of the accommodative mechanism is largely in accord with the description provided by Helmholtz in 1855^{1,78} (Fig. 3.10). Although Fincham⁷¹ and more recent investigations have added further to understanding the accommodative mechanism, the basic tenets are in

accord with those originally described by Helmholtz. When the young eye is unaccommodated and focused for distance, the ciliary muscle is relaxed. Resting tension on the zonular fibers spanning the circumlental space and inserting around the lens equator (collectively called the *anterior* zonular fibers⁵⁷) apply an outward directed tension around the lens equator through the lens capsule to hold the lens in a relatively flattened and unaccommodated state. For the eye to focus at near, the ciliary muscle contracts, the inner apex of the ciliary body moves forward and towards the axis of the eye⁷⁹ (Fig. 3.11). This inward movement of the apex of the ciliary muscle stretches the posterior attachment of the ciliary muscle and releases resting tension on all zonular fibers around the lens equator. The lens capsule then molds the lens into a more accommodated form.^{54,71} The capsule provides the force to cause the lens to become accommodated.^{54,71,72} A clear role for the lens capsule in accommodation stems from observations by Graves of the effect of accommodation on the empty lens capsule in an otherwise

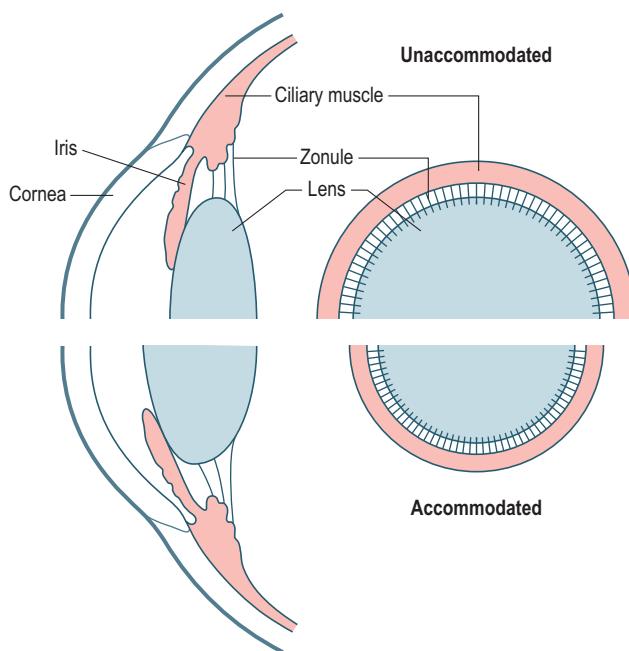

Figure 3.10 Diagram showing the Helmholtz accommodative mechanism. In the upper half of the diagram the eye is in the unaccommodated state. In the lower half the eye is in the accommodated state. The left side shows a sagittal section and the right side a frontal section through the anterior segment of the eye. In the unaccommodated state resting tension on the zonule at the lens equator holds the lens in a relatively flattened and unaccommodated state. When the ciliary muscle contracts, this resting zonular tension is released and the lens is allowed to round up through the force exerted on the lens substance by the lens capsule. Lens axial thickness increases, lens equatorial diameter decreases, anterior chamber depth decreases and vitreous chamber depth decreases with accommodation. The lens anterior and posterior surface curvatures increase to increase the optical power of the lens. (Redrawn from Koretz JF, Handelman GH. Sci Am 1988; July:92–99.)

healthy aphakic eye in which the lens was absent.^{80,81} When the patient looked at a distant object, the anterior and posterior capsule was taught and flat. When the patient focused on a near object, the capsule became mildly flaccid and the surfaces separated. An eserine stimulated contraction of the ciliary muscle resulted in a completely slack capsule (see Fig 3.7). Fincham concluded that resting zonular tension at the lens equator pulls outward on the capsule to hold the lens in the unaccommodated state and when the eye is accommodated, the resting tension on the zonular fibers is released to allow the capsule to mold the lens into the accommodated form.⁷¹

Further evidence of the role of the capsule comes from in vitro experiments. In dissecting a young human or monkey eye, when the zonular fibers around the lens equator are cut, the isolated young lens with the intact capsule assumes a maximally accommodated form. If the capsule is then cut and carefully removed from the isolated lens, the young decapsulated lens substance assumes a maximally unaccommodated form.^{71,72,82} Further, mechanical stretching studies of partially dissected young human and monkey eyes show that applying an outward directed stretching force to the lens via the capsule and anterior zonular fibers will pull the lens into a flattened and unaccommodated state and releasing

the zonular tension will allow the lens to become accommodated through the forces exerted by the capsule on the lens (Fig. 3.12). Such in vitro mechanical stretching studies reliably and reproducibly produce accommodative optical changes in the lens that match the accommodative optical changes in vivo in the living eye.^{54,55,83–85}

During accommodation, lens diameter decreases systematically in response to voluntary accommodation, brain stimulated accommodation or pharmacologically stimulated accommodation^{77,86–89} (Figs 3.13, 3.14 & 3.15). Lens thickness increases^{33–35,38,90} and the central anterior surface curvature and to a lesser extent the central posterior surface curvature increases.^{36–38} These physical changes in the lens are relatively linearly correlated with the accommodative optical changes in the eye (Fig. 3.16). The increased lens surface curvature results in an increase in the optical power of the crystalline lens. Anterior chamber depth decreases due to the forward movement of the anterior lens surface and the vitreous chamber depth decreases due to the posterior movement of the posterior lens surface^{33,34,38} (Fig. 3.16). About 75 percent of the increase in lens thickness is accounted for by the anterior movement of the anterior lens surface and about 25 percent of the increase in lens thickness is accounted for by a posterior movement of the posterior lens surface.^{33,34}

When the accommodative effort ceases, the ciliary muscle relaxes and the elasticity of the posterior attachment of the choroid pulls the ciliary muscle back into its flattened and unaccommodated configuration. The outward movement of the apex of the ciliary body once again increases the tension on the anterior zonular fibers around the lens equator to pull the lens via the capsule into a flattened and unaccommodated form.

Variants on the Helmholtz accommodative mechanism have been suggested to include an essential role for the vitreous and differential pressure changes in the eye.^{51,52,91} However, accommodation still occurs after vitrectomy⁵³ and mechanical stretching studies of dissected eyes in which the vitreous is absent and no pressure differential can exist, results in normal accommodative optical changes to the lens,^{54,83,85} thereby obviating a role for the vitreous or for differential pressure changes in the eye. A revisionist theory of accommodation originally proposed by Tscherning⁹² has been espoused.^{93–95} This theory is opposite to the Helmholtz accommodative mechanism in that it paradoxically requires an *increase* in lens equatorial diameter during accommodation, a flattening of the peripheral lens surfaces and an increase in curvature of the lens central surfaces. However, there exists no experimental evidence in support of the supposed accommodative increase in lens diameter. In fact, numerous studies demonstrate that lens diameter decreases systematically during accommodation.^{76,77,79,86,87,89}

Accommodative optical changes in the lens and eye

For the unaccommodated emmetropic eye to focus on a near object requires an increase in optical power of the eye. This occurs through an increase in optical power of the lens. The

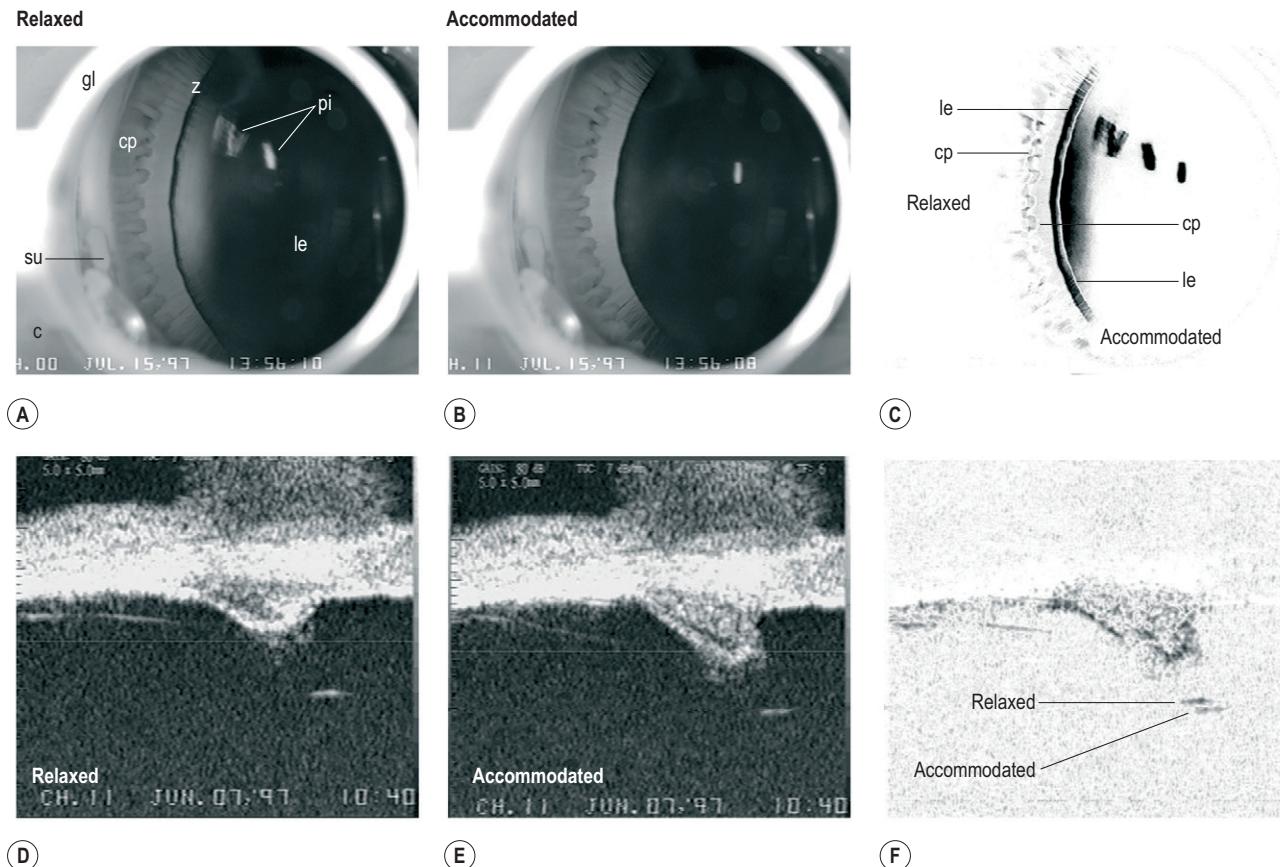

Figure 3.11 Gonioscopy images of an iridectomized rhesus monkey eye: (A) unaccommodated and (B) accommodated state. (C) The subtracted difference image shows the accommodative movements of the lens equator and ciliary processes as well as the relative stability of the eye. The lens equator and the ciliary processes move away from the sclera with accommodation to roughly the same extent. Key: c, cornea; gl, gonioscopy lens; su, suture; cp, ciliary processes; le, lens; z, zonule; pi, lens Purkinje images. Ultrasound biomicroscopy images of an iridectomized rhesus monkey eye in the (D) unaccommodated and (E) accommodated states. (F) The subtracted difference image shows the accommodative movements of the ciliary muscle and the lens equator. The apex of the ciliary muscle and the lens equator (short horizontal line and identified with arrows) move away from the sclera with accommodation. (Reprinted from Glasser A, Kaufman PL. Ophthalmology 1999; 106:863–72, with permission from Elsevier Science Ltd.)

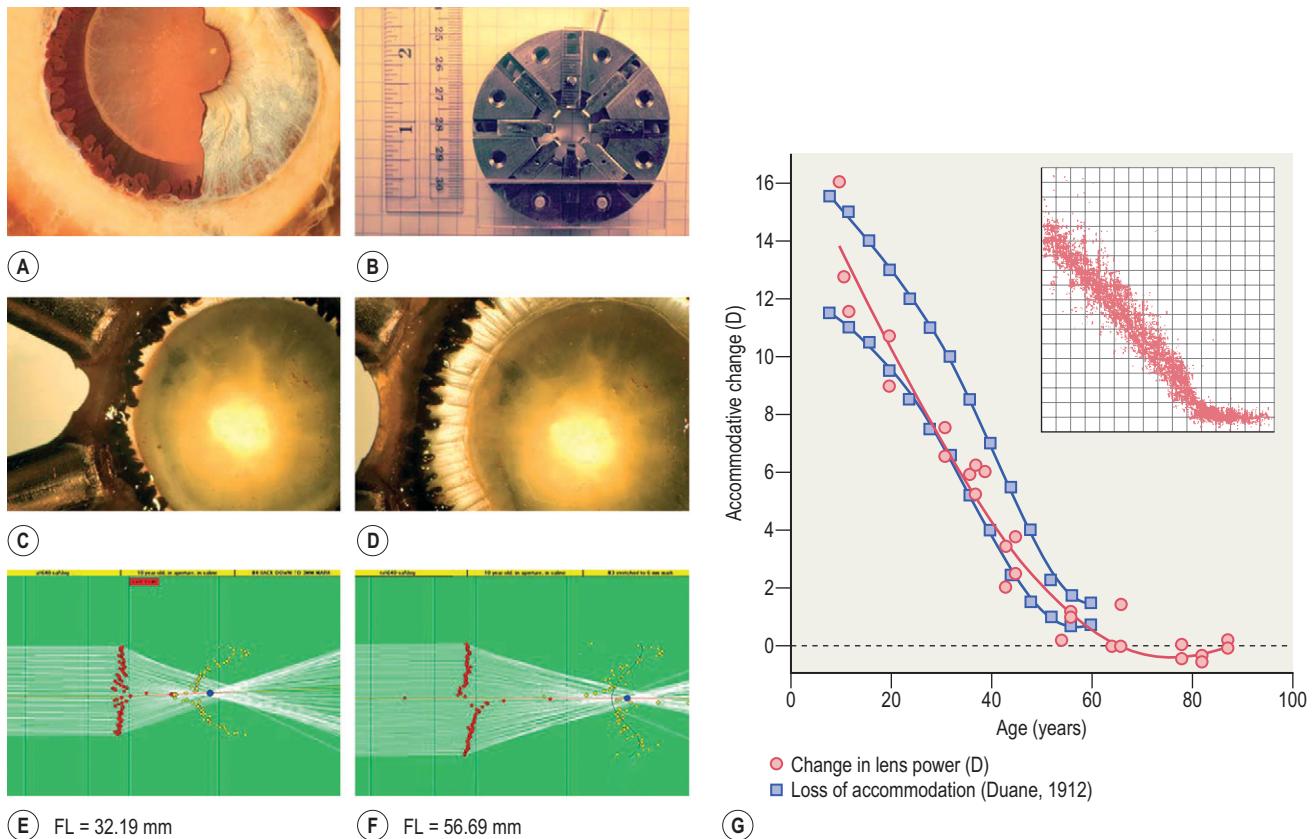

Figure 3.12 (A) The anterior segment of a partially dissected 54-year-old human donor eye glued to (B), the arms of a mechanical stretching apparatus. The zonule can be completely relaxed (C) allow the lens to become maximally accommodated, or (D) the zonule stretched to disaccommodate the lens. (E) Scanning laser measurements of the focal length of a 10-year-old human lens measured in the unstretched, accommodated state (focal length = 34.39 mm) and (F) in the maximally stretched and unaccommodated state (focal length = 57.69 mm). Parallel laser beams enter the lens, are refracted by the lens (at red symbols, left), and cross the optical axis (dark horizontal line) at the position identified (yellow symbols, right). The distance from the lens (red symbols, left) to the average focus of all rays (blue symbol) represents the lens focal length. (G) The change in focal length converted to diopters (red line and circles) as a function of the applied stretch shows that young lenses undergo 12–16 D of change in power with stretching, but that by age 60, the same extent of applied stretch results in no change in lens power. The data from the human lenses are plotted in the inset in G, together with Duane's (1912) data (blue lines, diamonds) showing the range of accommodative amplitudes from some 1500 subjects as measured with a push-up technique. Key: c, conjunctiva; cp, ciliary process; le, lens; pi, lens Purkinje images; Gl, Goldmann lens. (C) Subtracted difference image to show the accommodative movements of the lens. The lens undergoes a concentric decrease in diameter and the ciliary processes move concentrically inward with accommodation. There is a virtual absence of eye movements as evident from the absence of additional detail in the difference image. (D) The outlines of the accommodated and unaccommodated lens diameter are shown superimposed on the difference image demonstrating a concentric decrease in lens diameter with accommodation in accordance with the Helmholtz accommodative mechanism. Key: acc, accommodated; rel, relaxed. (From Glasser A, Kaufman PL. Ophthalmology 1999; 106:863–72, with permission from Elsevier Science Ltd.)

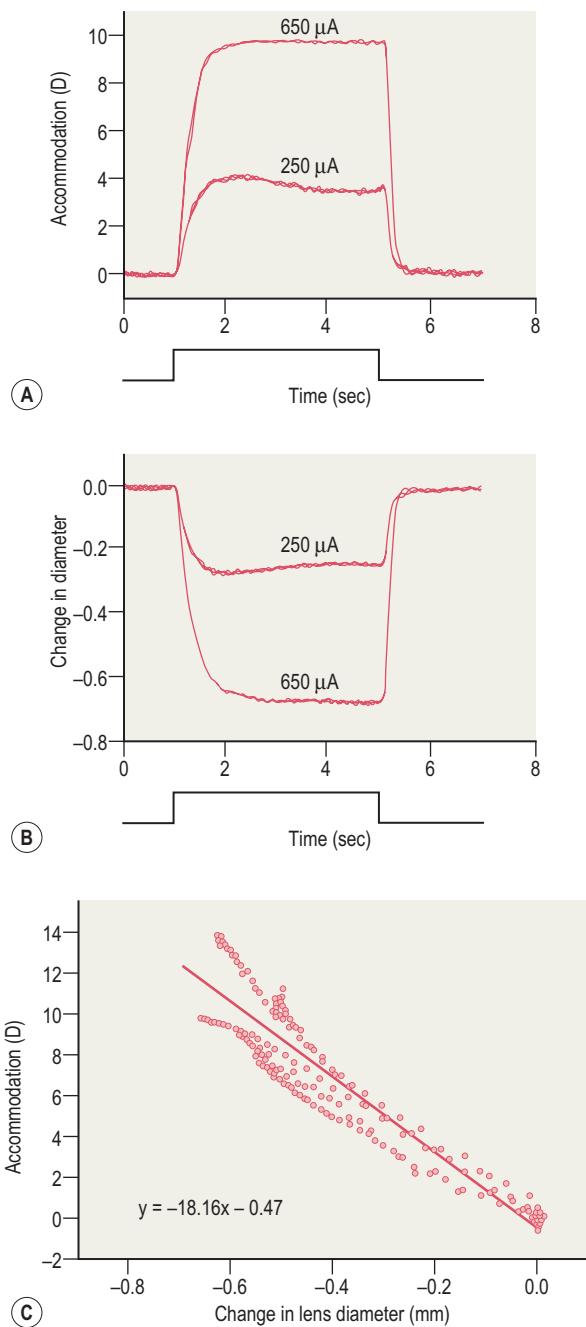

Figure 3.14 (A) Dynamically recorded accommodative refractive changes in response to two different stimulus current amplitudes applied to the Edinger-Westphal nucleus of the brain in an anesthetized rhesus monkey. (B) Dynamically measured accommodative decreases in lens diameter in response to the same two current stimulus amplitudes for which accommodation was measured in panel A. (C) Correlation of the optical refractive changes and decreases in lens diameter during accommodation from panels A & B. Lens diameter decreases linearly by about 600 μm for about 12 D of accommodation. (From Glasser A, Wendt M, Ostrin L. Invest Ophthalmol Vis Sci 2006; 47:278–86. Reproduced with permission from The Association for Research in Vision and Ophthalmology.)

accommodative increase in optical power of the lens comes about from an increase in the lens anterior and, to a lesser extent, posterior surface curvatures. Several other physical changes in the eye and lens also occur during accommodation that have optical effects on the eye. Lens thickness

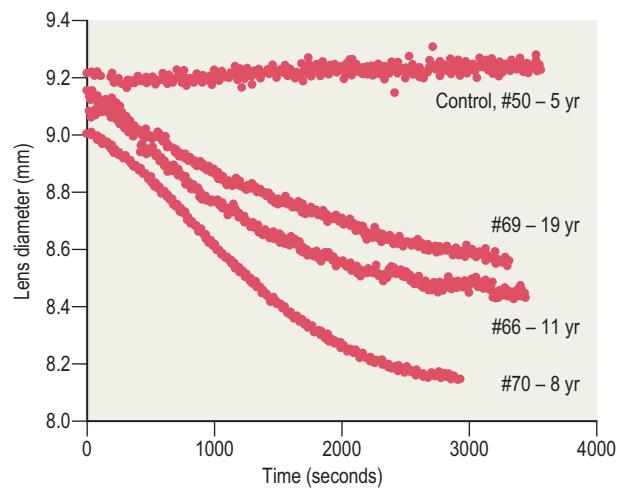

Figure 3.15 Time-course of topical pilocarpine stimulated accommodative changes in lens diameter in the eyes of anesthetized, iridectomized rhesus monkey and from a control experiment in which saline was applied to the eye. Pilocarpine stimulated accommodation causes a systematic and progressive decrease in lens diameter, the magnitude of which is larger for younger monkeys with higher accommodative response amplitudes. (From Wendt M, Croft MA, McDonald J, et al. Exp Eye Res 2008; 86:746–52. Reproduced with permission from Elsevier Science Ltd.)

increases, the lens anterior surface moves anteriorly to reduce anterior chamber depth and the lens posterior surface moves posteriorly to increase anterior segment length. The lens asphericity changes and the pupil constricts. In addition, because the lens has a gradient refractive index, the form of which is constrained by the shape and size of the lens, since the lens changes shape, so too must the form of the lens gradient refractive index. All of these accommodative physical changes in the eye and lens result not only in an increase in optical power, but also in other changes in the ocular aberrations of the eye.

Simple paraxial vergence calculations show that for parallel rays incident on a simple biconvex lens, if lens thickness alone is increased, lens power decreases. In an eye, however, if the lens thickness increases, this must occur in conjunction with either a decrease in anterior chamber depth or an increase in anterior segment length consequent to the increase in lens thickness. For a distant object, the lens inside the eye does not have parallel light incident on it, but rather convergent light due to refraction by the cornea. Simple paraxial schematic eye calculations show that if lens thickness alone is increased without a change in lens curvatures but with a resultant decrease in anterior chamber depth, the result is an overall increase in power of the eye. The accommodative increase in optical power of the lens however is primarily due to an increase in the lens surface curvatures.

Since the lens anterior surface is flatter than the lens posterior surface, for a given change in curvature the anterior surface will undergo a relatively greater increase in optical power than the posterior surface. The accommodative optical increase in power of the eye is therefore ultimately due to a complex combination of optical and physical changes in the lens and the eye. This results not only in an

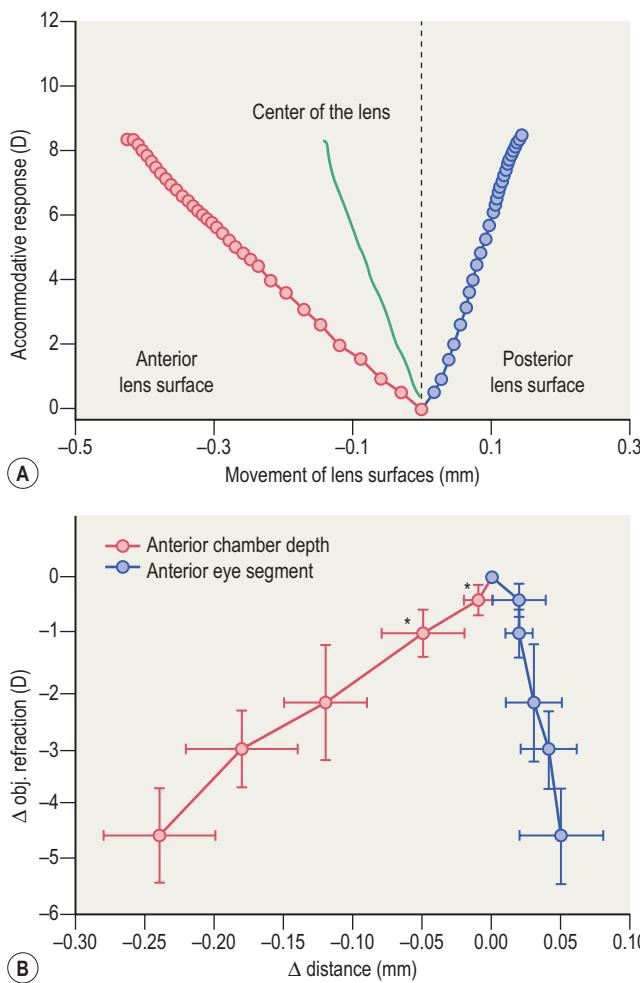

Figure 3.16 (A) Continuous a-scan ultrasound recordings of the changes in the anterior segment of the eye and the accommodative refractive change in a rhesus monkey eye in response to Edinger-Westphal stimulated accommodation. As the eye accommodates, the anterior lens surface (solid symbols) moves anteriorly towards the cornea and the posterior lens surface (open symbols) moves posteriorly towards the retina. The calculated geometric center of the lens (midway between the lens anterior pole and the lens posterior pole – thin line) shows a slight anterior movement towards the retina. (From Vilupuru AS, Glasser A. *Exp Eye Res* 2005; 80:349–60. Reproduced with permission from Elsevier Science Ltd) (B) Objective accommodative refractive changes measured with infrared photorefraction and anterior segment biometric changes measured with partial coherence interferometry simultaneously during visual stimulus driven accommodation in humans show changes similar to those recorded in the monkey eye. In this case, the accommodative refraction is graphed as negative numbers. The anterior surface of the lens moves anteriorly and the posterior surface of the lens moves posteriorly during accommodation. (From Bolz M, Prinz A, Drexler W, Findl O. *Br J Ophthalmol* 2007; 91:360–5. Reproduced with permission from the BMJ Group.)

increase in optical power of the eye, but also accommodative changes in ocular aberrations of the eye. In particular, accommodation is accompanied by an increase in negative spherical aberration of the eye and lens^{83,84,96–98} (Figs 3.17 & 3.18). In addition, the iris constricts during accommodation, to decrease the optical entrance pupil of the eye. This too has optical effects. Simply decreasing the entrance pupil diameter results in an overall reduction in optical aberrations of the eye.⁸⁴ Further, in an eye with negative spherical aberration, in which the paraxial rays are focused closer to

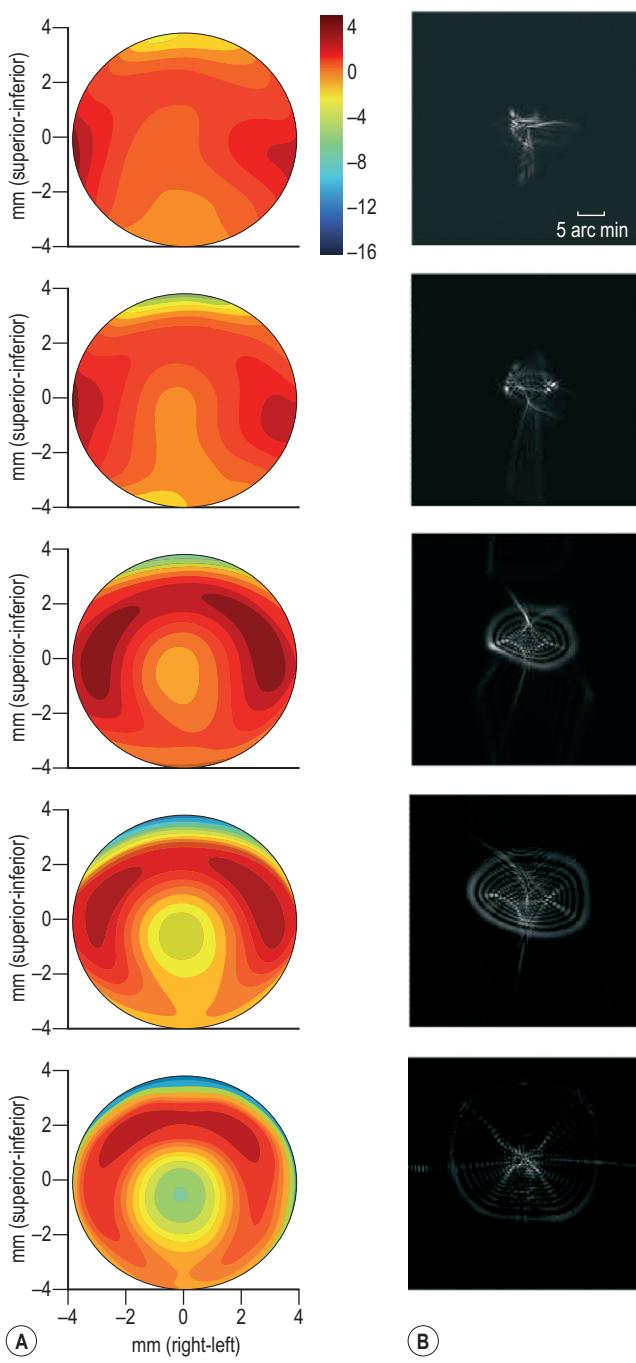

Figure 3.17 Accommodative changes in ocular wavefront aberrations in vivo in an iridectomized rhesus monkey eye. (A) Graphs show the wavefront maps with the defocus term removed calculated for an 8 mm entrance pupil diameter. (B) Images show the corresponding retinal point spread functions calculated with the defocus term removed. As accommodation increases progressively (top to bottom: 0 D, 1.41 D, 3.88 D, 5.93 D, and 10.91 D), there is a progressive increase in the ocular wavefront error resulting in an increase in the size of the retinal point spread function. There is a marked increase in negative spherical aberration with increasing accommodation with a relatively greater change in overall optical power of the eye towards the center than at the periphery. There is relatively little change in optical power near the periphery of the eye which is normally occluded by the iris. (From Vilupuru AS, Roorda A, Glasser A. *J Vis* 2004; 4:299–309. Reproduced with permission from The Association for Research in Vision and Ophthalmology.)

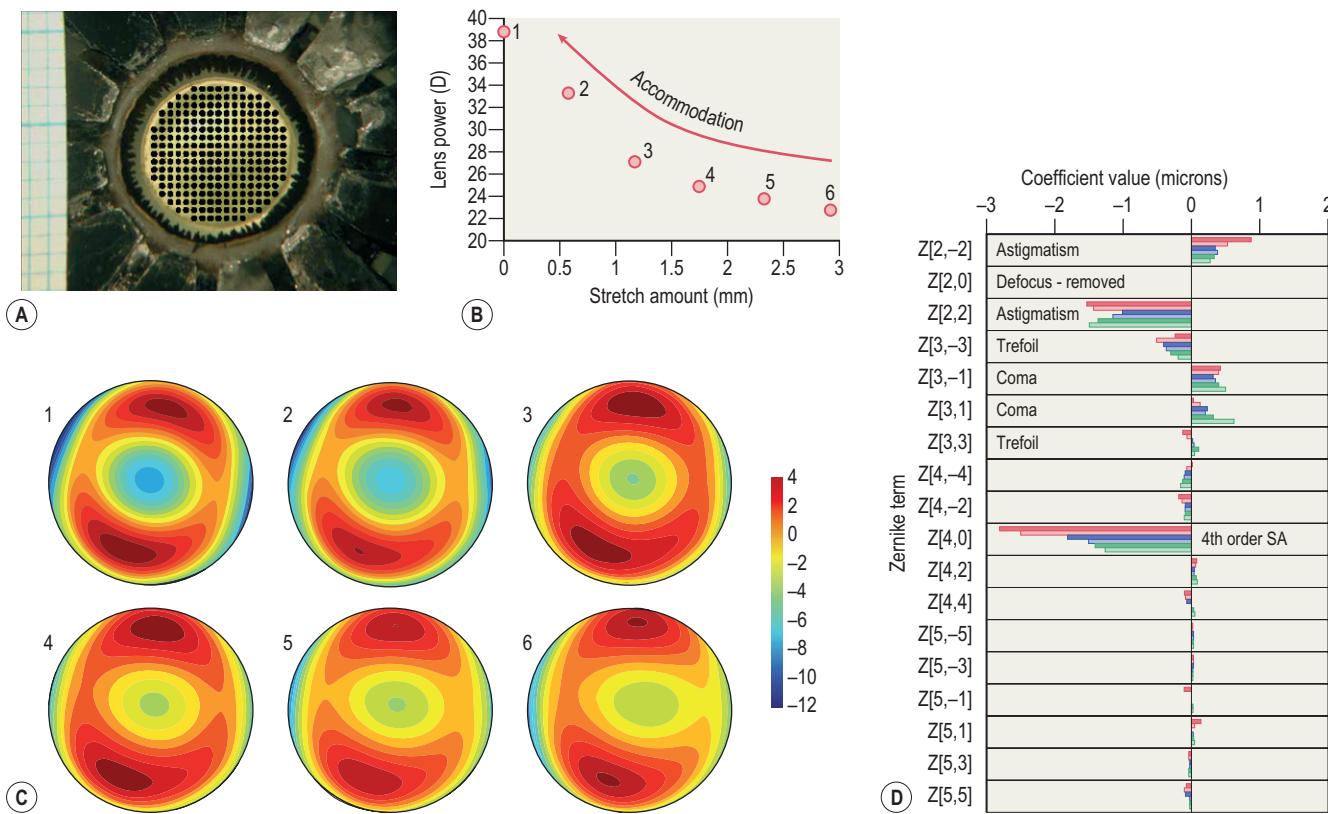

Figure 3.18 Accommodative optical changes during in vitro mechanical stretching of a rhesus monkey lens. **(A)** Optical scanning laser measurements of the rhesus monkey lens. A total of 241 laser beams are sequentially passed through the lens parallel to the optical axis. Reconstruction of the laser scans permits the optical wavefront aberrations of the lens to be calculated. **(B)** The optical accommodative change in lens power as a function of stretch applied to the lens. Position 1 corresponds to the unstretched, maximally accommodated lens. Position 6 corresponds to the maximally stretched, unaccommodated lens. **(C)** Wavefront aberration contour plots with the defocus term removed showing the decrease in wavefront error of the lens in going from the maximally accommodated, unstretched lens in position 1 to the maximally stretched and unaccommodated lens in position 6. **(D)** Graph showing the changes in the terms of the Zernike coefficients of the wavefront as the lenses are stretched. In particular, Zernike term $Z[4, 0]$ shows a systematic increase in 4th order negative spherical aberration (SA) of the lens as the lens progresses from the unaccommodated to the maximally accommodated state. (From Roorda A, Glasser A. J Vis 2004; 4:250–61. Reproduced with permission from The Association for Research in Vision and Ophthalmology.)

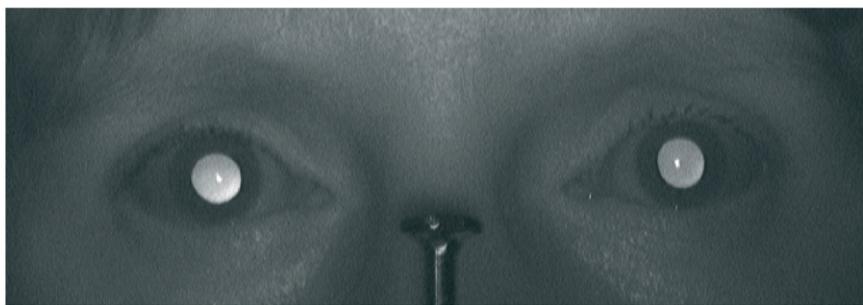

the lens than the peripheral rays, a pupil constriction alone would result in an overall increase in optical power of the eye simply due to the constricted iris occluding the more weakly refracted peripheral rays.⁸⁴ In a young eye, when accommodation occurs, all these various optical changes occur in concert.

The stimulus to accommodate

At rest, the eyes have some residual or resting level of accommodation amounting to approximately 0.5–1.5 D. This is called tonic accommodation or a lead of accommodation. In a young eye, an effort to focus at near causes three physiological responses; the eyes accommodate, the pupils constrict and the eyes converge (Fig. 3.19). Together these three physiological functions are referred to as the accommodative triad or the near reflex. These three actions are neuronally coupled through the preganglionic parasympathetic innervation extending from the Edinger-Westphal (EW) nucleus in the brain. The intraocular muscles (iris and ciliary muscle) are innervated by the postganglionic ciliary nerves entering

the sclera. The extraocular muscles of the eyes are innervated by the oculomotor (III), the trochlear (IV) and abducent (VI) nerves, the axons of which originate from motor nerve nuclei in the brainstem, which receive impulses from the EW nucleus. Accommodation and convergence and the accompanying pupil constriction are neuronally coupled in the brain and therefore in the two eyes. An accommodative stimulus such as minus lens induced blur or a proximal stimulus presented monocularly to one eye results in binocular accommodation, convergence and pupil constriction. Similarly, a convergence stimulus presented monocularly to one eye results in pupil constriction, convergence and accommodation in both eyes.

Accommodation can be stimulated in a variety of ways. It can be driven by blur cues alone – if myopic blur is presented to one or both eyes by placing a negative powered lens in front of the eye(s), both eyes will accommodate to attempt to overcome the imposed defocus (Fig. 3.20). If convergence is stimulated in a young eye, such as by having the subject fixate a distant target and placing base-out prisms in front of the eyes, pupil constriction and accommodation will also occur. In an emmetropic eye,

(A)

(B)

Figure 3.19 Infrared photorefraction of the eyes showing the accommodative triad of accommodation, pupil constriction and convergence as the subject changes fixation from **A**, a distant object to **B**, a near object held a few centimeters beyond the nose. The accommodative optical change in power of the eye is evident from the photorefraction images by virtue of the brighter crescents of light in the lower parts of the pupils when the eyes are focused on the near object.

blur and vergence driven accommodation can be induced simultaneously with a proximal stimulus. If a near object is presented, coupled accommodation and convergence occur. As the accommodative stimulus increases, the objectively measured accommodative response is typically less than the magnitude of the stimulus. This is called the lag of accommodation.

Studies in which the accommodative response is measured with a wavefront aberrometer show that calculated retinal image quality for the near object actually improves when the lag of accommodation is taken into account.⁹⁹ Therefore, although the overall refraction of the eye lags the accommodative stimulus the lag may serve to maximize retinal image quality for near objects due to the ocular aberrations of the eye. As the stimulus amplitude increases, there is a linear increase in the accommodative response, which due to the lag of accommodation has a slope less than 1. As the stimulus is increased further, lag increases as the maximum accommodative response amplitude is reached. The accommodative stimulus function is therefore "S" shaped with the initial lead, the intermediate linear region with some lag, and the final plateau region. Studies aimed at addressing how the eye detects defocus have shown that the longitudinal chromatic aberration (LCA) of the eye plays a role. The imperfect optics of the eye cause considerable LCA with the result that shorter wavelengths of light are focused closer to the lens than longer wavelengths. Removing the LCA by using monochromatic light or optically neutralizing or reversing the LCA disrupts the normal reflex accommodative response.^{100–103}

Accommodation can also be pharmacologically stimulated. Topical application of muscarinic cholinergic agonists, such as pilocarpine, results in direct pharmacological stimulation of the ciliary muscle.^{46,48,104} In rhesus monkeys

pharmacologically stimulated accommodation is of higher amplitude than centrally stimulated accommodation.^{105–107} This is attributed to a supramaximal pharmacological contraction of the ciliary muscle and iris which is greater than the contraction due to a parasympathetically driven stimulus from the brain.¹⁰⁸ In addition, drug stimulated accommodation ultimately produces a net forward movement of the natural lens that does not occur with centrally stimulated accommodation in monkeys¹⁰⁹ or voluntary accommodation in humans.¹¹⁰ Rapid and strong pupil constriction also occurs with pharmacological stimulation, but convergence does not. Anticholinesterases, such as echothiophate iodide, when applied topically produce a resting tonus of accommodation.²² This is due to the spontaneous release of acetylcholine at the neuromuscular junction, normally broken down by cholinesterases, inducing an accommodative tonus. Accommodative esotropia, often occurring in uncorrected hyperopes due to the need to accommodate to focus on distant objects, can be treated with topical echothiophate. By producing increased accommodative tonus without increased neuronal input, the stimulus for convergence is reduced, and the accommodation convergence /accommodation (AC/A) ratio is reduced, helping to alleviate the accommodative esotropia.¹¹¹ Anticholinesterases produce a long response to a single administration and so are more therapeutically useful than shorter-acting cholinomimetics like pilocarpine.

The pharmacology of accommodation

Accommodation occurs when the post-ganglionic parasympathetic innervation to the ciliary muscle releases the neurotransmitter acetylcholine at the neuromuscular junctions.

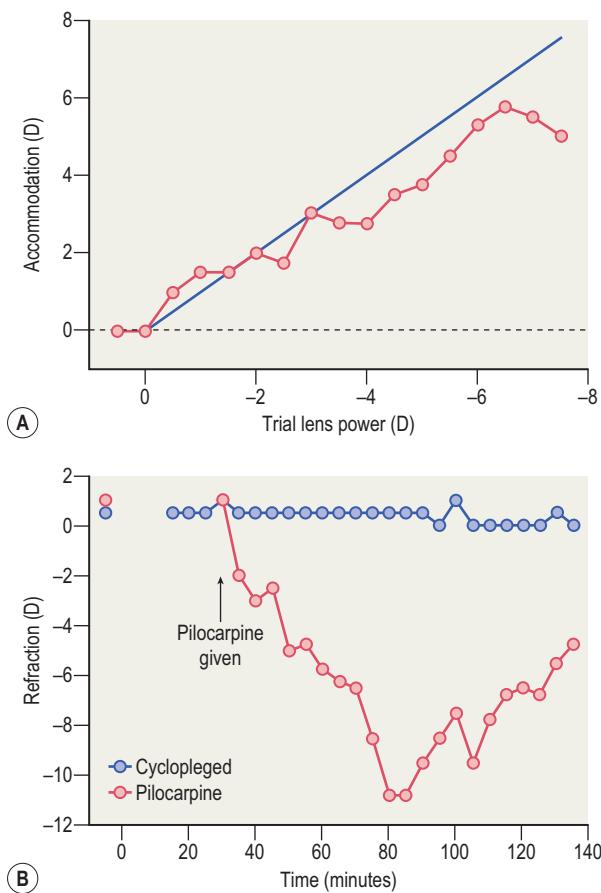

Figure 3.20 Two techniques for objective measurement of accommodation in humans. **(A)** The accommodative response of the right eye is measured with a Hartinger coincidence refractometer as increasingly powered negative trial lenses are placed in front of the left eye of a 35-year-old subject viewing a distant letter chart. As the letter chart is viewed through increasing powered negative trial lenses, the accommodative response increases towards the maximal accommodative amplitude of about 6 D. A further increase in lens power results in no further increase in accommodation. **(B)** The right eye is dilated with one drop of phenylephrine and the baseline resting refraction is measured 4 times in both eyes. The left eye (blue symbols) is then cyclopleged with 1 percent cyclopentolate and accommodation is stimulated in the right eye (red symbols) with one drop of 6 percent pilocarpine. Refraction is measured in each eye three times at the end of each 5-minute interval with a Hartinger coincidence refractometer. The pilocarpine stimulated accommodative response in the right eye of the same 35-year-old subject as in (A) reaches a maximum of 11 D approximately 30 minutes after instillation of pilocarpine. In this subject, the pilocarpine stimulated accommodative response is greater than the voluntary accommodative response elicited from negative lens induced defocus.

Acetylcholine is a muscarinic agonist which binds with the ciliary muscle muscarinic receptors to cause the muscle to contract. Topically applied muscarinic agonists, such as pilocarpine also bind to the muscarinic receptors and cause ciliary muscle contraction. Thus accommodation can be stimulated by topically applied pilocarpine.^{46,48,104,110} This results in an involuntary monocular accommodative response which in some individuals can be of higher amplitude than voluntary accommodation and is greater in eyes with lighter colored irides than in eyes with darker

Box 3.2 Measurement of Accommodation

- Subjective measurement of accommodation relies on a subject's perception of the clarity of focus of a visual target as the target is moved towards the eyes
- Subjective estimation of near reading distance overestimates the accommodative response amplitude, largely due to depth of field of the eye
- Depth of field of the eye increases as the pupil constricts and since the pupil constricts during accommodation, this will further increase the depth of field of the eye
- Objective measurement of accommodation can be accomplished by measuring the refractive change in optical power of the eye with an objective instrument such as an autorefractor or an aberrometer as the eye changes focus from a distant target to a near target

colored irides.⁴⁸ Individuals with dark irides (brown) are less sensitive to topically applied drugs because of increased pigment epithelium in the iris and ciliary muscle which binds topically applied agents and decreases their bioavailability. The effect of ocular pigmentation on the ocular hypotensive response to pilocarpine through the action of the drug on the ciliary muscle, is well known.¹¹² Accommodation can also be pharmacologically blocked. This is accomplished by temporary pharmacological paralysis of the ciliary muscle and is called cycloplegia. Cycloplegia can be induced by topical application of muscarinic antagonists such as atropine, cyclopentolate or tropicamide. These agents competitively bind to and block the muscarinic receptors, thereby preventing the agonists from causing accommodation.

Measurement of accommodation

Although objective methods are available for measurement of accommodation (Box 3.2), unfortunately, clinically the subjective measurement of the near point of clear vision is most often used. Subjective measurements overestimate the true accommodative optical change in power of the eye (Fig. 3.21). The subjective push-up method requires the patient to gradually move a near letter chart towards the eyes and report when a near letter chart can no longer be maintained in clear, sharp focus. The reciprocal of the distance from the eyes and the near reading chart is then used as a measure of accommodative amplitude in diopters. There are many reasons why subjective measurement of accommodation should be avoided. The endpoint of the subjective push-up test requires a subjective evaluation of best image focus by the subject and this endpoint varies between individuals. Subjective evaluation of the point of best focus can be influenced by depth of focus, visual acuity, contrast sensitivity of the eye, and contrast of the image, for example. A dimly illuminated reading chart may provide a poor stimulus to accommodate or may not allow an accurate recognition of defocus. Different levels of illumination alter pupil diameter and therefore depth of focus of the eye thus influencing the near point of clear vision. Subjective push-up measurements are also confounded by the increasing angular subtense of the object. As a reading chart is brought closer to the eye,

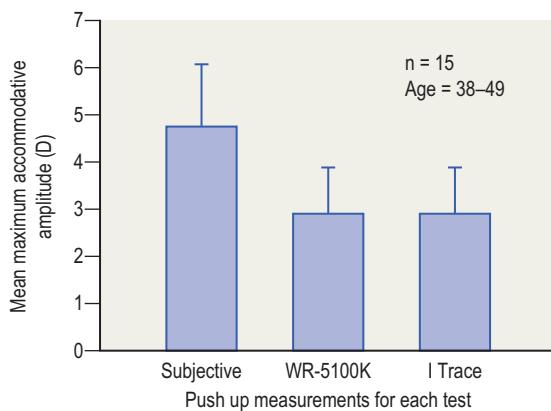

Figure 3.21 Comparison of subjectively measured and objectively measured accommodative amplitudes in 15 human subjects ranging in age from 38 to 49 years. Subjectively measured accommodation was assessed with the push-up test in which the subjects report the nearest point of clear vision. Accommodative amplitude is determined as the reciprocal of the distance between the eyes and the near reading chart in meters. This is compared with objective measurements of the dioptric change in power of the eye as measured with two objective instruments – the WR-5100K Grand-Seiko autorefractor and the iTrace aberrometer. For the objective tests, first distance refraction was measured and then the near stimulus was pushed-up towards the eyes as the objective instruments measured the refraction of the eyes. Objectively measured accommodative amplitude is determined as the maximum dioptric change in spherical refraction of the eyes. The subjective push-up test significantly overestimates the objectively measured accommodative response amplitudes. (From Win-Hall DM, Glasser A. J Cataract Refract Surg 2008; 34:774–84. Reproduced with permission from Elsevier Science Ltd.)

this results in an increased retinal image size and hence increased legibility of the letters as they are brought closer. Although this can be avoided by carefully controlling the image angular magnification with scaled letter sizes, this is not done with the subjective push-up test.

Subjective measurement of accommodative amplitude can also be done by placing negative powered trial lenses in front of one or both eyes to blur a distant letter chart. The optically induced blur stimulates accommodation in an attempt to maintain a sharp focused image on the retina. The negative lens power is progressively increased until the smallest legible letter line of a distance Snellen letter chart can no longer be maintained in clear focus.¹¹³ Accommodative amplitude is determined by the strongest powered negative lens through which the smallest legible Snellen letter line can still be read clearly. This is still a subjective test and prone to the same sources of errors as the subjective push-up test. Subjective push-up tests are also an inaccurate measure of accommodative amplitude because of the lag of accommodation. It is well known that the accommodative optical response of the eye lags behind the stimulus and that this lag increases as the stimulus amplitude increases. Therefore the dioptric vergence of the stimulus is expected to be less than the accommodative response. Subjective methods traditionally used for evaluating accommodative amplitude are inherently inaccurate and overestimate true accommodative amplitude. Near vision can be improved through non-accommodative optical means. Multifocal intraocular lenses or multifocal contact lenses for example allow some degree

of functional near vision to presbyopes, but through static, non-accommodative, optical means. Similarly, astigmatism or ocular aberrations provide some degree of multifocality to the eye. The ability to read at near does not unequivocally imply that accommodation occurs, and subjective methods to measure accommodation cannot differentiate between true accommodation, depth of field or optical compensation such as with multifocal optics.

Since accommodation results in a change in the optical refractive power of the eye, accommodation can readily be measured objectively. Objective methods provide a true measure of accommodative amplitude of the eye. Accurate objective measurement of accommodation can be done statically^{44,113,114} or dynamically.^{115–119} Autorefractors, refractometers or aberrometers are suitable instruments for objective accommodation measurements. These instruments provide a measure of the refraction of the eye as the eye changes focus between a distant and a near target. The accommodative response amplitude is then determined as the difference between the refraction when looking at a distant target and the refraction when looking at a near target. Subjective measurements in presbyopes may suggest some accommodation is present, but it is only when objective methods are used that a complete loss of active accommodation is demonstrated at the endpoint of presbyopia.^{45,46} The success of objective instruments to measure maximal accommodation relies on the accuracy of the instrument as well as on the ability to elicit the maximum accommodative response from the subject. If the subject does not produce an accommodative response, no accommodation can be measured.

Objective instruments differ in whether they measure statically or dynamically. If a single static measurement is made, this may miss the point of maximum accommodation. Dynamic measurements can provide an indication of how much the accommodative response varies over time. Dynamic optometers provide a real-time graphic display of the accommodative response and record data from which a reliable measure of true accommodative amplitude can be calculated. The success of these instruments at measuring maximal accommodation also depends on how well a distance and near target can be presented to the subject and whether the near target can be viewed monocularly or binocularly by the subject. To stimulate accommodation, the subject must be presented with a compelling accommodative stimulus and the subject must elicit an accommodative response.

Accommodation can be stimulated in a number of ways. If a negative powered trial lens is placed in front of one eye while viewing a distant letter chart, the consensual accommodative response can be measured in the contralateral eye.^{46,48} This method of measuring the accommodative response suffers the disadvantage that the convergence response accompanying accommodation occurs entirely in the eye being measured since the eye being defocused with the trial lenses maintains primary gaze position as it fixates on the distant letter chart. Unless the instrument being used to measure accommodation is realigned with the optical axis of the converged eye, an off-axis refraction measurement will result which can introduce inaccuracies. Accommodation can also be stimulated by topically applied muscarinic agonists (pilocarpine, for example) and the resulting

accommodative response measured periodically over 30–45 minutes using a refractometer or an autorefractor until the maximal accommodative response is attained^{46,48} (see Fig. 3.20B). This is a slow time-course for an accommodative response, but if the refraction is measured frequently enough, the maximum accommodative response amplitude can be determined. The accommodative amplitude measured in this way is independent of a visual accommodative stimulus and of patient subjectivity since the application of the drug produces the accommodative response. However, the magnitude of the accommodative response does depend on drug concentration, intraocular pharmacokinetics, iris pigmentation and other non-accommodative factors that influence how much drug or how quickly the drug reaches the ciliary muscle.

Presbyopia

Presbyopia (Box 3.3) is the gradual age-related loss of accommodative amplitude which begins early in life and ultimately culminates in a complete loss of accommodation by about 50 years of age.^{45,46,120} Subjective measurements of accommodation may suggest that about one diopter of accommodation remains after about 50 years of age.^{24,45,46} However, this small remaining apparent response is due to depth of field effects that are inherent in the subjective measurement of accommodation. Objective measurement shows a linear decline of accommodation by about 2.5 D per decade to zero at about 50–55 years of age.^{45,46,120}

Presbyopia results in the complete loss of the normal physiological function of accommodation roughly two-thirds of the way through the human life-span. Few other

normal physiological functions undergo such a profound and systematic deterioration so soon and with such certainty in so many. Presbyopia is likely a consequence of age-related changes in the accommodative apparatus that begin early in life and continue beyond the point at which accommodation is ultimately completely lost, possibly continuing until death. Since two-thirds of human accommodative amplitude is lost between ages 15 and 45, this is the age group that may be of most interest in trying to understand the progression of presbyopia. However, while what happens after the age of 45–50 may not be of particular relevance as far as causes of presbyopia, these age-related changes may well represent a part of the continuum that earlier in life leads to presbyopia. The causes of presbyopia may be best understood by studying how and why accommodation is lost, but understanding the age-related changes that continue beyond 50 years of age may also provide important insights.

Factors contributing to presbyopia

Since the accommodative apparatus is composed of many different tissues and systems and accommodation is a complex interaction of these components, there are potentially many factors that contribute to the loss of accommodation. Aging affects many of these tissues and systems to differing extents and so the reasons why accommodation is lost as a consequence of aging are potentially many and complex. Although several fundamental changes occur, such as stiffening of the lens, which must have a profound impact on the ability of the eye to accommodate, other aspects of ocular aging may also impact accommodative amplitude. Further, many studies show age-related changes in the accommodative structures that progress well beyond that age at which accommodation is lost. Ultimately, at its endpoint, presbyopia is due to a loss of the fine balance of forces that permit the accommodative structures to cause a change in optical power of the lens in the young eye. In the following sections, age-related changes in the ciliary muscle, lens, lens capsule, zonule and associated tissues are considered in terms of their possible roles in presbyopia.

Age-related changes in rhesus ciliary muscle

Since accommodation is lost with increasing age, and accommodation is mediated by the ciliary muscle, the question arises whether presbyopia is due to a loss in ability of the ciliary muscle to contract. Since pupillary constriction and convergence are part of the near reflex but do not decrease with increasing age, this suggests that loss of muscle contractility is not a normal part of presbyopia.¹²¹ The iris, like the ciliary muscle, is an intraocular muscle and the iris continues to contract with light stimulus and with an accommodative effort even in presbyopes, therefore it is likely that the ciliary muscle continues to contract with an accommodative effort in presbyopes. Accommodative excursion of the ciliary muscle is reported to be reduced in presbyopic rhesus monkeys, as seen from both direct observation in surgically aniridic animals in which accommodation is stimulated by an electrode placed in the Edinger-Westphal nucleus,¹²² and from histologic study of ciliary muscle topography in eyes

Box 3.3 Presbyopia

- Presbyopia is the age-related loss of accommodative amplitude
- The accommodative optical change in power of the eye with an effort to focus at near is completely lost by about 55 years of age
- Many aspects of the accommodative apparatus of the eye change with increasing age
- Lens thickness increases, the lens anterior surface curvature increases, anterior segment length increases, the apex of the unaccommodated ciliary body progressively moves inward towards the axis of the eye, the elastic modulus of the capsule increases
- Lens stiffness increases exponentially with increasing age
- The stiffness gradient of the human lens increases with increasing age. In the young lens, the nucleus is softer than the cortex, but with increasing age the nucleus undergoes a greater increase in stiffness than the cortex such that in the older lens the nucleus becomes stiffer than the cortex
- Ultimately, the human lens completely loses the ability to undergo accommodative changes in optical power
- The ciliary muscle retains the ability to contract and to undergo accommodative movements in the presbyopic eye
- Presbyopia is, at its endpoint, due to a complete loss in accommodative ability of the lens

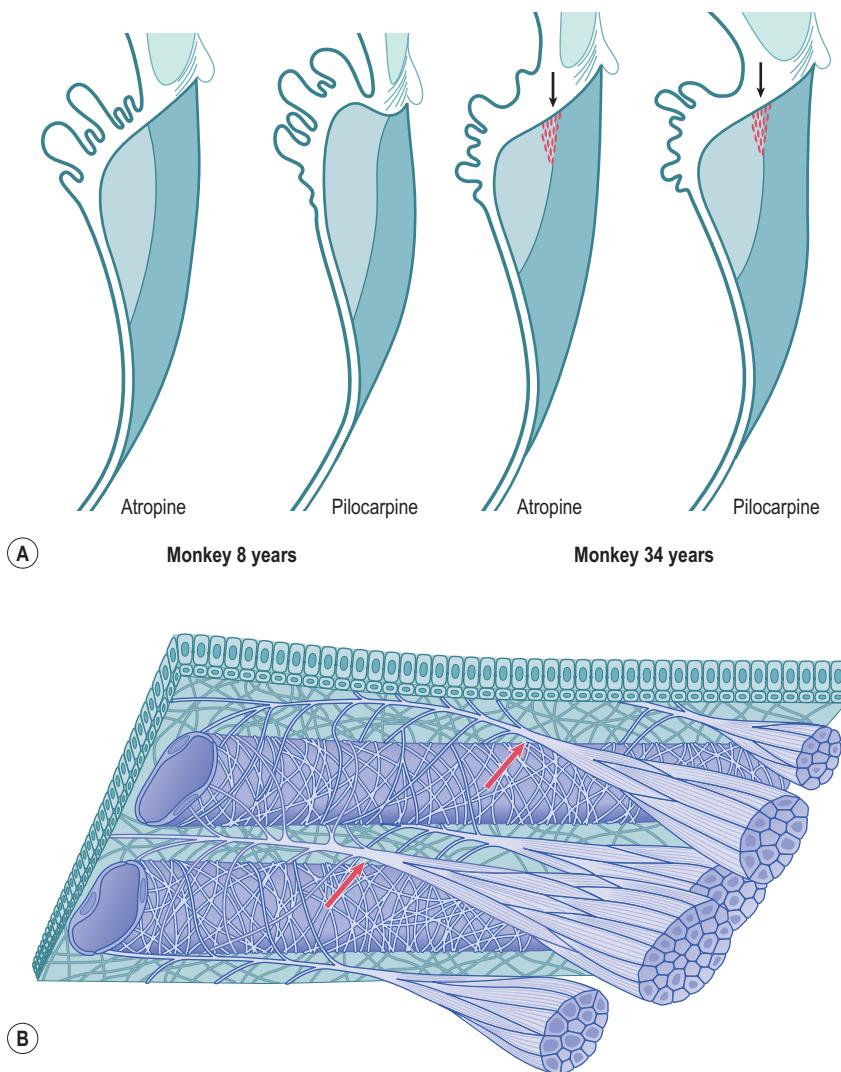

Figure 3.22 (A) Diagrams of the configuration of the ciliary muscle from an 8-year-old (left pair of images) and a 34-year-old (right pair of images) enucleated rhesus monkey eye after each globe was bisected with one half (left) placed in an atropine solution and the other half (right) placed in a pilocarpine solution. Representative sections based on histologic specimens. In the young, but not the old eye, the pilocarpine treated ciliary muscle showed a configurational accommodative change. The ciliary muscle from the older eye fails to undergo an accommodative configurational change due to the loss of elasticity of the posterior attachment of the ciliary muscle to the choroid. The 8-year-old rhesus monkey exhibits essentially no intramuscular connective tissue whereas the 34-year-old rhesus monkey exhibits connective tissue (arrows) only anteriorly between longitudinal and reticular zones of the ciliary muscle. (B) Diagram of the posterior attachment of the ciliary muscle (CM) in rhesus monkeys. The meridional muscle fiber bundles (arrows) are attached to the elastic layer of Bruch's membrane via the elastic tendons. Smaller elastic fibers connect (arrowheads) the tendons of different bundles to the elastic network that surrounds the vessels of the pars plana. (Panel B from Tamm, Lutjen-Drecoll, Jungkunz & Rohen. Invest Ophthalmol Vis Sci 1991; 32:1680, with permission from the Association for Research in Vision and Ophthalmology and from the author.)

fixed in the presence of pilocarpine or atropine¹²³ (Fig. 3.22). The posterior attachment of the rhesus ciliary muscle, comprising elastic tendons continuous with Bruch's membrane, shows structural changes with increasing age.¹²⁴ While the elastic tendons of the young monkey eye stain strongly for actin and desmin, in the aging eye this region exhibits increased collagen fibers that adhere to the elastic fibers, thickening of the elastic tendons and increased microfibrils.¹²⁴ These anatomical changes may lead to decreased compliance of the posterior attachment of the ciliary muscle and the choroid. This is supported by the observation that in aged rhesus monkey eyes in which the posterior attachment of the ciliary muscle is severed prior to pilocarpine stimulation, a configurational change occurs that is otherwise absent.¹²⁵ However, the contractile force of isolated rhesus ciliary muscle strips to pilocarpine stimulation is not reduced with increasing age¹²⁶ (Fig. 3.23). Although there is some loss of ciliary muscle mass, there is no loss of muscarinic receptor number or binding affinity, and no change in cholineacetyltransferase or acetylcholinesterase activity.¹²⁷

These histological, histochemical and ultrastructural studies show that the reduced ciliary muscle accommodative

movement in presbyopic monkey eyes is due to a loss of elasticity of the posterior attachment of the ciliary muscle and choroid. This tissue is normally elastic and is stretched during accommodation in the young eye. If the tissue becomes less extensible with advancing age, the ciliary muscle must work harder to move forward during accommodation. Studies comparing the accommodative movements of the ciliary processes and lens equator in iridectomized monkeys show that both ciliary process and lens edge movements are reduced with increasing age and the loss of accommodation. However, accommodative movements of the ciliary processes are always greater than accommodative movements of the lens edge, irrespective of age^{128,129} (Fig. 3.24). Ciliary process movements are also greater than lens edge movements even in young monkeys.¹²⁸ Together this suggests that lens movement limits the accommodative amplitude at all ages, not ciliary body movement. Ultimately at the endpoint of presbyopia ciliary process movement still occurs even in the absence of accommodative movements of the lens.¹²⁹ Thus, although accommodative movement of the ciliary muscle/ciliary body may be systematically reduced with increasing age in rhesus monkey eyes, it is not the reduced ciliary body

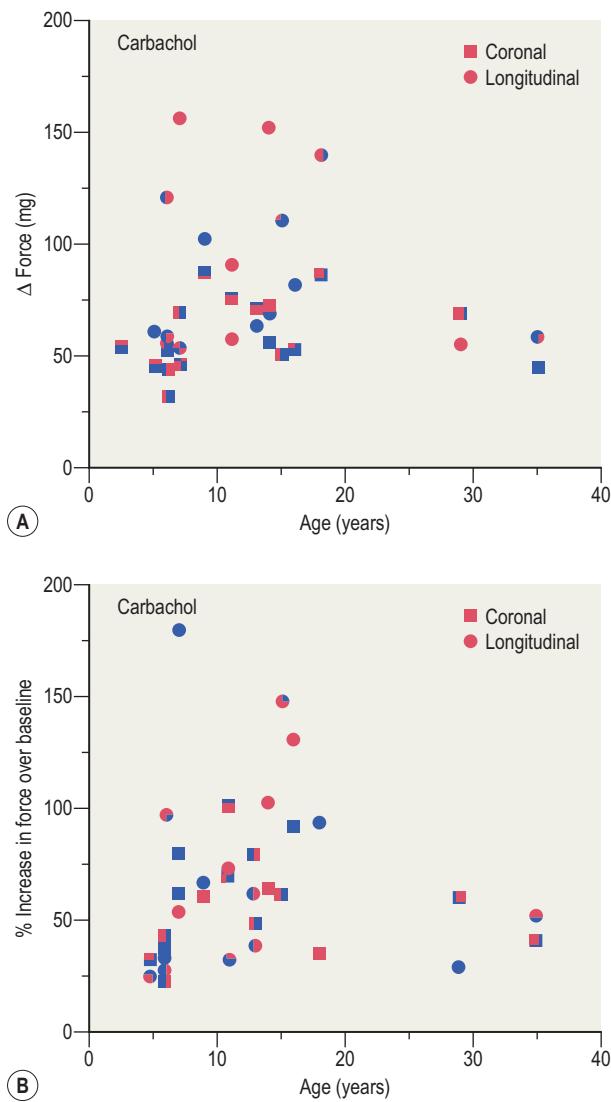

Figure 3.23 (A) Force of contraction and (B) percent increase in force of contraction over baseline of longitudinal (circles) and coronal (squares) strips of isolated rhesus monkey ciliary muscle strips stimulated with muscarinic agonists aceclidine (50 µM) or carbachol (1 µM). No age dependence in force of contraction of the isolated ciliary muscle was observed. movements that limits accommodative amplitude in rhesus monkeys.

Age-related changes in human ciliary muscle

With increasing age, the human ciliary muscle shows a loss of muscle fibers and an increase in connective tissue.^{125,130,131} Despite this, studies using impedance cyclography^{132,133} or modeling¹³⁴ to indirectly infer force of contraction of the human ciliary muscle, suggest that human ciliary muscle contractile force does not decrease, but indeed may increase and reach a maximum at the age at which presbyopia is manifest. These findings are consistent with observations of continued accommodative movement of the ciliary body with accommodative effort in human presbyopes and

pseudophakic eyes.^{76,135,136} Histological study of the atropinized human ciliary muscle shows that total area, area of longitudinal and reticular portion, and length of the muscle decrease with age. In addition, there is a decrease in ciliary ring diameter⁷⁶ and the inner apex of the unaccommodated ciliary muscle resides further forward and inward towards the anterior-posterior axis in the aging eye so that the configuration of the older unaccommodated ciliary muscle appears more like that of the young accommodated ciliary muscle¹²⁵ (Fig. 3.25). Whether this is a cause or a consequence of the anterior zonule gradually pulling the ciliary muscle inward is not clear. Based on this result it has been suggested that, at rest, the aged human ciliary muscle may be less able to hold or pull the crystalline lens into its flattened and unaccommodated configuration.¹²¹

Age-related changes in the zonule

The anterior zonular attachment all around the equatorial region of the lens serves a fundamental role in the accommodative process. It is the outward force directed through these zonular fibers and the resulting tension on the lens capsule that maintains the unaccommodated lens in its flattened state. The release of this resting tension during accommodation allows the capsule to mold the lens into its more spherical and accommodated form.⁷¹ Thus any age-related changes that may affect this zonular attachment are likely to impact the accommodative process and so may contribute to presbyopia. This is a very fine, delicate network of fibers and is especially difficult to study, and thus relatively few studies have been done on this tissue. Zonular spring constants determined indirectly by stretching human tissues show no correlation with age.¹³⁷ Scanning electron microscopic studies of human eyes over a range of ages show an anterior zonular/capsular shift on the lens with increasing age.¹³⁸ The distance from the zonular/capsule insertion to the lens equator increases, the distance from the zonular/capsule insertion to the ciliary processes is unchanged, the circumlental space decreases with age (see below), and the rate of increase in distance from zonular/capsular insertion to lens equator remains relatively constant until the 5th decade and then increases dramatically.¹³⁸ Based on the constancy of the distance between the zonular/capsular insertion and the ciliary body, it is suggested that there would be no change in zonular length or zonular tension with increasing age provided zonular elasticity remains unchanged.

It is therefore possible that the decreased circumlental space described above is due to centripetal pulling of the ciliary body by the zonule as the zonule/capsular shift occurs with increasing lens thickness or due to the inward expansion of the ciliary muscle.¹²⁵ The decreased circumlental space is not due to an age-related increase in equatorial diameter of the lens since lens diameter does not increase systematically with age (see below). Farnsworth & Shyne¹³⁸ theorized that the anterior zonular shift occurs because the capsule is thinner on the posterior lens surface and is stretched more than the anterior capsule as the lens continues to grow within the capsule. A zonular/capsular shift could reasonably occur since the posterior capsule is thinner^{70,71} and therefore likely to stretch more than the anterior capsule as lens thickness increases. As a consequence of this zonular/capsular shift, in older eyes the attachment

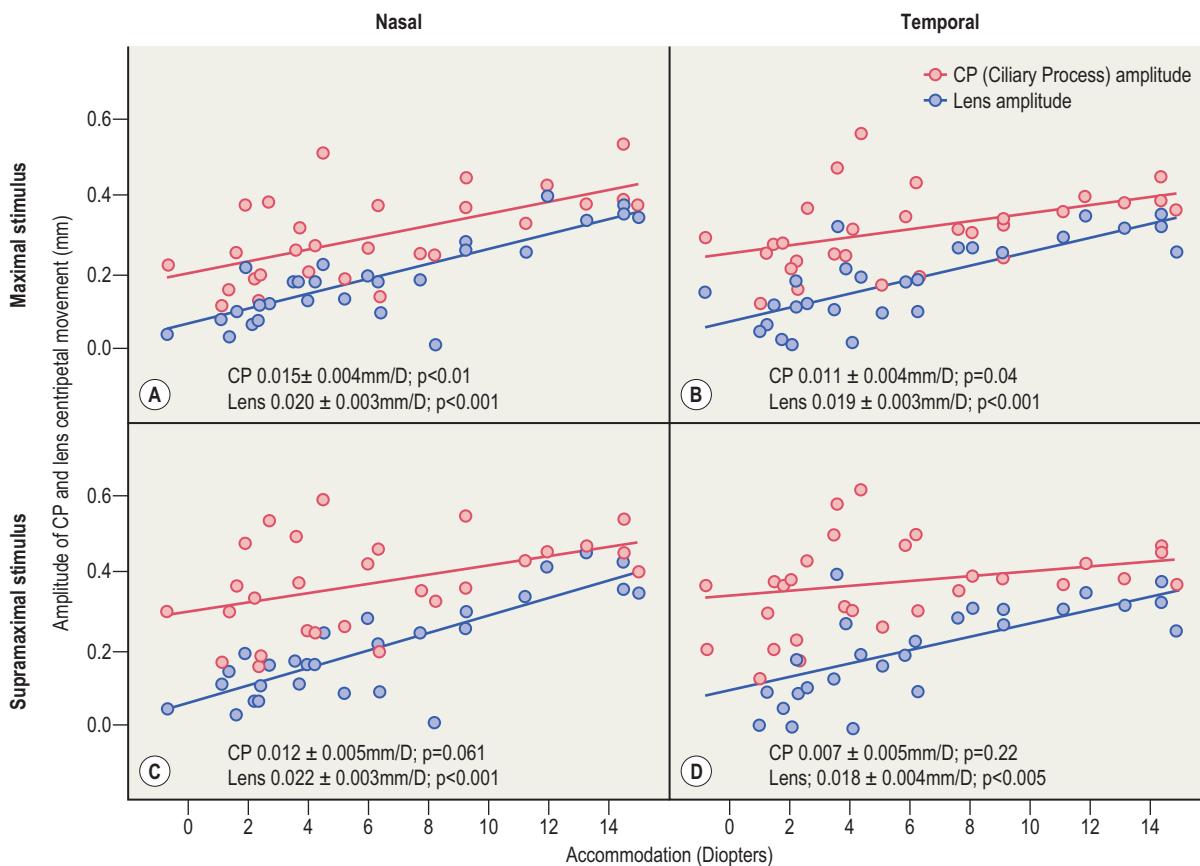

Figure 3.24 Graphs showing the accommodative excursions of the ciliary processes (solid symbols) and lens edge (open symbols) from the eyes of iridectomized rhesus monkeys. Quantitative goniovideographic analysis of the accommodative movements from the nasal (left) and temporal (right) sides of the monkey eyes for Edinger-Westphal stimulated accommodative responses to either maximal (top) or supramaximal (bottom) stimulus amplitudes. Accommodative movements of the lens and ciliary processes are reduced with the age-related loss of accommodative amplitude, but in all eyes, the magnitude of ciliary process movement exceeds the magnitude of the lens edge movements. With supramaximal stimulation there is a greater ciliary process movement than with the stimulus required to elicit maximum accommodation, and more so in the older eyes. This demonstrates that although increasing ciliary body movements can be produced even in the oldest eyes, this is without an increase in accommodative lens movements. of the anterior zonular fiber to the lens is anterior to the equator, the fine zonular fibers which reside at the lens equator in the young eye are found anterior to the equator, and there are fewer zonular fibers at the equator.¹³⁸ This would result in diminution of the outward directed force on the lens equator by the anterior zonular fibers as a whole and is suggested as a contributing factor in the age related loss of accommodation.¹³⁸ Measurements on unfixed human eyes from which the lens substance was removed by phaco-emulsification also show an age-dependent increase in the distance from the anterior zonular/capsular insertion to the equatorial edge of the capsular bag, a decrease in circumlental space, and an age-dependent increase in the distance from the anterior zonular/capsular insertion to the ciliary body.¹³⁹ However absence of the lens substance from the capsular bag complicates interpretation of these measurements.

Age-related changes in the capsule

The thickness of the anterior lens capsule has been reported to increase from about 11 microns at birth to approximately 20 microns at 60 years of age and then decreases slightly

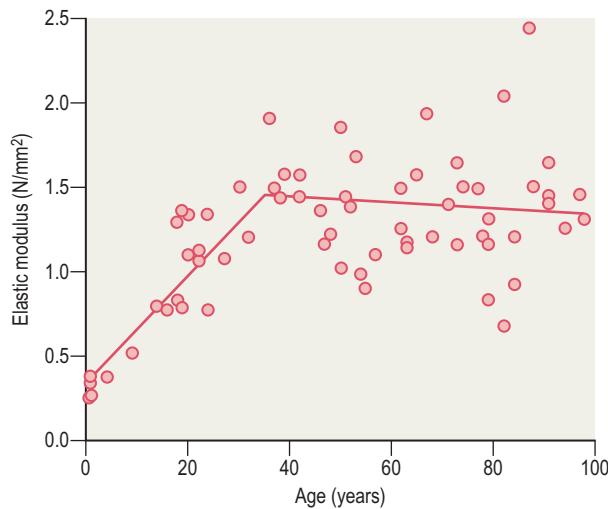

Figure 3.26 Age-related changes in the elastic modulus of the human anterior lens capsule in the 0–10 percent range of strain, the level of strain relevant for accommodation. Data are obtained from stretching isolated rings from the anterior capsular surface. (From Krag S, Andreassen TT. Prog Retin Eye Res 2003; 22:749–67. Reproduced with permission from Elsevier Science Ltd.)

thereafter.¹⁴⁰ Krag¹⁴¹ found an increase from 11 to 33 microns up to age 75 and then a slight decrease thereafter. More recent results show an increase in thickness of the anterior mid peripheral capsule with increasing age and a thinning of the mid peripheral posterior capsule.⁷⁰ Fisher¹⁴⁰ measured the extensibility of the human lens capsule by applying a fluid pressure behind the central part of the anterior lens capsule clamped between two rings and found it to be 29 percent and age independent. Despite the increased capsular thickness with increasing age, Fisher¹⁴⁰ showed a decrease in Young's modulus of elasticity of the capsule from 6×10^7 dyn/cm² in infancy to 2×10^7 dyn/cm² in old age. Fisher suggests that the force that can be transmitted per unit thickness of the capsule decreases by half by age 60, but that the increased thickness offers some compensation for the loss of elasticity. Age-related change in lens volume may account for the variations in thickness of the capsule at a specified region on the lens. Krag et al's¹⁴¹ measurements of extensibility of a ring cut from the anterior capsule show that while the young capsule can be stretched to 108 percent of its unstretched length, there is a linear decline in strain to 40 percent at age 98. The force required to break the capsular ring remained constant until age 35 and decreased linearly thereafter. In the 0–10 percent strain level, the level of strain relevant for accommodation, there is a linear increase in elastic modulus of the anterior lens capsule up to about 35 years of age and a slight decrease after this age (Fig. 3.26). With increasing age the capsule gets thicker, less extensible and more brittle.^{141,142}

Growth of the crystalline lens

The crystalline lens continues to grow throughout life. In humans, this results in a linear increase in mass of the isolated lens between age 5 and 96 years of age⁷² (Fig. 3.27). The human lens also undergoes an increase in axial thickness as a consequence of the addition of lens fiber cells.^{45,143–145}

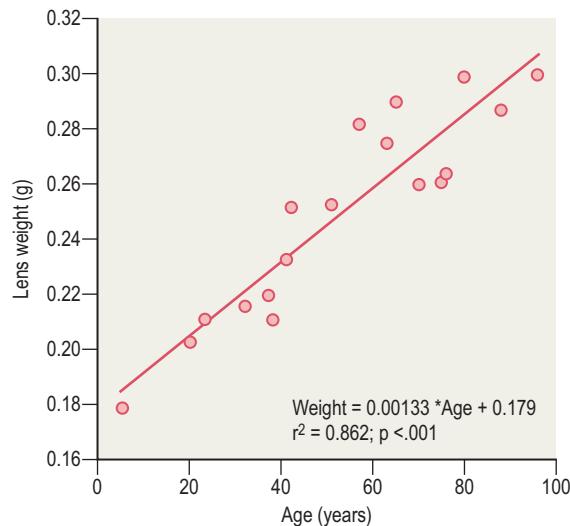

Figure 3.27 The human lens continues to grow throughout life as evident from an increase in mass of the isolated human lens. The wet weight of 18 human lenses was measured after isolating the lenses from human eye-bank eyes ranging in age from 5 to 96 years of age. (Reprinted from Glasser A, Campbell MCW. Vision Res 1999; 39:1991–2015, with permission from Elsevier Science Ltd.)

However, lens equatorial diameter in the unaccommodated state does not increase systematically with increasing age^{74,76,77,145} (Figs 3.28 & 3.29). Scheimpflug slit-lamp phakometry and MRI measurements show that the anterior lens surface curvatures increase systematically with increasing age, but posterior lens surface curvature is found to increase in some studies and not in others.^{38,145,146} The increase in axial thickness of the lens results in a decrease in anterior chamber depth and an increase in anterior segment length¹⁴⁵ (Fig. 3.30). The distance between the cornea and the center of the lens does not change with increasing age.¹⁴⁷ Qualitatively similar age-related changes have been described in the anterior segment of the rhesus monkey eye.¹⁴⁸ Since the thickness and anterior and posterior surface curvatures of the lens increase with increasing age, but without an increase in lens equatorial diameter, the external shape of the aged lens begins to look more like that of an accommodated lens. However, the increased axial thickness with age is due to an increase in thickness of the anterior and posterior cortex whereas accommodation in a young lens is due to an increase in thickness of the nucleus.^{29,146,147} In addition, with increasing age, the cortical layers of the lens increase to a greater extent than the nucleus.¹⁴⁷ Although the surface curvatures in the aging lens appear to be more like an accommodated lens, the presbyopic eye is clearly not focused for near since presbyopia results in a loss of near vision.

The incongruity between the increasing lens surface curvatures and the gradual loss of near vision has been termed the *lens paradox*.¹⁴⁹ The reason the presbyopic eye does not become nearsighted despite the increasing lens surface curvatures is due to a gradual age-related decrease in the equivalent refractive index of the lens.^{75,145,150} The optical changes in the lens with accommodation and aging differ in several respects. While accommodation results in an increase in the extent of the negative spherical aberration of young lenses,

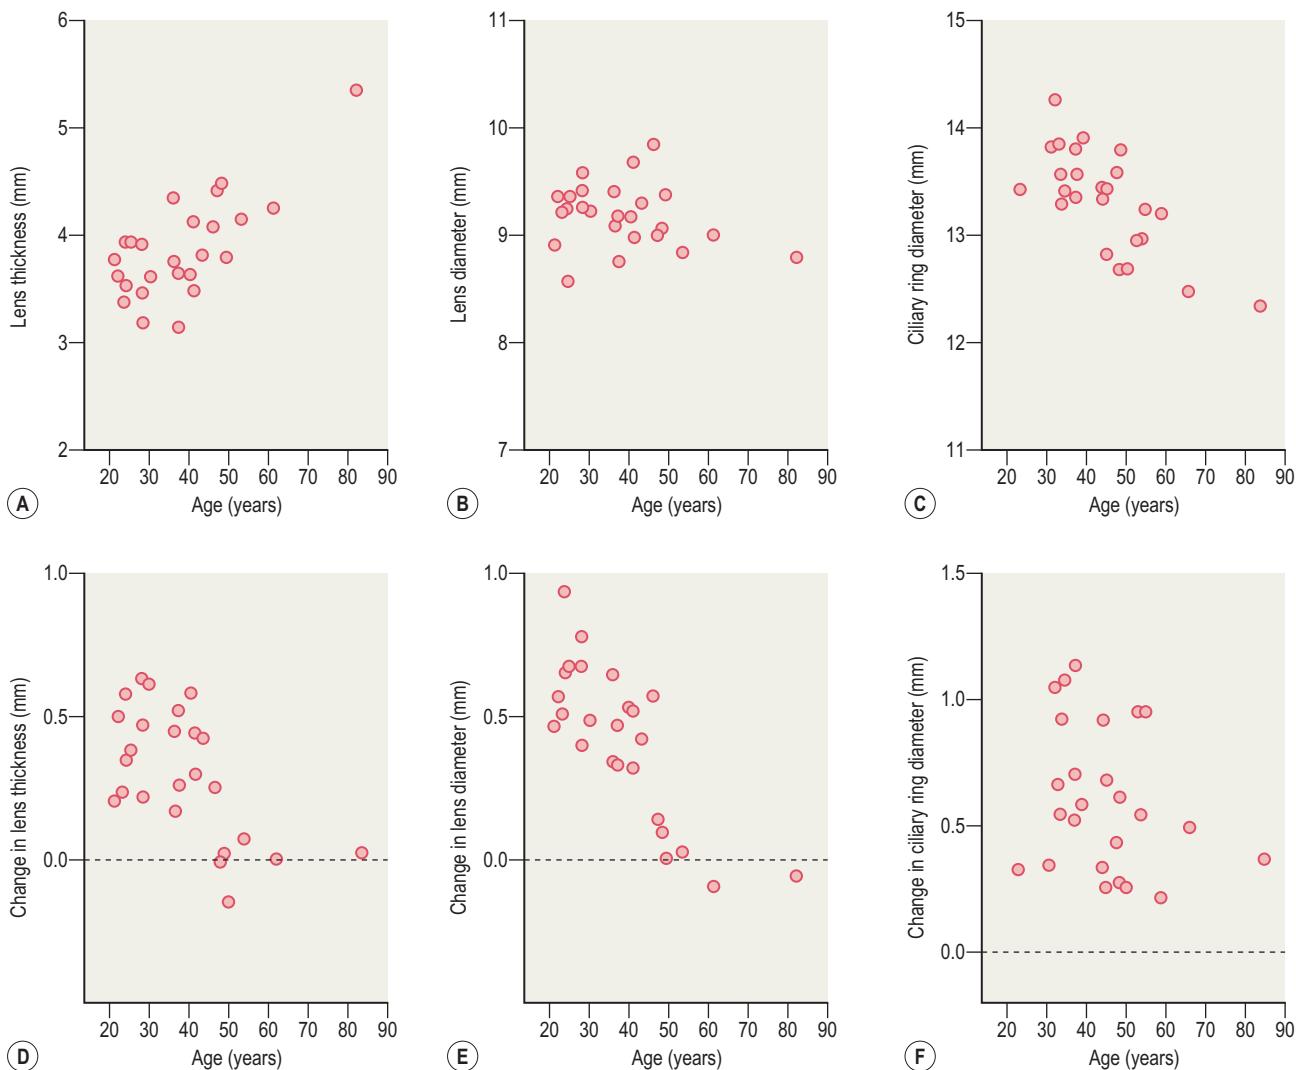

Figure 3.28 MRI measurements of resting, unaccommodated lens thickness (**A**), lens diameter (**B**) and ciliary ring diameter (**C**) in human eyes as a function of age. Subjects viewed a near target (8 diopters of accommodative demand) and MRI measurements were repeated to determine the change in lens thickness (**D**), the change in lens diameter (note: the change in lens diameter is graphed as positive values, but this actually represents a decrease in lens diameter with accommodation) (**E**) and the change in ciliary ring diameter (**F**) with accommodation. The accommodative changes in lens thickness and lens diameter reach zero (horizontal lines) by approximately 50 years of age, while the accommodative change in ciliary ring diameter, although reduced with increasing age, does not. (From Strenk SA, Semmlow JL, Strenk LM et al. Invest Ophthalmol Vis Sci, 1999; 40:1162–9. Reproduced with permission from The Association for Research in Vision and Ophthalmology.)

aging results in a systematic change in sign of spherical aberration from negative to positive.^{54,72} The increased axial thickness of the lens would also tend to reduce the lens refractive power if no other changes occurred in the lens. Although the refractive index value at the center of the lens does not change systematically with increasing age, the shape of the lens gradient refractive index changes with increasing age – resulting in a larger plateau in the refractive index in the central regions of the lens and a steeper change in the gradient refractive index in the more peripheral lens cortical regions⁴¹ (Fig. 3.31).

It has been suggested that lens equatorial diameter increases systematically with increasing age^{94,151,152} and this has been suggested to be the primary cause of presbyopia.¹⁵³ The only evidence cited in support of an age-related increase in lens diameter is data from an original study by Priestly

Smith in 1883 in which lens equatorial diameter was measured in isolated human lenses.¹⁵⁴ Smith and others^{54,71,72} recognized that when the zonular fibers are cut and the lens is isolated and removed from the eye and from external zonular traction forces, younger lenses tend to become accommodated and undergo a decrease in equatorial diameter while older presbyopic lenses do not undergo any change in shape upon removal from the eye.^{54,71,72} Therefore, the diameter of isolated lenses is relatively smaller in young isolated lenses than in older isolated lenses. Measurements of lens equatorial diameter of isolated lenses, therefore compare young accommodated lenses with older unaccommodated lenses. Although such studies show an age-dependent increase in lens diameter, this trend is not due to age, but is due to the different accommodative states of isolated lenses.¹⁵⁴ Measurements from isolated adult lenses,

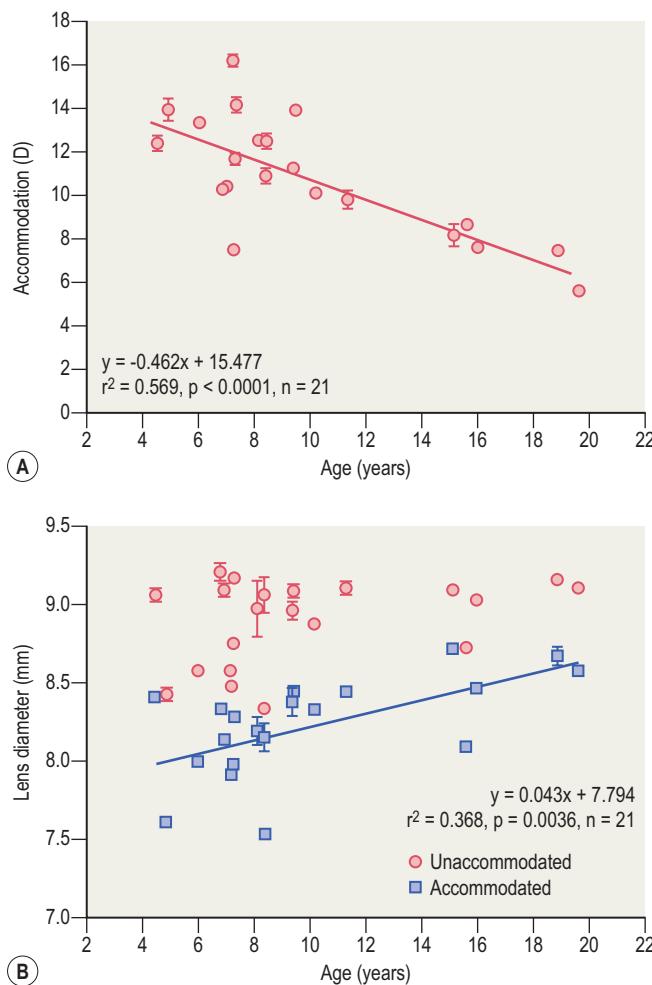

Figure 3.29 In rhesus monkeys in which (A), there is an age-related decrease in accommodative amplitude, (B), there is no systematic age-related change in unaccommodated lens equatorial diameter (circles) and accommodative decrease in lens diameter decreases with increasing age (squares). (Wendt M, Croft MA, McDonald J, et al. Exp Eye Res 2008; 86:746–52. Reproduced with permission from Elsevier Science Ltd.)

therefore, do not reflect the equatorial diameter of the lens in vivo. Recent studies have measured lens thickness and equatorial diameter in the living human^{74,76,145} and monkey⁷⁷ eye. These studies show that although lens growth occurs as is evident from an increase in lens axial thickness, the progression of presbyopia occurs without a systematic increase in lens equatorial diameter.

Loss of ability of the human lens to accommodate

In vitro studies show that the human lens progressively loses the ability to undergo accommodative changes. Fisher subjected isolated human lenses to high-speed rotational forces designed to simulate the forces that act on the lens to hold the lens in an unaccommodated state in the living eye.¹⁵⁵ The results show an age-dependent decline in deformability of the human lens. For a given rotational stress, the equatorial and polar strain (change in lens diameter and thickness) decrease by about one-third between the ages of 15 and 65.

Fisher's calculated Young's modulus of polar and equatorial elasticity show a more than three-fold increase over this age range.¹⁵⁵ From these studies Fisher suggested that a decrease in elastic modulus of the capsule, an increase in elastic modulus of the lens substance and a flattening of the lens are sufficient to account for the loss of accommodation by the age of 61 years.¹⁵⁶ However Fisher's assumptions of no age-related change in lens shape or zonular insertion onto the lens are inaccurate^{138,146} and the theoretical assumptions on which the calculations are based are questioned.¹⁵⁷ Although Fisher's calculated Young's modulus values may be inaccurate, his experiments do demonstrate reduced deformability of the aging human lens due to rotational forces.

Mechanical stretching experiments show that young human lenses undergo 12–16 D of changes in optical power from stretching forces applied through the intact zonular apparatus.⁵⁴ These mechanically induced changes in optical power of the lens correspond well with the accommodative dioptric change in power of the young eye in vivo. The change in optical power that the human lens undergoes with mechanical stretching gradually decreases with increasing age^{54,134} (see Fig. 3.12). By about 55 years of age, human lenses are unable to undergo any change in optical power with the same degree of stretching that produces 12–16 D of change in optical power of young lenses.⁵⁴ Phacoemulsification and aspiration of the presbyopic lens and injection of a soft silicone polymer to refill the capsule restores the ability of the refilled lens to undergo accommodative changes in optical power with mechanical stretching.⁸⁵ These experiments show that regardless of what other age-related changes may occur in the human accommodative apparatus, the human lens ultimately completely loses the ability to undergo accommodative optical changes and that this is due to the increased stiffness of the lens. Presbyopic human lenses are unable to undergo any change in optical power from forces exerted on the lenses either through zonular traction or rotational forces.^{54,155}

After the zonule is cut, and the young lens is removed from the eye, the young isolated lens is in a maximally accommodated form due to the forces exerted on the lens by the lens capsule.^{71,72,154} When the lens capsule is removed from the isolated young lens, the decapsulated lens substance takes on an unaccommodated form^{71,72} (Fig. 3.32). Removing the capsule from young lenses results in a decrease in optical power. However, removing the capsule from lenses over about 50 years of age results in no change in optical power.⁷² This, together with the results from mechanical stretching experiments,⁵⁴ shows that the lens substance of older human lenses ultimately is incapable of undergoing capsule-induced optical alterations required for accommodation and disaccommodation.

High resolution magnetic resonance imaging (MRI) studies in living human eyes provide insights on aging of the accommodative apparatus.⁷⁶ When subjects are presented with an 8D accommodative stimulus, in the young subjects there is an accommodative increase in lens thickness and decrease in lens equatorial diameter, but with increasing age, these accommodative changes in the lens decline to zero by about age 50 (see Fig. 3.28). However, an accommodative decrease in ciliary ring diameter still occurs even in the oldest subjects. This shows that in presbyopes, an effort to focus at near results in a ciliary muscle contraction

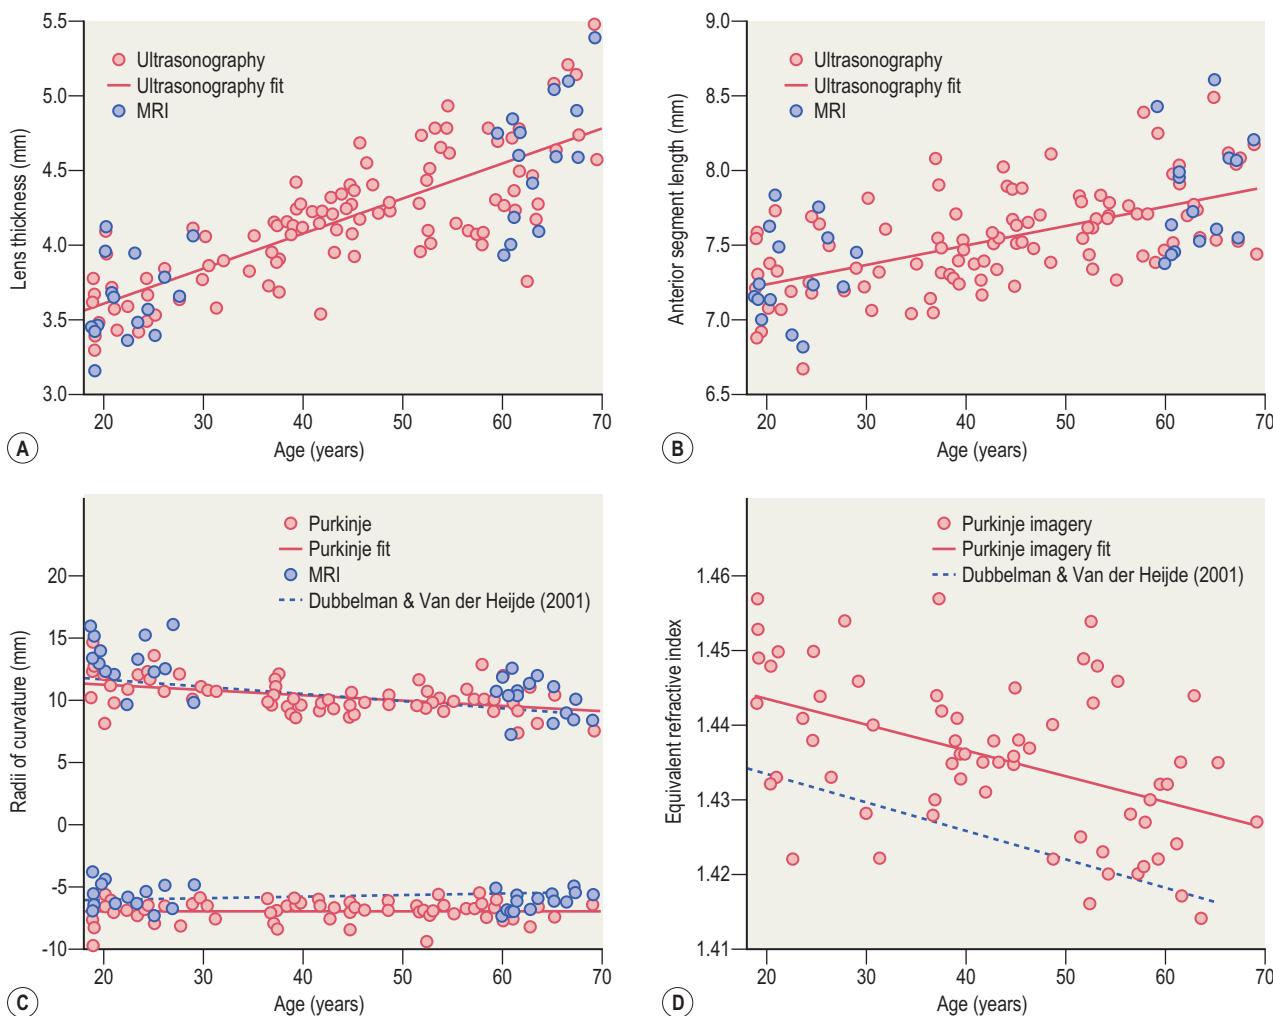

Figure 3.30 Age-related changes in the human lens. **(A)** Lens axial thickness as measured with A-scan ultrasound (red symbols) and MRI (blue symbols) increases with increasing age. **(B)** Anterior segment length as measured with A-scan ultrasound (red symbols) and MRI (blue symbols) increases with increasing age. **(C)** Lens anterior radius of curvature as measured from phakometry (red symbols) and MRI (blue symbols) decreases with increasing age, but lens posterior radius of curvature does not change systematically. **(D)** Calculated lens equivalent refractive index decreases with increasing age. (From Atchison DA, Markwell EL, Kasthurirangan S, et al. J Vis 2008; 8:29–30. Reproduced with permission from The Association for Research in Vision and Ophthalmology.)

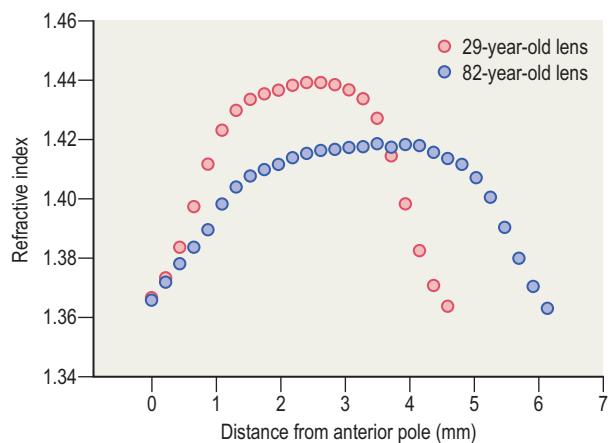

Figure 3.31 Since lens thickness increases systematically, but the refractive index at the center of the lens does not change systematically, the overall form of the gradient refractive index of the lens changes with increasing age. The refractive index profile becomes steeper near the lens surfaces and it becomes flatter near the lens center. (From Moffat BA, Atchison DA, Pope JM. Optom Vis Sci 2002; 79:148–50.)

and accommodative movements of the ciliary body, but without the required accommodative changes in the lens. Presbyopia, therefore results in a failure of the crystalline lens to undergo accommodative changes.

Age-related increase in stiffness of the human lens

The human lens undergoes an exponential age-related increase in stiffness.^{72,158,159} In the young lens, the nucleus is softer than the cortex, but with increasing age, there is a relatively greater increase in the stiffness of the cortex^{158,159} (Fig. 3.33). In the young eye, accommodation occurs through an increase in thickness of the lens nucleus, but not the cortex. In the young eye, it may be that the relatively stiffer cortical layers surrounding the nucleus mold the nucleus to change its shape during accommodation. With increasing age as the rate of stiffening of the nucleus exceeds that of the cortex, the cortical stiffness begins to exceed that of the nucleus by about 35 years of age.¹⁵⁸ There is a stiffness gradient to the lens (Fig. 3.34). In the young lens, stiffness progressively

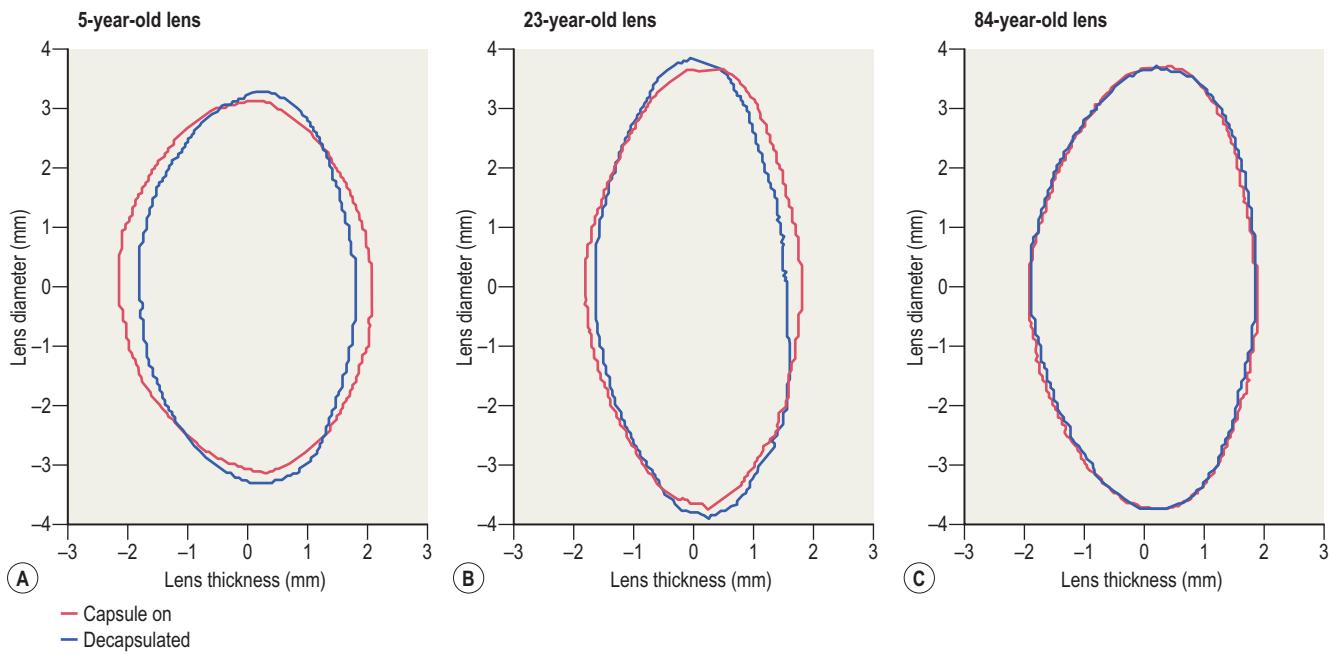

Figure 3.32 Effect of removing the capsule (blue profile) on (A) 5-year-old, (B) 23-year-old, and (C) 84-year-old isolated human lenses. In the youngest lens, the capsule causes the isolated lens to become maximally accommodated. Removing the capsule results in the isolated lens substance taking on a more unaccommodated form. This effect of the capsule is reduced in the intermediate aged lens and removal of the lens capsule has no effect on the shape of the oldest lens. (From Glasser A, Croft MA, Kaufman PL. In: Friedlander MH, ed. International Ophthalmology Clinics. Philadelphia, PA: Lippincott Williams & Wilkins, 2001; vol. 41(2), ch. 1.)

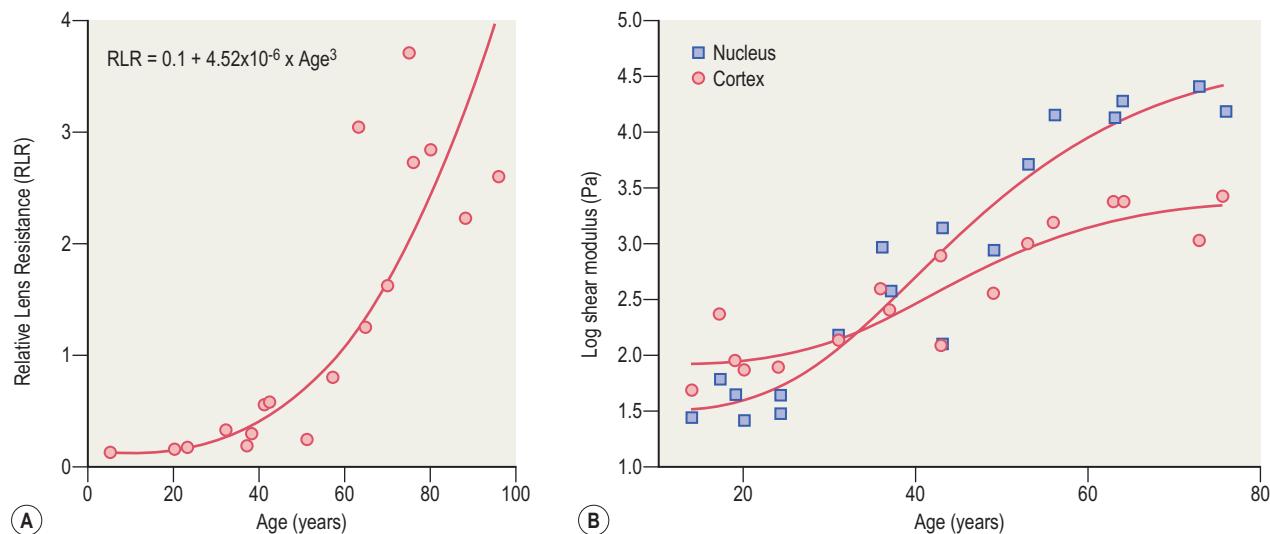

Figure 3.33 Age-related increase in stiffness of human lenses. (A) Nineteen human lenses ranging in age from 5 to 96 years show an exponential increase in stiffness with an over four-fold increase in stiffness over the human life-span which continues well after the age at which accommodation is completely lost. (B) The nuclear regions of young lenses have a lower shear modulus than the cortex, but there is an exponential increase in stiffness of both the nucleus and the cortex of the lens with a relatively greater increase in shear modulus of the nucleus. (Panel A from Glasser A, Campbell MCW. Vision Res 1999; 39:1991–2015, with permission from Elsevier Science Ltd. Panel B from Heys KR, Cram SL, Truscott RJ. Mol Vis 2004; 10:956–63.)

decreases from the surface of the cortex to the center of the nucleus, whereas in older lenses the stiffness gradient increases from the surface of the cortex to the center of the nucleus. It may be this change in stiffness gradient that leads to an age-related change in the fine balance of forces that ultimately results in a loss of accommodation.^{159,160} It is an essential requirement that if accommodation is to occur,

the lens substance must remain sufficiently pliable for capsular and zonular forces to flatten the lens to hold it in an unaccommodated form and for capsular forces to increase the surface curvatures to mold the lens into an accommodated form. Since accommodation relies on forces exerted by the capsule on the lens, a small change in the fine balance of capsular and lens nuclear and cortical elastic forces would

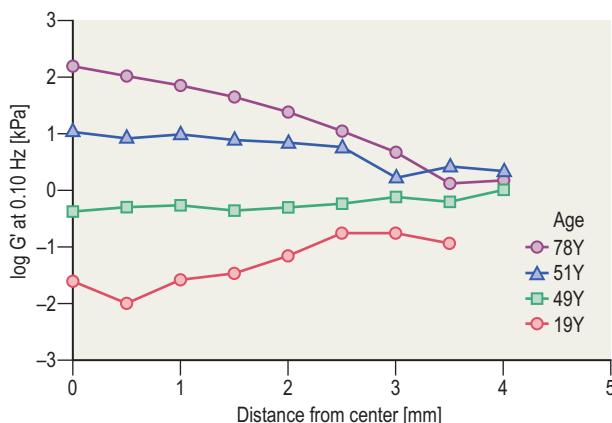

Figure 3.34 In younger human lenses, lens stiffness is lowest nearer the center of the nucleus and lens stiffness increases towards the periphery of the cortex. With increasing age, there is a progressive change in stiffness gradient of the lens. In the oldest lenses, the stiffness gradient has altered such that the center of the nucleus is stiffer than the periphery of the cortex. (From Weeber HA, Eckert G, Pechhold W, van der Heijde RGL. Graefe's Arch Clin Exp Ophthalmol 2007; 245:1357–66 with kind permission of Springer Science + Business Media.)

diminish the accommodative ability of the lens. Although presbyopia results in a complete loss of accommodation by the age of about 50 years, the stiffness of the human lens continues to increase beyond this age throughout the remaining years of the human life-span. The age-related stiffening of the lens may simply represent a continuation of the age-related changes that ultimately lead to cataract.

The progressive loss of compliance of the lens from early in life parallels the decline in accommodative amplitude. If no other age-related changes were to occur in the accommodative apparatus of the eye, increased stiffness of the lens and a change in the stiffness gradient of the lens could completely account for the loss of accommodation with advancing age. Presbyopia has classically been attributed to the hardening or “sclerosis” of the lens. Some confusion may exist regarding the meaning of the term “lenticular sclerosis”. Evidence suggests that there is a gradual and progressive increase in stiffness of the lens with a relatively greater increase in stiffness of the nucleus than the cortex that occurs throughout life to ultimately lead to an inability of the lens to undergo the optical changes required for accommodation.

Cornea and Sclera

Daniel G. Dawson, John L. Ubels & Henry F. Edelhauser

Introduction

The outermost, fibrous tunic of the human eye is the cornea and the sclera (Fig. 4.1A,B).¹⁻⁵ Both are soft connective tissues designed to provide structural integrity of the globe and to protect the inner components of the eye from physical injury. The clear, transparent cornea (Fig. 4.1A,C) covers the anterior 1/6th of the total surface area of the globe, while the white, opaque sclera (Fig. 4.1A) covers the remaining 5/6ths. The cornea and the lens are the eye's primary refractive structures and both have two key optical properties to this end – refractive power (light refraction) and transparency (light transmission). The presence of a healthy cornea is essential for good vision as it is basically the window of the eye. The cornea is most analogous to the external lens of a compound lens camera. By comparison, the sclera predominantly serves more of a biomechanical function and is analogous to the housing of the camera and lens.

The cornea is 540 to 700 µm thick and is arranged in five basic layers – epithelium, Bowman's layer, stroma proper, Descemet's membrane, and endothelium (Fig. 4.1D); each having distinctly different structural and functional characteristics.⁶ It also is composed of three major cell types – epithelial, stromal keratocyte, and endothelial cells. Two of these, epithelium and endothelium, form cellular barrier layers to the stroma. Thus, their resistance to diffusion of solutes and bulk fluid flow are of considerable importance to maintaining normal corneal function (resistance to diffusion of solutes and fluid flow: epithelium [2000] >> endothelium [10] > stroma [1]). All 3 can replicate through mitosis, but vary considerably in their in vivo proliferative capacity with epithelial cells having the highest rates of cell division and endothelial cells being the least renewable. This fact is seen clinically since epithelial cells can completely regenerate after injury (e.g. corneal abrasions), while endothelial cells, as a result of limited in vivo proliferation, are most commonly involved in age-related (e.g. Fuchs' dystrophy) or injury-related disease (e.g. pseudophakic bullous keratopathy – PBK) ultimately resulting in corneal edema and bullous keratopathy. Corneal stromal keratocytes are a middle ground compromise between these two extremes. One major disadvantage of the epithelium's high proliferative potential is that it can occasionally go unchecked, resulting in cancer (e.g. squamous cell cancers of the cornea), whereas keratocytes and endothelial cells do not have this risk.

The sclera is 0.3 to 1.35 mm thick and is arranged into three layers – episclera, scleral stroma proper, and lamina fusca; each having distinctly different structural and functional characteristics. The sclera is composed of only one major cell type, the sclera fibrocyte, which has moderate proliferative potential, like that of the corneal stromal keratocyte. As the sclera has no cellular barrier layers, its permeability properties are quite similar to that of the corneal stroma. The sclera is an excellent example of a tissue made for biomechanical stability as it is stiff, strong, and tough. As such, disease of the sclera commonly results in loss of tectonic support, abnormal size due to dysregulated growth as well as inflammatory conditions that commonly also affect the joints in the body. Many animals have a very rigid sclera that is often supported by bone or cartilage. Humans deviate from this extreme in that their sclera is a less rigid fibrous connective tissue, perhaps reflecting its need to maintain an even blood flow to the choroid and retina during large excursions in eye motility.

This chapter reviews and explains the structure and function of the cornea and sclera, providing a framework for understanding normal health and disease of each tissue with an emphasis on function.

Cornea

Embryology, growth, development, and aging

The foundations of contemporary corneal embryology and development stem from pioneering embryonic chick studies. Since few such detailed studies have been carried out in primates or other mammals, the information that follows has potential gaps in knowledge since species-related differences may exist. Following lens vesicle formation between 4 to 5 weeks' gestation (27–36 days), surface ectodermal cells cover the defect left by lens vesicle invagination and become the primitive, undifferentiated corneal epithelium, composed initially of two cell layers.⁷ Similar to the avian cornea, the primitive corneal epithelium of primates and higher mammals immediately produces a primary acellular corneal stroma, or post-epithelial layer.^{8,9} In primates, this is seen as the gradual subepithelial addition of diagonal and then randomly oriented fibrillar elements, which later thicken into collagen fibrils that are slightly smaller in diameter than

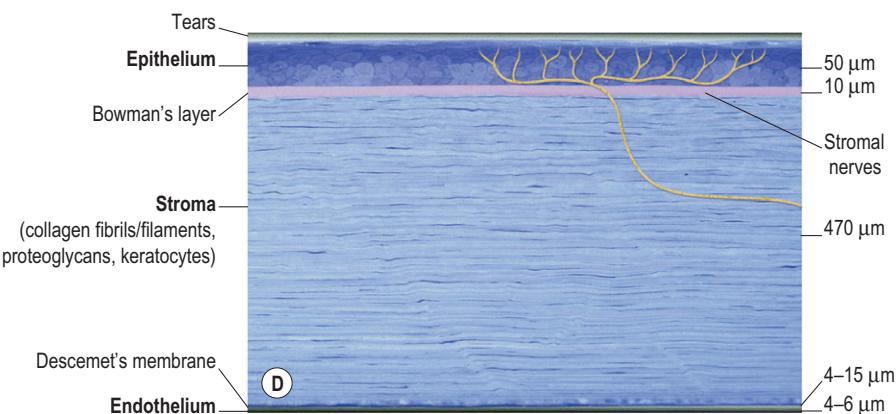

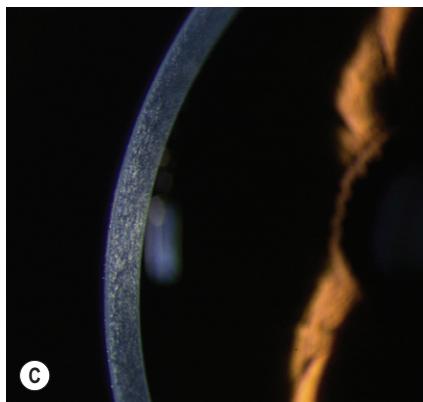

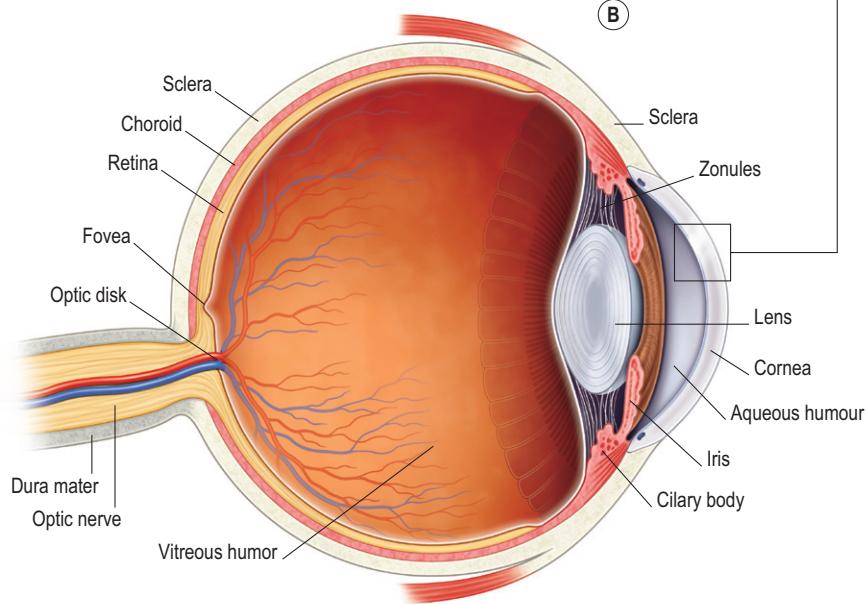

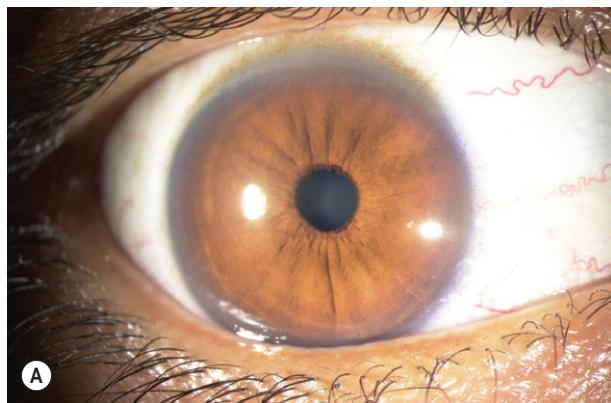

Figure 4.1 (A) Diffuse illumination slit-lamp image of the human cornea and sclera. (B) Main anatomical components of the globe with detailed emphasis on the corneal and scleral components. (C) Slit-beam illumination slit-lamp image of the human cornea shows an optical section of the tissue. Notice the slight light scattering that occurs in the tissue, mainly from cellular components in cornea. (D) Histologic section of the human cornea labeling the five main cellular and extracellular matrix layers (toluidine blue $\times 25$).

stromal collagen fibrils.⁹ The Bowman's layer is thought to be a distinct, dense anterior-most remnant of this embryologic layer, which is first detectable by light microscopy around 20 weeks' gestation.^{9–11} In contrast to humans, lower mammals, such as rabbits and rodents, have an underdeveloped primary acellular corneal stroma and its residual

remnant, the Bowman's layer, is indistinct and rather thin.¹² Around 12 weeks' gestation, a time period between eyelid fusion at 8 weeks' gestation and eyelid opening at 26 weeks' gestation, the epithelium differentiates to become a stratified, squamous epithelium 4 cell layers thick, which then produces an epithelial basement membrane. It remains 4

cell layers thick until approximately 6 months after birth when it reaches adult levels of 4–6 cell layers thick. Early in gestation, the epithelial basement membrane and anchoring complexes on the basal surface of the epithelium are absent. Rudimentary epithelial basement membrane and anchoring complexes only become detectable by 17 weeks of gestation. With further development in utero, the thickness and number of these structures gradually increases.

A first wave of neural crest-derived mesenchymal cells begins to extend beneath the corneal epithelial cells from the limbus around 5 weeks' gestation (33 days); these cells form the primitive endothelium. The primitive endothelium is initially composed of two-cell layers. By 8 weeks' gestation, it becomes a monolayer that starts to produce Descemet's membrane, which becomes recognizable on light microscopy at 3–4 months' gestation. The epithelium and endothelium remain closely opposed until 7 weeks' gestation (49 days), when a second wave of mesenchymal cells begins to migrate centrally from the limbus between the epithelium and endothelium invading below and into most of the primary acellular stroma. The cells do not enter the anterior-most 10 µm of stroma, which lacks keratocan, a proteoglycan core protein signal thought to be required for cellular invasion.¹⁰ This second wave of cells forms the stroma proper, or secondary cellular corneal stroma, as production of lamellar collagen begins within a few days in a posterior-to-anterior fashion. It is believed that the invading mesenchymal cells, destined to become keratocytes, use the primary acellular stroma as a scaffold, primarily in the anterior third of stroma proper. This concurs with the significant lamellar interweaving and oblique lamellar orientation in the anterior third of post-natal human corneal stroma as well as the fact that each successive lamellar layer is rotated 1–2 degrees clockwise. This directional rotation is the same in both right and left eyes. In the posterior two-thirds of the stroma, the corneal stroma is composed of essentially orthogonal lamellae. By 3 months' gestation, corneal nerves invade the stroma and eventually penetrate through the Bowman's layer so that nerve endings develop in the epithelium. Studies also suggest that by 5 months' gestation, tight junctions form around all the corneal endothelial cells and, by 5 to 7 months' gestation, the in utero cornea becomes transparent as the density of functioning endothelial Na⁺/K⁺-ATPase metabolic pump sites increase to adult levels.^{13,14} By 7 months' gestation, the cornea resembles that of the adult in most structural characteristics other than size. At birth in the full-term infant, the horizontal corneal diameter is about 9.8 mm and the corneal surface area is around 102 mm². The cornea of the newborn infant is approximately 75–80 percent of the size of the adult human cornea (Fig. 4.2A,B,C), while the posterior segment is < 50 percent of adult size (Fig. 4.2D).¹⁵ At birth, the cross-sectional thickness of the 4-cell layer epithelium averages 50 µm, the Bowman's layer averages 10 µm, the central stroma proper averages 500 µm, Descemet's membrane averages 4 µm, and the endothelium averages 6 µm thick (total mean central corneal thickness ~ 570 µm).^{16–18}

During infancy, the cornea continues to grow, reaching adult size around 2 years of age with a horizontal diameter of 11.7 mm, surface area of 138 mm², anterior surface curvature of 44.1 D (Fig. 4.2A), and mean central corneal thickness of 544 µm (Fig. 4.2C).^{15,17,18} Thereafter, it changes very little in size, shape, transparency, or curvature, although a

shift from with-the-rule to against-the-rule astigmatism has been associated with aging (Fig. 4.2B).^{19–22} Post-natal aging is associated with several structural changes to the corneal tissue including: (1) epithelial basement membrane growth or thickening of an additional 100 to 300 nm or a rate of approximately 30 nm per decade of life; (2) decreased keratocyte, sub-basal nerve fiber, and endothelial cell density, presumably from stress-induced premature senescence; (3) increased stiffness, strength, and toughness of the stroma, from enzymatic maturation- and non-enzymatic age-related glycation-induced cross-linking of collagen fibrils; (4) Descemet's membrane thickening of an additional 6–11 µm or a rate of approximately 1 µm per decade of life; and (5) possible degeneration of extracellular matrix structures.^{19,20,23} These structural and cellular changes, however, minimally affect the optical and barrier functions of the cornea and perhaps improve the mechanical function. For example, corneal ectasia from natural causes, like keratoconus, is rarely seen after 40 years of age. Only three documented negative functional consequences are associated with aging – impaired corneal wound healing, decreased corneal sensation, and decreased extensibility of its tissue.^{19–31} In elderly individuals or younger individuals with lipid abnormalities, the cornea often becomes yellowish in the periphery of the cornea due to a fine deposition of lipid. This condition is called arcus senilis.

Major corneal reference points and measurements

When viewed anteriorly in the living eye, the adult human cornea appears elliptical (Fig. 4.3A) as the largest diameter is typically in the horizontal meridian (mean 11.7 mm) and the smallest is in the vertical meridian (mean 10.6 mm).¹ This elliptical configuration is brought about by anterior extension of the opaque sclera superiorly and inferiorly. When viewed from the posterior surface, the cornea is actually circular (Fig. 4.3A), with an average horizontal and vertical diameter of 11.7 mm. The average radius of curvature of the anterior and posterior corneal surface is 7.8 mm and 6.5 mm, respectively, which is significantly less than the 11.5 mm average radius of curvature of the sclera. This results in a small 1.5–2 mm transition zone that forms an external and internal surface groove, or scleral sulcus, where the steeper cornea meets the flatter sclera (Fig. 4.3A). This sulcus typically is not obvious clinically because it is filled in by overlying episclera and conjunctiva externally. The tissue in this transition zone is known as the limbus (Fig. 4.3B), which averages 1.5 mm wide in the horizontal meridian and 2 mm wide in the vertical meridian. It is important because it contains adult corneal stem cell populations, contains the trabecular meshwork, which is the conventional outflow pathway for the aqueous humor, and is the inciting site of pathology in a few immunologic diseases.³² The limbus is also a major anatomic reference point for planning surgical entry into the anterior segment because it appears clinically as a blue transition zone. Therefore, an incision placed anterior to the blue zone is anatomically in the peripheral cornea, safely inside the trabecular meshwork and stem cells. The cornea is thinner in the center, measuring on average 544 ± 34 µm (range: 440–650 µm) with ultrasound pachymetry, and increases in thickness in the periphery to

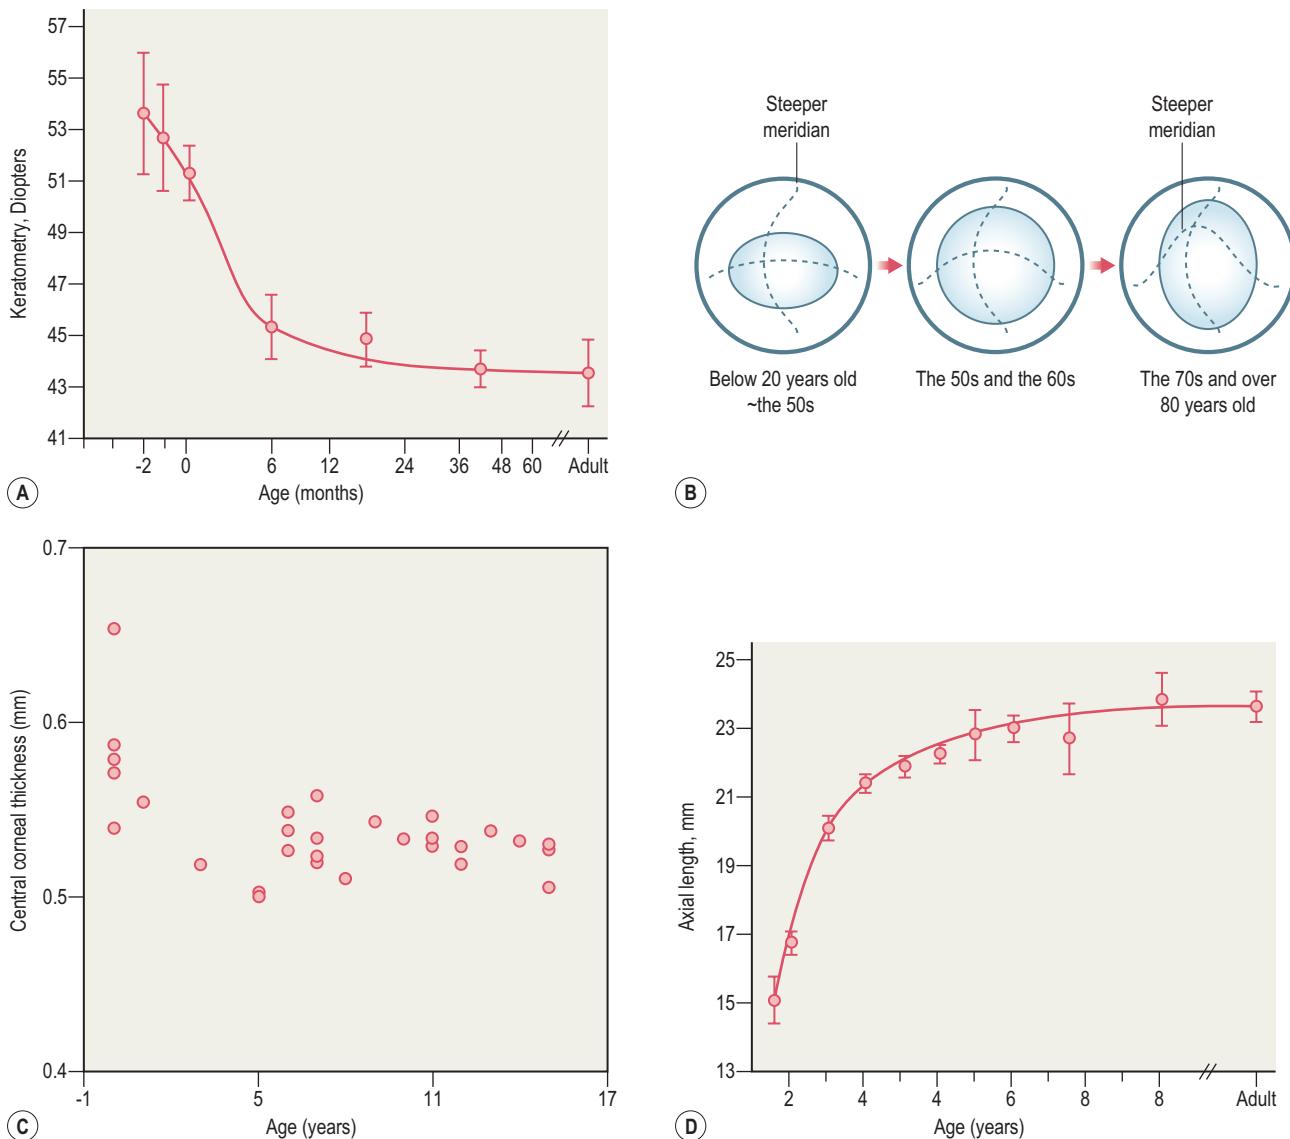

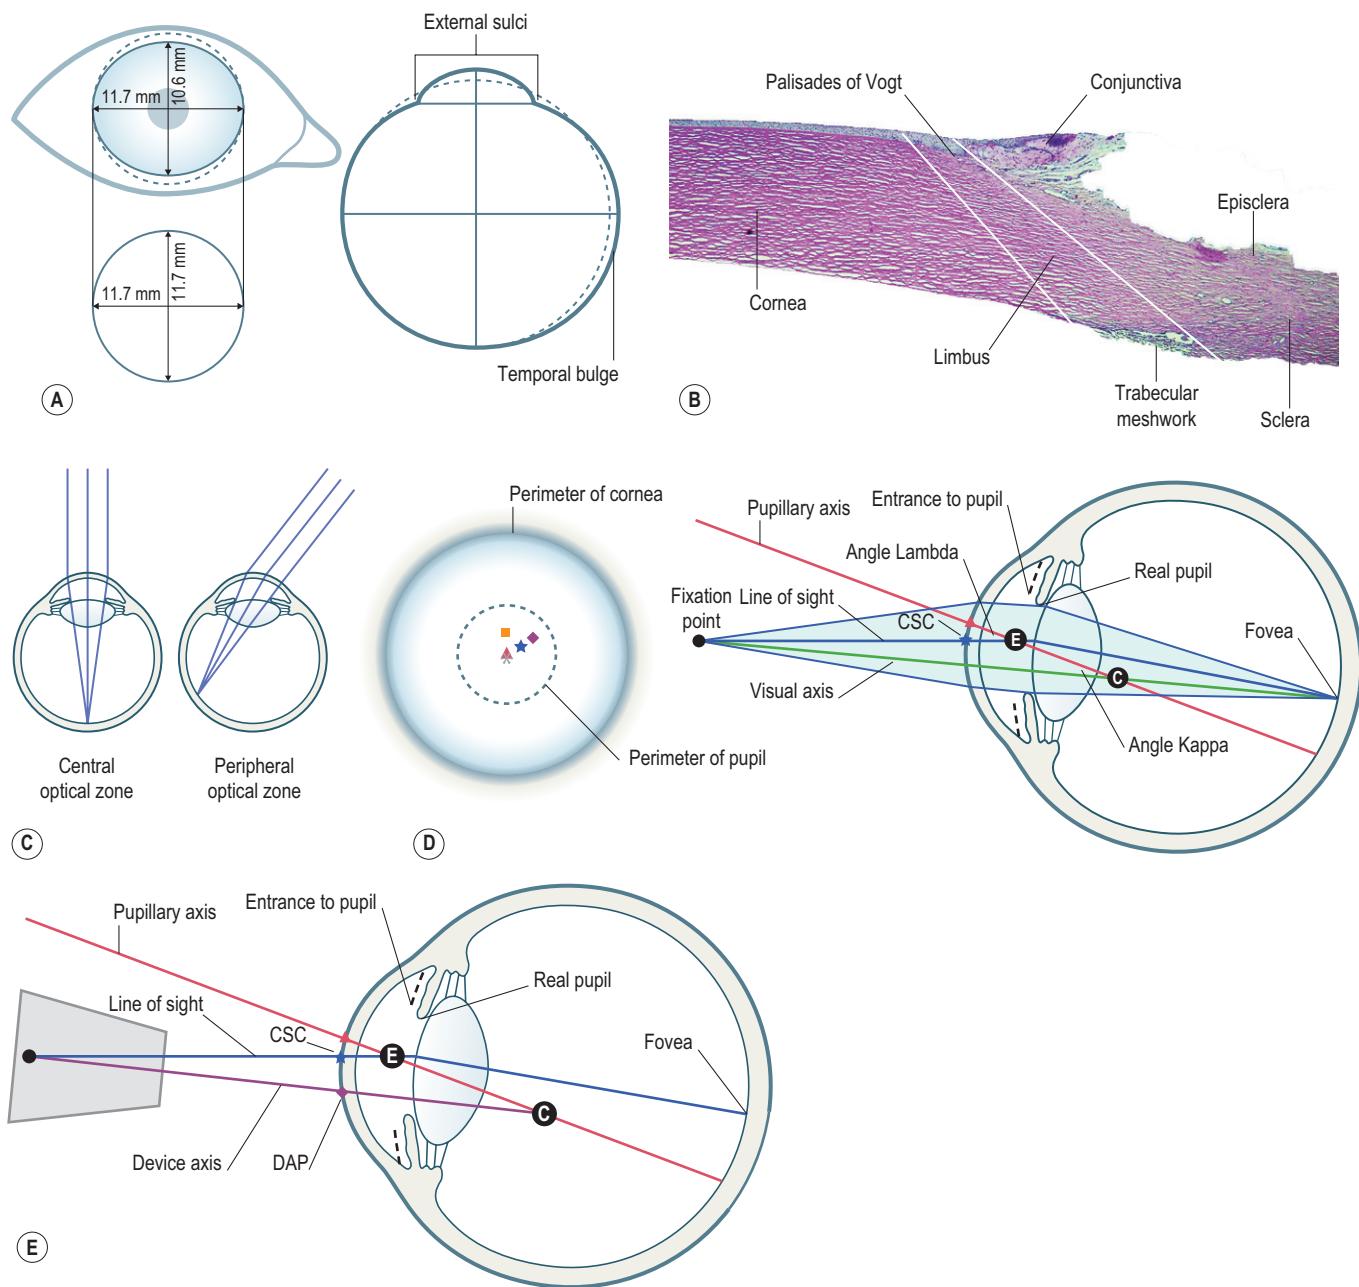

Figure 4.2 (A) Keratometry values plotted with respect to age on a logarithmic scale. Negative numbers represent months of prematurity; dot = mean value for each age group and bar = standard deviation. (From Gordon RA, Donzis PB. Arch Ophthalmol 1985; 103:785–9.) (C) Scatterplot showing the relationship between age and central corneal thickness from various studies in the published literature. (From Doughty MJ, Laiquzzaman M, Muller A, et al. Ophthalm Physiol Optics 2002; 22:491–504.) (D) Axial length plotted with respect to age. Dots = mean values for age group; bars = standard deviation. (From Gordon RA, Donzis PB. Arch Ophthalmol 1985; 103:785–9.)

Figure 4.3 (A) Coronal views show the elliptical shape of the right cornea when viewed anteriorly (upper left) and the circular shape when viewed posteriorly (lower left). Superior axial view (right) illustrates how the right globe deviates from a perfect sphere. Dashed lines = theoretical spherical globe; solid lines = actual contour of the globe. ES = external sulcus; TB = temporal bulge. (Modified from Bron AJ, Tripathi R, Tripathi B. In: Wolff's anatomy of the eye and orbit, 8th edn. London, UK: Chapman & Hall, 1997.) (B) Locations of the peripheral cornea, limbus, sclera, episclera, and conjunctiva (PAS $\times 20$). (C) The cornea overlying the entrance pupil, known as the central or effective optical zone, directly impacts foveal vision, whereas the cornea peripheral to the entrance pupil, known as the peripheral optical zone, primarily impacts peripheral vision. (Modified from Uozato H, Guyton D. Am J Ophthalmol 1987; 103:264–75.) (D) The clinically definable and practically useful principal axes of the eye (left), line of sight and pupillary axis, and major corneal reference points of the cornea (right [right cornea shown]), corneal sighting center (CSC), corneal apex, and thinnest corneal point (TCP) are illustrated in reference to the theoretical, but not practically useful visual axis. The line of sight is the line from the fixation target to the corneal sighting center (CSC) that typically continues through the cornea into the eye, at or near the center of the entrance pupil, where it is refracted by the cornea and lens to finally reach the fovea. The light rays from the fixation target (shown by shaded areas) are usually centered on or near the entrance pupil, E, and are nearly symmetric around the line of sight. The line of sight is often confused with a theoretical principle axis of the schematic eye called the visual axis. Technically, there is no visual axis of the real human eye because the non-centered optics of the real eye do not allow a single straight line to describe this theoretical pathway of chief light rays, defined as an undeviated line from the fixation target that passes through the nodal points of the eye and ultimately onto the fovea. The visual axis is used for calculating the relation between object and image sizes using Gaussian optics and Gullstrand's schematic eye, but it has no meaning or usefulness in the real eye. The pupillary

axis is an easily definable line from the center of the real pupil to the perpendicular or normal surface of the cornea, which is aligned with the center of curvature of the cornea, C_r. Angle kappa is the angle between real pupillary axis and theoretical visual axis; angle lambda is the angle between the real pupillary axis and real line of sight. In the clinical setting, it is the angle lambda that is measured by observing the displacement of the coaxially viewed corneal reflex from the pupil center of a fixating eye, even though it is erroneously called angle kappa. Usually angle lambda measures between 3° to 6°. The visual axis and line of sight are often assumed to be parallel, but this is only true for very distant objects near infinity. Pink dot = pupillary axis intercept with cornea; blue dot = line of sight intercept with cornea or CSC; yellow dot = corneal apex; violet dot = imaging device's axis point (DAP); gray dot = TCP. (E) The standard alignment position for all imaging devices occurs when a patient directly looks at a luminous fixation point centered in the circular rings of the imaging device and its reflected image is then aligned by the examiner so that it is centered in the operator's screen of the device. When in standard alignment position, the imaging device's optical axis is aimed perpendicular or vertex normal to the surface of cornea and directed toward the center of curvature of the cornea, C_r; it also is approximately twice the distance from the pupillary axis as the line of sight. The anterior corneal surface intercept with the device axis is the device axis point (DAP). The center of the circular rings of the imaging device's operator screen and the reflected first Purkinje image of the luminous fixation target are perfectly aligned in the standard alignment position. Only if angle lambda is zero will standard alignment position coincide with the line of sight and the corneal sighting center. E = center of entrance pupil. (Modified from Mandell R, Horner D. In: Gills J, Sanders D, Thornton S, et al, eds. Corneal topography. The state of the art. Thorofare, New Jersey: Slack, 1995.)

approximately 700 µm as it reaches the limbus.^{1–4,6} A meta-analysis of all cross-sectional and longitudinal corneal thickness studies over a 30-year time period showed that no significant age-related change in central corneal thickness occurred beyond the infant years.¹⁸

The central cornea overlying the entrance pupil, which is a virtual image of the real pupil and is typically located 0.5 mm anterior to and 14 percent larger than the real pupil, contains the central or effective optical zone of the cornea (Fig. 4.3C). The central optical zone is the portion of the cornea that can successfully refract a cone-like bundle of light from a distant or near fixation target through the pupil of the eye and then directly refracts it onto the fovea. The central location and size of this central optical zone dynamically changes according to the location of the fixation target in relation to the cornea (e.g. more distant fixation target = larger-diameter central optical zone, off-center fixation target = off-center central optical zone) and the aperture of the real pupil in various lighting conditions since the bundle of light has the same cross-sectional shape (e.g. an oval pupil results in an oval central optical zone) as the pupil and its diameter are defined by the pupil's diameter as well as the location of fixation target. The central optical zone's diameter typically averages 3.6 ± 0.8 mm in photopic lighting and 5.8 ± 0.9 mm in scotopic light with a range between 1.5 to 9.0 mm depending on the lighting condition.^{33–36} The remaining cornea peripheral to this central optical zone is the peripheral optical zone, which can refract light through the entrance pupil, but it does so at such an acute angle that it only affects the more peripheral aspects of the retina including the macula (Fig. 4.3C); it rarely directly impacts foveal vision.

Within the central optical zone are three major corneal reference points (Fig. 4.3D) that are extremely useful in determining the shape, refractive power, and biomechanical properties of the cornea, since they are statically fixed reference points.³⁷ The first is called the corneal apex; it is defined as the steepest point or area of the cornea. It typically is measured using a corneal keratograph, topographer, or tomographer and thus its exact location on the cornea is referenced in relation to the corneal intercept of the imaging device's optical axis (Fig. 4.3E).³⁸ The corneal intercept of the imaging device's optical axis is termed the device's axis point (DAP). On average, the corneal apex usually is located 0.8 mm temporal and 0.2 mm superior to the DAP or 0.5 mm temporal and 0.5 mm superior to the corneal intercept of the line of sight of the eye (Fig. 4.3D), but considerable inter-individual variability is found in the location of the corneal apex in comparison to the average.³⁹ The clinical utility of the corneal apex is that it is of paramount importance in the selection and fitting of contact lenses and in determining the geometric aspheric shape of the cornea.³⁷ Significant decentration of the corneal apex from the DAP may give a false interpretation of corneal shape (e.g. asymmetric shape). The easiest way to clarify whether this is real or due to artifact is to aim the imaging device's optical axis directly at the corneal apex, which is more cumbersome and difficult to do than standard alignment position.

The second major corneal reference point is the corneal intercept of the line of sight, also known as the corneal sighting center (CSC).^{37,40} The line of sight is an actual principal axis of the real eye as opposed to a theoretical construct of a schematic eye (e.g. visual axis) and it is defined as the

principal axis joining a distant fixation point to the fovea. It theoretically is always thought to cross the center of the entrance pupil, which may not be true in the real eye since it is known that the center of the entrance pupil dynamically and unpredictably shifts up to 0.7 mm in direction with changes in pupil diameter, whereas the line of sight is a statically fixed axis line. Thus, it perhaps is best thought of as a line connecting the fixation target to the CSC on the anterior surface of the cornea and then via an unknown non-linear pathway is refracted in the cornea and by the lens to focus on the fovea. The location of the line of sight and CSC are of utmost importance to know in certain clinical situations for getting the best visual results with keratorefractive surgery, particularly with retreatments and customized ablations, and for calculating the proper posterior chamber intraocular lens (PCIOL) power to put in during cataract extraction (CE), especially after previous refractive surgery or with anterior surface irregularities, since subclinical decentrations ≥ 0.5 mm or torsional misalignments $\geq 15^\circ$ can yield unwanted visual symptoms (e.g. coma or other higher-order aberrations [HOAs]).^{37,40–43} On average, the CSC is 0.4 mm nasal and 0.3 mm superior to the dynamically, unfixed pupillary axis or 0.5 mm inferior and 0.5 mm nasal to the static, fixed corneal apex reference point (Fig. 4.3D), but its location overall is highly variable between different individuals.⁴⁰ Using a keratographer, topographer, or tomographer in non-standard alignment position, the CSC can be directly determined by having the patient directly look at a luminous fixation point centered in the circular rings of the imaging device and then it is marked in reference to the center of the operator's screen. Because of practical difficulties in non-standard alignment, some clinicians approximate the CSC's position using the coaxially sighted corneal reflex, where the patient looks directly at a luminous fixation point centered in the circular rings of the imaging device and the anterior corneal surface's first Purkinje image is used to approximate the location of the CSC.⁴⁰ This approximation method reportedly locates a point on average 0.02 ± 0.17 mm (range: -0.43 mm to $+0.68$ mm) from the actual CSC in normal eyes; this, however, may not be the case in diseased or surgically altered corneas.⁴⁰

The third major and newest corneal reference point is called the thinnest corneal point (TCP), defined as the thinnest point or zone of the entire cornea. It is measured using various tomography instruments, which enable a mathematical 3D reconstruction of the *in vivo* pachymetric distribution map, allowing one to evaluate the spatial variation of the thickness profile over the entire cornea. In the normal cornea, the average location and value of the TCP is 0.4 mm inferior and 0.4 mm temporal to CSC and 5 µm less thicker than the central corneal thickness at the CSC. The location and value of TCP is important because it allows clinical differentiation of corneas with normal biomechanical properties from those with current or previous keratectasia since no normal cornea was found in a group with a TCP more than 1 mm distance from the CSC and less than 500 µm of thickness.

If the central optical zone of the anterior corneal surface is regular, yet not uniformly spherical in each meridian, the condition of astigmatism usually results. With astigmatism, a distant fixation point is refracted by the cornea and lens to become two focal lines rather than a sharp image point. On

the other hand, if the central optical zone is irregular, then irregular astigmatism usually results. In adult humans, the conjunctival surface area has been measured at approximately 17.65 cm² and the corneal surface area measures 1.38 cm², giving a conjunctival-to-corneal surface area ratio of 12.8, which is important for drug delivery calculations.¹

Optical properties

Light refraction

The main optical measurements that determine the total refractive power of the eye are the anterior and posterior curvatures of both the central cornea and lens, the depth of the anterior chamber, and the axial length of the eye (Fig. 4.4A).³⁵ As this chapter is strictly about the cornea and sclera, we will focus only on the optical properties of the cornea. Refractive power and aberrations induced by the optics of the cornea are primarily due to corneal curvature and contour, respectively. Both are descriptors of corneal shape. The contour of the anterior corneal surface is basically of an aspheric geometry with the corneal apex defining the point of greatest refractive power or steepest curvature and then it gradually and variably flattens from the apex to the periphery.⁴⁴ Corneal asphericity has been known for over 100 years and has been modeled by various mathematical formulas in order to derive a quantitative approximation of contour.^{45,46} The central optical zone of the anterior corneal surface best corresponds to that of a conic section using the following formula, which requires only knowing two conic fit parameters – Q and R.⁴⁷

$$Q = p - 1 = \left(\frac{b}{a} \right)^2 - 1 = \frac{R}{a} - 1 = (1 - e^2) - 1$$

Q is a unitless asphericity factor or expression of the rate of curvature change from the apex of the cornea to the periphery (Fig. 4.4B); p is a geometric form factor; a and b are horizontal and vertical semi-meridian hemi-axes; R is the apical radius of curvature; and e is the eccentricity. Q averages -0.4 in early childhood, but then gets gradually slightly less negative with age such that the central optical zone has a mean Q of -0.2 in adulthood (range: -0.81 to +0.47).⁴⁷⁻⁴⁹ Q < 0 describes a prolate contour where the rate of curvature change from the apex is less than that of a sphere (Fig. 4.4C); most normal corneas are prolate as it is advantageous in that it compensates for spherical aberrations induced by larger pupil sizes, which project misaligned peripheral rays of light on the fovea. Q = 0 describes a spherical contour where the rate of curvature change from the apex to the periphery is zero, while Q > 0 describes an oblate contour where the rate of curvature change from the apex is more than that of a sphere (Fig. 4.4C). Oblate contours are typically present in ≤ 20 percent of the normal population. Interestingly, asphericity can significantly change after surgery, especially excimer laser keratorefractive surgery, usually resulting in various oblate contours. Although the contour of the central optical zone of the anterior corneal surface is the most important for directly impacting foveal vision and on-axis aberrations (spherical aberrations, coma, and other HOAs), recent study has also shown that the peripheral optical zone is important for off-axis aberrations (e.g. glare, halos, starbursts). This peripheral optical zone does not fit a conic section well, but rather fits a ninth-order polynomial formula

best and has a measured Q of -0.4 in adulthood when the central 10 mm of cornea is best fit to this formula.⁵⁰ A few reports on the posterior corneal surface suggest it also has a prolate contour too with a Q of -0.4, but its contribution to the total optical aberrations of the eye are less well known.^{46,48}

The actual total corneal dioptric power of the central 4.0 mm of cornea reportedly averages 42.4 ± 1.5 D (range: 38.4–46.3) of the eye's total dioptric power of 60 D.^{35,45,51} The location of the corneal apex compared to the CSC (generally less than 1 mm from the CSC and on average 0.7 D steeper than that at the CSC), the degree of asphericity of the anterior corneal surface, and the degree of anterior corneal surface-to-posterior corneal surface ratios can vary widely from one individual to another or even change with age in an individual.^{48,52–54} For these reasons, it is difficult to take these general population-averaged results as an empirically useful value. An individual's total corneal power along the line of sight of the eye should probably best be measured using the Gaussian optics formula:

$$P_{totalcornea} = \frac{n_c - n_{air}}{r_{ant}} + \frac{n_a - n_c}{r_{post}} - \left(\frac{d}{n_c} \times \left(\frac{n_c - n_{air}}{r_{ant}} \right) \times \left(\frac{n_a - n_c}{r_{post}} \right) \right)$$

Where $P_{totalcornea}$ equals diopters of optical power; n_{air} , n_c , and n_a are the indices of refraction in air (1.000), cornea (1.376), and aqueous humor (1.336), respectively; r_{ant} and r_{post} are the radii of curvature of the anterior (0.0078) and posterior (0.0065) corneal surface in meters, respectively; and d is the central corneal thickness (0.00054) in meters.

$$42.18 \text{ D} = \frac{1.376 - 1}{0.0078} + \frac{1.336 - 1.376}{0.0065} - \left(\frac{0.00054}{1.376} \times \left(\frac{1.376 - 1}{0.0078} \right) \times \left(\frac{1.336 - 1.376}{0.0065} \right) \right)$$

Therefore, the calculated total optical power of the cornea using known average major reference values is 48.21 – 6.15 + 0.12 = 42.18 D, which agrees closely with the actual mean of 42.4 D found in the study above.

Because the cornea is thinner in the center than in the periphery, it should act as a minus lens, but functions as a plus lens because the aqueous humor neutralizes most of the minus optical power on the posterior corneal surface. If we compute the power of the posterior corneal surface in air, we find the following:

$$P_{postcornea} = \frac{n_a - n_c}{r_{post}} = \frac{1 - 1.376}{0.0065} = -57.85$$

The resulting calculated total optical power of the cornea would then be 48.21 – 57.85 + 1.12 = -8.52 D, which is a minus lens.

From the foregoing calculations, it is obvious that the most important refractive surface for humans is the anterior corneal surface. However, if a large air bubble is placed in the anterior chamber so that it contacts the corneal endothelium or if the anterior surface of the cornea is submerged in water, tremendous changes in the refractive power of the eye occur. For example, when the eye is open underwater during swimming, the optical imagery is extremely blurred; the index of refraction of water (1.333) is quite similar to that of the tear film and cornea (1.376). Thus, most of the optical power of the anterior corneal surface is lost. If the air-tear

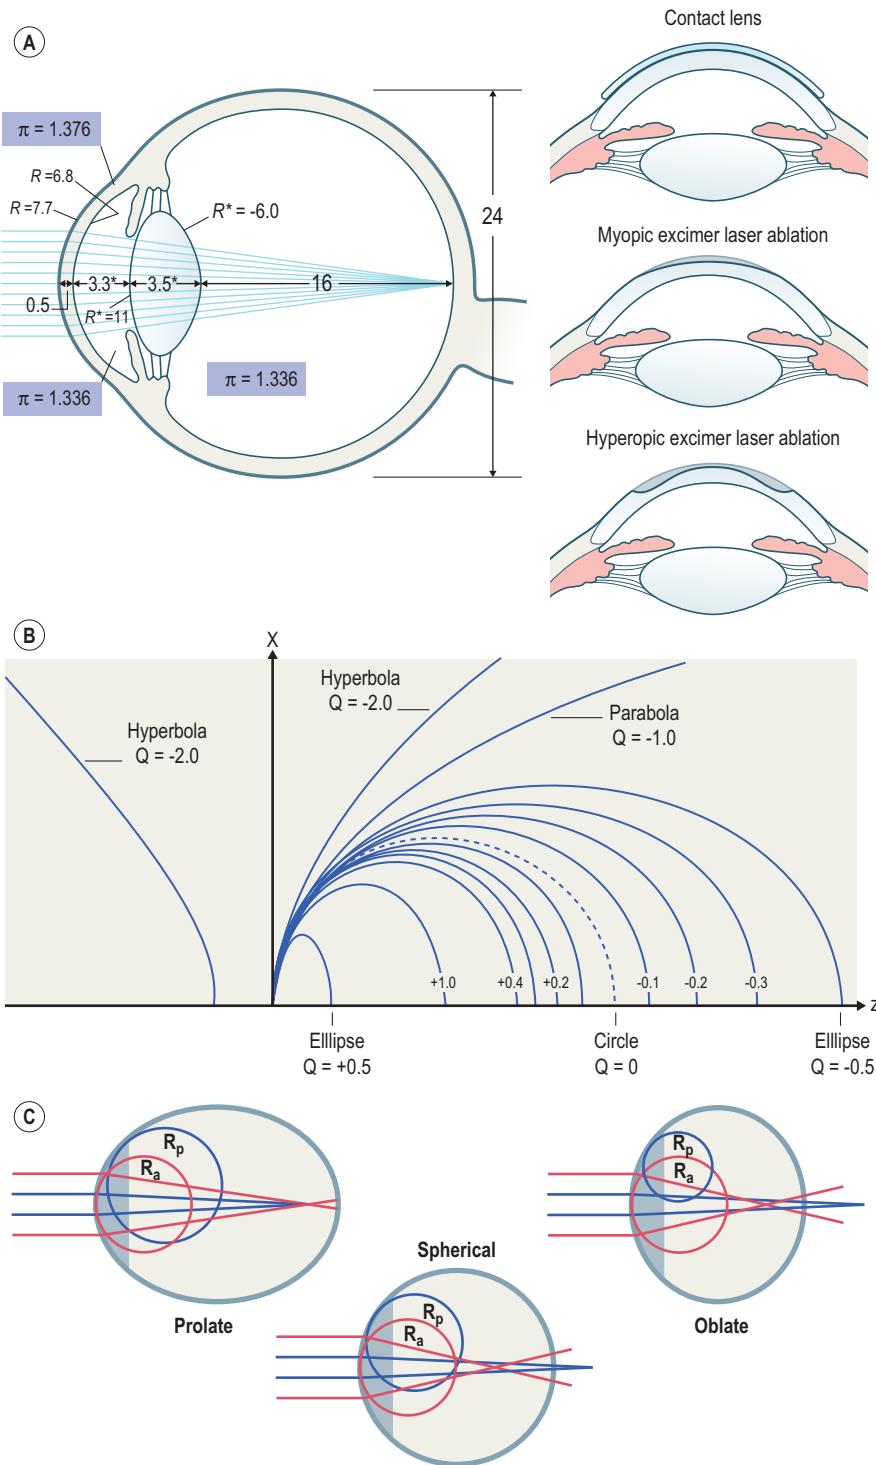

Figure 4.4 **(A)** Diagram of the schematic eye with representative average dimensions in millimeters and refractive indices of the relaxed, non-accommodating eye. The starred values change with accommodation. These dimensions are average values used to construct a representative or schematic eye – in real life, all dimensions of the eye can vary greatly between individuals and from these average values. Upper-right diagram shows that the principle of corneal contact lens wear is to make the anterior corneal surface ineffective as it is now bathed with aqueous tears and the new anterior refractive surface is the air-anterior contact lens interface. Middle-right diagram shows that the principle of myopic correction using the excimer laser is based on a graded removal of central anterior corneal tissue to decrease the central anterior corneal curvature, analogous to the removal of a biologic contact lens that is thicker in the center. Lower-right diagram shows that the principle of hyperopic correction using the excimer laser is based on a graded removal of a peripheral and paracentral concave lenticule of tissue to increase the central anterior corneal curvature (i.e. a donut-shaped trough) analogous to the removal of a biologic contact that is thicker in the periphery and of no or minimal thickness in the center. **(B)** Variations in conicoid shape for different asphericities, or Q-factors, with the same radius of curvature. **(C)** Schematic diagrams showing the three possible anterior corneal surface contours with ray tracings from a distant fixation point being refracted onto the retina. Upper left diagram is of a prolate cornea (Q factor < 0), which has a larger peripheral radius of curvature than at the apex ($R_p > R_a$). Lower middle diagram is of a spherical cornea (Q factor $= 0$), which has equal peripheral and apical radii of curvature ($R_a = R_p$). Upper right diagram is of an oblate cornea (Q factor > 0), which has a smaller peripheral radius of curvature than at the apex ($R_a > R_p$). As a prolate cornea reduces spherical aberrations, its image is more tightly or precisely focused than spherical or lastly oblate corneas. The mean value of the Q factor for normal healthy adult corneas is -0.2 , which reduces natural spherical aberration by about half; a Q factor of -0.50 eliminates all spherical aberration. Thus, the human cornea typically is not designed to induce zero spherical aberrations. In fact, the human lens is optically coupled to cornea in such a way that spherical aberrations are reduced close to zero in youth since during childhood and young adulthood the lens has negative asphericity. Lens asphericity dynamically changes with aging, usually resulting in a Q of zero around age 40 and then has positive asphericity after age 40. The overall effect on the optical properties of the human eye is that it gains progressively more spherical and other optical aberrations with increasing age, which perhaps best explains the direct association of deterioration of visual performance and quality with aging. Most degradation of image quality is due to age-related changes in the lens. (Modified from Gatinel D, Haouat M, Hoang-Xuan T. J Fr Ophthalmol 2002; 25:81–90.)

film interface is maintained by the use of a mask or goggles, then underwater vision is as sharp and clear as normal terrestrial vision.

Light transmission

The cornea is an excellent example of the structural characteristics that a tissue needs to fulfill its dual role of transparency and mechanical support. Tissue transparency is rarely

seen in the animal kingdom outside the eye.^{2–3} In fact, the only structures in humans where this property is seen are in the eye (e.g. cornea, lens, and vitreous). Corneal transparency has occupied scientists for over half a century and initial transparency theories focused on the extracellular stromal matrix while ignoring the cells of the stroma.⁶⁶ Corneal transparency is now thought to be attributable to both the lattice-like arrangement of collagen fibrils in the

Box 4.1 Keratometry, corneal topography, and corneal tomography

Until recently, total corneal power was usually derived clinically from keratometric or topographical measurements of anterior corneal radius of curvature.^{35,51} The cornea was regarded as a single refractive surface with an effective refractive index of 1.3375, also known as the keratometric index of the cornea, because no accurate measurement of an individual's posterior corneal radius of curvature could be measured clinically. Although not individualized for each patient, this mathematical approximation was used primarily for its convenience in the clinical setting; however, with the advent of clinical Scheimpflug tomography (e.g. Pentacam, Oculus Inc., Lynnwood, WA, USA) and other new tomography instruments soon to come on the market, the problems of accurately measuring an individual's actual posterior corneal surface curvature and corneal thickness along the line of sight in the clinical setting have been predominantly resolved, although finding the exact location of the line of sight is still sometimes cumbersome, particularly in post-refractive surgery patients.⁵⁵ Alternatively, total corneal power can still be approximated using these older devices, but at least now more accurately since the keratometric index has been calculated to be around 1.328.⁵¹

corneal stroma and the transparency of cells that reside in the cornea.^{66–71} In summary, all currently viable transparency theories agree with these major points:

1. Each corneal collagen fibril is an ineffective scatterer of light. Although inefficient, based on the large number of fibrils in the human corneal stroma, destructive interference of scattered light must occur due to the short range order of collagen fibrils in the stroma.
2. Each keratocyte nucleus mildly scatters some light, but since the cell body is an ineffective scatterer of light because of transparent intracellular cytoplasmic water-soluble corneal crystallins, its thinness, and because keratocytes are evenly distributed in the corneal stroma through a clock-wise circular arrangement, light transmission is hardly affected.
3. Scattering of light is minimal in the cornea because it is thin.
4. If an increased refractive index imbalance occurs between fibrils, keratocytes, or extrafibrillar matrix, light scattering can increase tremendously in the corneal stroma resulting in loss of transparency.

In order to understand these theories and generalized principles, one needs to start with the structure of the corneal stroma.

The corneal stroma accounts for 90 percent of the corneal thickness. It is predominantly composed of water (3.5 gram H₂O/gram dry weight) that is stabilized by an organized structural network of insoluble and soluble extracellular and cellular substances (Table 4.1).⁷² The dry weight of the adult human corneal stroma is made up of collagen, keratocyte constituents, proteoglycans, corneal nerve constituents, glycoproteins, and salts (Table 4.1).^{72,73} Overall, these corneal components work together to maintain and establish a transparent cornea. Although the cornea primarily absorbs most ultraviolet (UV) light, it transmits almost all visible

Box 4.2 Contact lenses

The principle of using contact lenses to correct refractive errors is that one essentially replaces the powerful anterior corneal refractive surface to that of the anterior contact lens surface (Fig. 4.4A, right top diagram). Upon application of a contact lens, the cornea's anterior surface is rendered ineffective as it is bathed with aqueous tears and the air–contact lens interface now becomes the predominate refractive surface of the eye.^{56,57} Soft contact lenses typically are used to treat spherical and regular astigmatism and rarely cause any permanent pathologic changes or alterations to the cornea unless there is a complication, such as corneal infection, infiltrate, or toxic conjunctivitis.

The prevalence of complications in contact lens wearers is currently about 5 percent per year of wear.^{56,57} Soft contact lenses, however, have been noted to cause some acute physiologic changes to the cornea, including epithelial thinning, hypoesthesia, superficial punctate keratitis, epithelial abrasions, stromal edema, and endothelial blebs. They also cause chronic changes including corneal neovascularization, stromal thinning, corneal shape alterations, and endothelial cell polymegathism and pleomorphism (signs of endothelial cell stress).⁵⁸ These are all thought to result from the contact lens-induced hypoxia and/or hypercapnia of the tissue.

Most of these physiologic alterations, particularly the chronic ones, are markedly less common now with the introduction of daily-wear high oxygen transmissibility lenses, like silicone hydrogel contact lenses. In contrast, hard contact lenses treat spherical, regular astigmatism, and even some cases of irregular astigmatism. Hard contact lenses cause the same acute and chronic physiologic changes to cornea as soft contact lenses, although they do more commonly cause corneal shape alterations to occur because they induce more mechanical pressure on the anterior corneal surface.⁵⁷ In fact, this is the basis for the practice of deliberately fitting tight, overly flat rigid gas-permeable contact lenses with the aim of flattening the central cornea to reduce myopia in a technique known as orthokeratology.⁵⁹ The fitting of contact lenses is highly empirical. Considerable trial and error can be involved in adjusting variables such as contact lens material, size, curvature, and other patient-related factors that are used to arrive at an appropriate correction and comfort level for each individual contact lens wearer.

(400–700 nm) and infrared (IR) light up to a wavelength of 2500 nm, with its peak transmission rate of 85–99 percent in the visible spectrum (Fig. 4.5A).^{74,75} The remaining portion (1–15 percent) is scattered in all directions by the cornea in a wavelength-dependent fashion with violet light being most affected.⁷⁶ Clinical slit-lamp examination and *in vivo* confocal microscopy suggest that most of the light scatter is due to cellular components in the cornea rather than extracellular matrix. Relative amounts of light scattering due to each stromal constituent are the following: endothelial cells > epithelial cells > nerve cells > keratocytes >> collagen fibrils or extracellular matrix (Fig. 4.5B).^{77,78} In fact, the *in vivo* confocal microscope shows that the highest area of the light scatter occurs where differences in the indices of refraction are high, such as at the air–tear film interface of the epithelium.^{71,77} Within the corneal stroma, light scatter predominantly comes from the stroma–plasma membrane interface of nerve cells and the cytoplasm–nuclear interface of keratocytes. With corneal edema or corneal scarring, loss of corneal transparency has been found to be primarily due to changes

Box 4.3 Refractive surgery

Several keratorefractive surgical procedures have been developed to permanently alter the curvature of the anterior corneal surface, thereby reducing refractive errors.^{60,61} The procedures most commonly performed today use the 193-nm argon fluoride (ArF) excimer laser and include laser *in situ* keratomileusis (LASIK), a thin-flap variant of LASIK known as sub-Bowman's keratomileusis (SBK) as well as the surface ablation techniques, photorefractive keratectomy (PRK), laser-assisted subepithelial keratectomy (LASEK), and EpiLASIK.⁶⁰ The excimer laser reshapes the curvature and contour of the anterior corneal surface by removing anterior corneal stroma in a microscopically precise process known as ablative photodecomposition. This results in non-thermal, photochemical breakage of carbon–carbon covalent molecular bonds in the corneal tissue with submicron accuracy. Thus, excimer laser-based keratorefractive surgery is a very accurate, precise, and safe means to permanently change the curvature and contour of the anterior cornea surface. In fact, it has become the most commonly performed refractive procedure performed in the US since it was approved by the US Food and Drug Administration (FDA) in 1995.

The main reason that photoablation of stroma is effective is that the corneal stroma does not regenerate after it is ablated. It only undergoes reparative stromal scarring that at most replaces 5–20 percent of the ablated stromal tissue.⁶² Excimer laser-based keratorefractive surgery has been used to successfully treat myopic and hyperopic refractive errors with mild to moderate degrees of astigmatism resulting in stable long-term (at least 12 years) uncorrected visual outcomes. However, it still is known to potentially deteriorate visual quality due to induction of on- or off-axis aberrations.⁶³ This occurs mainly because:

- (1) the actual laser ablation profile is sometimes different from the intended profile
- (2) the laser ablation profile is based on spherical geometry whereas the preoperative anterior corneal surface is an aspheric ellipse
- (3) the myopic ablation profile makes the cornea more oblate in shape with a flatter curvature in the center and a steeper one in the periphery
- (4) visually significant subclinical lateral decentrations or torsional misalignments occasionally occur
- (5) the ablation zone is sometimes less than the diameter of the entrance pupil, particularly under low lighting conditions.^{64,65}

The basic principle of myopic correction using the excimer laser is based on the graded removal of central tissue to flatten or increase the radius of curvature of the anterior corneal surface (Fig. 4.4A, right middle).⁶⁵ In contrast, the correction of spherical hyperopia involves the graded removal of peripheral and paracentral tissue to steepen or decrease the radius of curvature of the anterior corneal surface (Fig. 4.4A, right bottom).⁶⁵ Finally, the goal behind various astigmatic ablations is to reshape the anterior corneal surface to bring the two focal points of the eye to the same plane and then ultimately onto the retina with a subsequent second spherical treatment step, if needed.⁶⁵ The first step requires selective flattening of the steep meridian and/or steepening of the flat meridian, usually using plus or minus cylinder formats depending on which one removes the least amount of tissue.

Table 4.1 Composition of cornea and sclera

Component	Wet weight (percent)	Dry weight (percent)
Cornea		
Water	78	—
Matrix	66

Proteoglycans	1	3
Fibrocytes	1	3
Other	2	6

in the light-scattering characteristics of keratocytes rather than alterations in the extracellular matrix.^{71,72} In these conditions, the cell body of keratocytes scatters considerably more light than normal corneas, particularly their cell bodies and dendritic processes.

Collagen

Collagen is a structural protein organized into a relatively inextensible scaffold of water-insoluble fibrils that form the basic structural framework of a connective tissue. The corneal collagens are functionally important in establishing tissue transparency and in resisting tensile loads, ultimately defining the size and shape of the tissue. Collagen molecules measure 1.5 nm in width by 300 nm in length and are composed of a triple helix of three alpha chains.⁷³ Of the 28 different types of collagen, there currently are 13 known collagen types in the human cornea.^{80,81} Upon secretion from the cell, the propeptide form of the collagen molecule is cleaved and the monomer of the collagen molecule is assembled into fibril-forming, non-fibril-forming, or fibril-associated collagens with interrupted terminals (FACIT) in a surface recess on the keratocyte or, sometimes, begins assembly inside the cell.

The most common collagen molecule in the cornea is type I (58 percent), which usually aggregates into structural, banded fibrils (Fig. 4.6B), as seen on transmission electron microscopy, by ordering themselves into a quarter-staggered parallel arrangement that is further stabilized in position by covalent intramolecular and head-to-tail intermolecular immature divalent cross-links in a post-translational enzymatic step using lysyl oxidase (Fig. 4.6A and 4.6C, top diagram).⁸² With increasing maturity, a spontaneous conversion to mature cross-links occurs where intramolecular, intermolecular, and interfibrillar mature trivalent cross-links replace the immature divalent ones resulting in corneal collagen fibrils resulting in more optimal mechanical properties (Fig. 4.6C, middle diagram). Both immature and mature cross-links occur between lysine and hydroxylysine

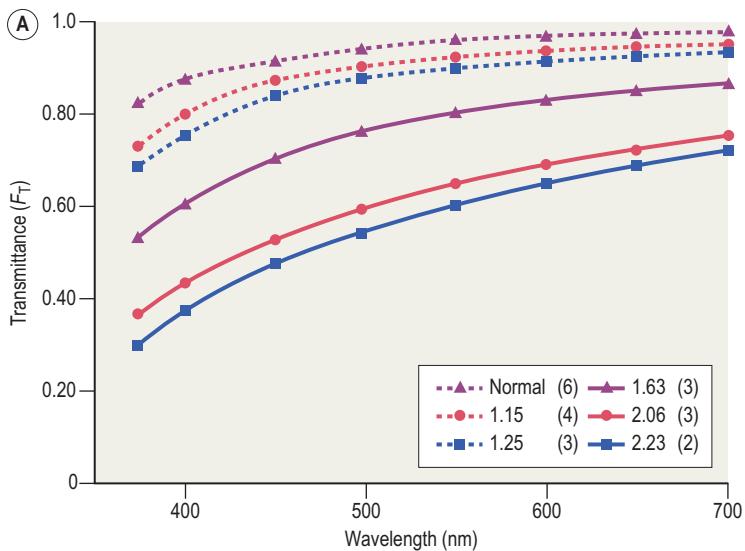

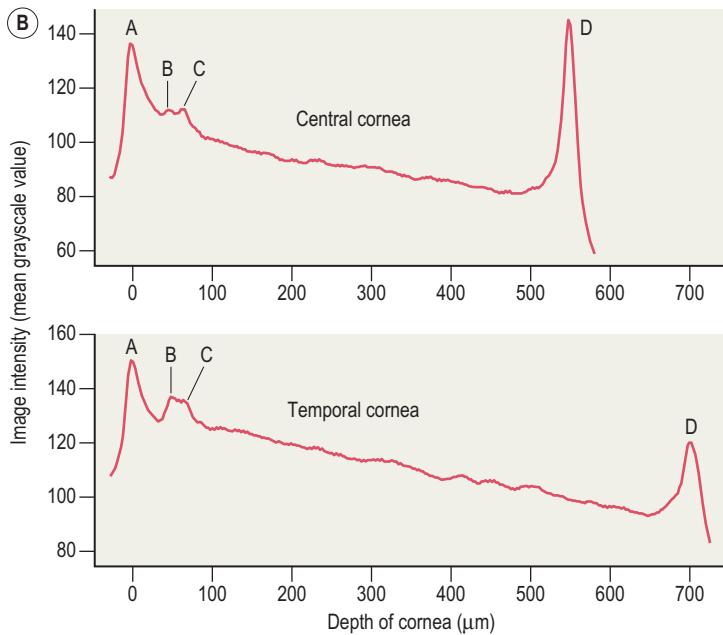

Figure 4.5 **(A)** Experimental values for the percentage of light transmitted through normal and edematous rabbit corneas as a function of wavelength. The ratio of the thickness of the edematous corneas to normal thickness values and the number of corneas used for each curve are given in the key. (From Farrell RA, McCally RL, Tatham PE. J Physiol 1973; 233:589–612). **(B)** In vivo confocal microscopy back-scattered light intensity profile from the central and temporal portions of a 25-year-old normal, healthy human cornea. Intensity peaks correspond to the (A) epithelium, (B) sub-basal nerve plexus, (C) most anterior keratocyte layer, and (D) endothelium. (From Patel S, McLaren J, Hodge D, Bourne W. Invest Ophthalmol Vis Sci 2001; 42:333–9.)

side-chains.⁸² After maturation, the turnover or half-life of collagen molecules and fibrils becomes very slow; the concentration of mature cross-links, however, remains stable, whereas high levels of random intramolecular, intermolecular, and interfibrillar non-enzymatic glycation cross-links accumulate, predominantly between lysine and arginine residues (Fig. 4.6C, bottom diagram).^{81,82} These non-enzymatic age- or diabetes-related glycation cross-links initially enhance the mechanical properties of fibrils resulting in stiffer, stronger, and tougher fibrils than normal, but occasionally they can go too far, making the tissue too brittle or inextensible to function normally. Type I fibrils are generally heterotypic (type I and type V [15 percent] collagen molecules) since they are composed of two or more types of collagen molecules (Fig. 4.6B). This may serve as a fine-tuning mechanism for controlling a fibril's structural characteristics, such as fibril size and interfibrillar connectivity.

Type I fibrils usually reach certain specific diameters based on their composition and ratio of heterotypic collagen molecular types, are restricted from further lateral accretion or growth, and are permitted to fuse and grow axially due to interactions with small leucine-rich proteoglycans covalently bound to its external surface, and through surface interactions connect to various other fibril-forming, non-fibril-forming, or FACIT collagens, which overall links different levels of structural organization (Fig. 4.6).⁸³ Thus, the surface properties of type I fibrils are a major determinant of intrafibrillar and interfibrillar biomechanical properties of the tissue. The other major determinants are the direction of the fibrils and the suprafibrillar architectures of the tissue, which overall defines the hierarchical structure of the tissue. They typically form uniform 25 nm diameter fibrils in the stroma proper with only slight variability (note: the diameters used in this chapter are based on transmission

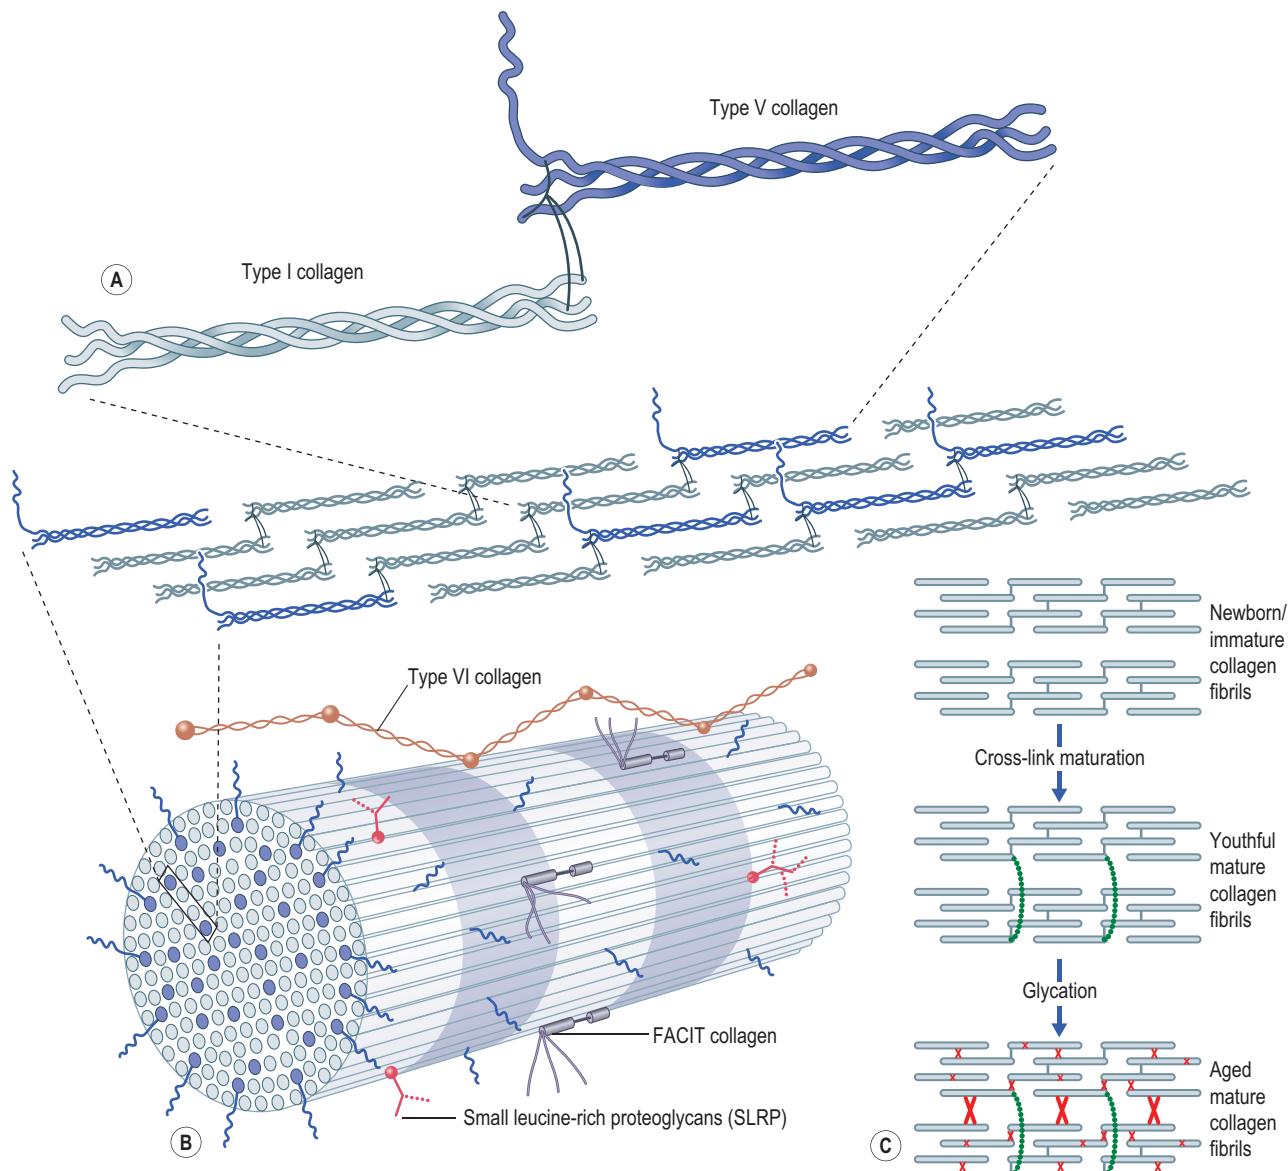

Figure 4.6 (A,B) Cross-sectional oblique view of a 25 nm diameter, heterotypic, banded (periodicity = 65 nm) corneal stromal collagen fibril composed of type I (white) and V (blue) collagen molecules (bottom). The amino-terminal domains on the type V collagen molecules appear to be important in regulating collagen fibril diameter as they project externally to the fibril surface and presumably block further accretion of collagen molecules through steric and/or electrostatic hindrance effects. The collagen molecules on longitudinal view are aligned in a parallel, quarter-staggered (68 nm) arrangement with 40 nm gaps between molecules (middle). The longitudinal view also clearly shows that the ends of the alpha chains in each collagen molecule form intermolecular cross-links with adjacent collagen molecules as well as intramolecular cross-links (top). **(C)** With maturity, these immature divalent cross-links become mature trivalent cross-links with the addition of interfibrillar cross-link branches. Finally, with aging, intramolecular, intermolecular, and interfibrillar non-enzymatic glycation cross-links form.

electron microscopic (TEM); x-ray scattering of ex vivo unprocessed human tissue suggests that a 24–36 percent shrinkage artifact occurs by fixing and processing tissue for TEM studies).^{84–86} Bowman's layer is the main exception as it has uniform 22 nm diameter type I fibrils, which are epithelial in origin as opposed to keratocyte in origin. The diameter of type I fibrils remains constant across most of the central cornea (mean: 25 ± 2 nm; range: 18–32 nm), but then gradually thickens another 4 nm at about 5.5 mm from the center of the cornea, eventually increasing to up to 50 nm at the limbus.^{86,87} Similarly, interfibrillar spacing between nearest neighbor type I fibrils remains constant in

the central cornea (mean: 20 ± 5 nm; range: 5–35 nm), then gradually increases another 5 nm at about 4.5 to 5 mm from the center of the cornea before increasing even more rapidly up to the limbus.⁸⁶ Type I fibril diameters and interfibrillar spaces do not seem to vary significantly with depth in the cornea.⁸⁶ Although the refractive index of type I fibrils (1.47) is different from that of the extrafibrillar matrix (1.35), the highly uniform small size and highly uniform small interfibrillar spaces along with the predominantly parallel directionality of these fibrils results in a highly ordered, lattice-like arrangement. This arrangement is not a true crystalline lattice, but more of a short-range

order that allows transparency of the cornea due to destructive interference (Fig. 4.7).⁶⁶

Type VI collagen (24 percent) is the second most common type of collagen in the corneal stroma. It is present in an unusually high amount compared to most other connective tissues in the body, but it is also unique in that it is only able to aggregate into repeating tetramers of type VI molecules that are stabilized by disulfide cross-links (Fig. 4.8A).^{88,89} Thus, it forms 10–15 nm diameter, non-banded filaments with 20–30 nm diameter beaded ovals having a periodicity of 100 nm. Functionally, type VI filaments act as a bridging structure in the interlamellar space since it binds corneal lamellae together diffusely throughout the stroma where they directly cross one another (Fig. 4.8B,C). Along with type XII and XIV FACIT collagens, it also may bridge fibrils together in the interfibrillar space (Fig. 4.8D).⁸⁹ Overall, this suprafibrillar architecture results in a one-dimensionally-ordered Bowman's layer and a three-dimensionally ordered stroma proper.^{6,90–92}

Although difficult to count precisely, the central corneal stroma reportedly consists of approximately 300 corneal lamellae, while the peripheral cornea consists of approximately 500.⁹⁰ Although most corneal stromal lamellae extend from limbus to limbus and cross adjacent lamellae at various angles, randomly in the anterior stroma and nearly orthogonal to one another in the posterior two-thirds, various regional differences in lamellar size, directionality, and amount of interweaving are also found (Figs 4.9 & 4.10). The anterior third of the stroma proper has thinner (0.2–1.2 µm thick), narrower (0.5–30 µm wide), and mostly obliquely oriented lamellae (mean $18^\circ \pm 11^\circ$ [range 0–36°]) with extensive vertical and horizontal interweaving (Fig. 4.9A,B), while the posterior two-thirds has thicker (1–2.5 µm thick), wider (100–200 µm wide), and mostly parallel-oriented lamellae (mean $1^\circ \pm 2^\circ$ [range 0–5°]) with only slight horizontal interweaving (Figs 4.9C & 4.10B,C).^{90,93} In the most superficial layers of the stroma, the interwoven lamellae actually attach or possibly seem to originate from the posterior surface of Bowman's layer in a polygonal fashion creating an anterior corneal mosaic pattern (Fig. 4.9A, inset) that can be seen on the anterior corneal surface under certain circumstances (the attached fibrils to Bowman's layer seem to be homologous to sutural fibers in the shark cornea and embryologically may be remnants of the primary acellular stroma).¹ Those attaching or originating fibril bundles usually are oriented obliquely to Bowman's layer, but sometimes are noted to be almost perpendicular to it.⁹⁴ Finally, except those fibrils and lamellae in the anterior-most region of the stroma that attach to Bowman's layer, the remaining type I fibrils and corneal lamellae stretch across the cornea from limbus to limbus in a belt-like fashion where they turn and form a circumferential annulus approximately 1.0–2.5 mm wide around the cornea. This annulus is thought to maintain the curvature of the cornea, while blending with limbal collagen fibrils.^{95,96}

Keratocytes

Keratocytes make up the second major component of the corneal stroma's dry weight. They are sandwiched between collagenous lamellae forming a closed, highly organized syncytium. They function as modified fibroblasts during neonatal life forming most of the extracellular matrix of the

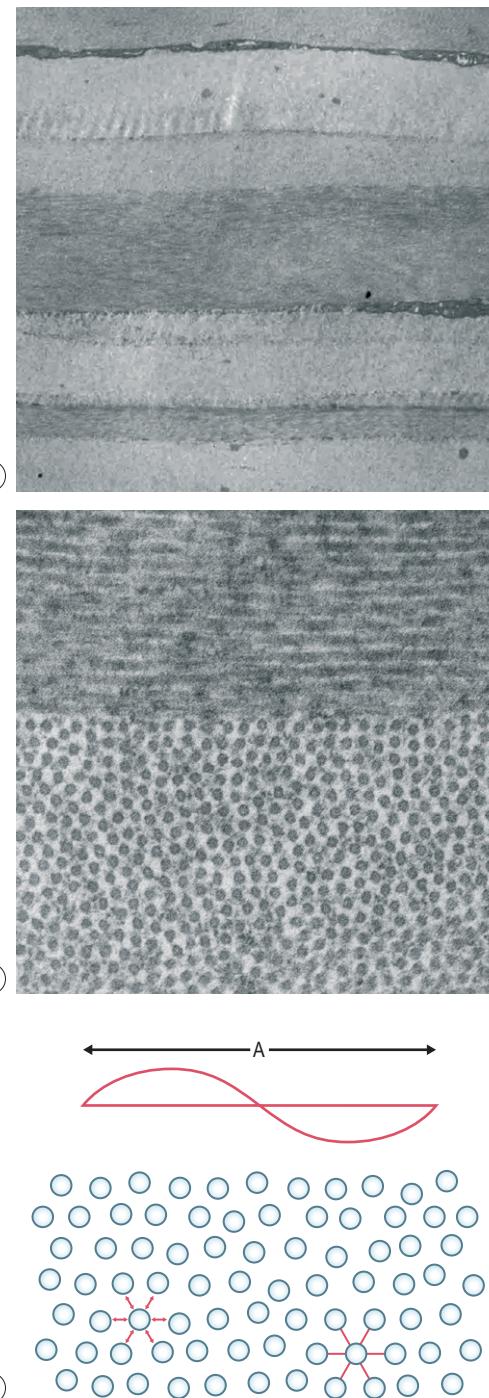

Figure 4.7 (A) Low-magnification ($\times 4750$) TEM of predominantly orthogonally stacked lamellae in the middle third of stroma proper. (B) Higher magnification ($\times 72,500$) TEM of two lamellae in the middle third of stroma proper. One lamella is in longitudinal view (top portion) and the other is in cross-sectional view (bottom portion). Notice the uniform 25 nm diameter type I collagen fibrils and uniform 20 nm diameter interfibrillar spaces, which demonstrates only a short-range order, but not a true crystalline lattice arrangement. (C) Cross-sectional diagram of collagen fibrils arranged in a true crystalline lattice arrangement. Size of a wavelength of light is shown above for comparison. (Modified from Maurice DM. J Physiol 1957; 136(2):263–86).

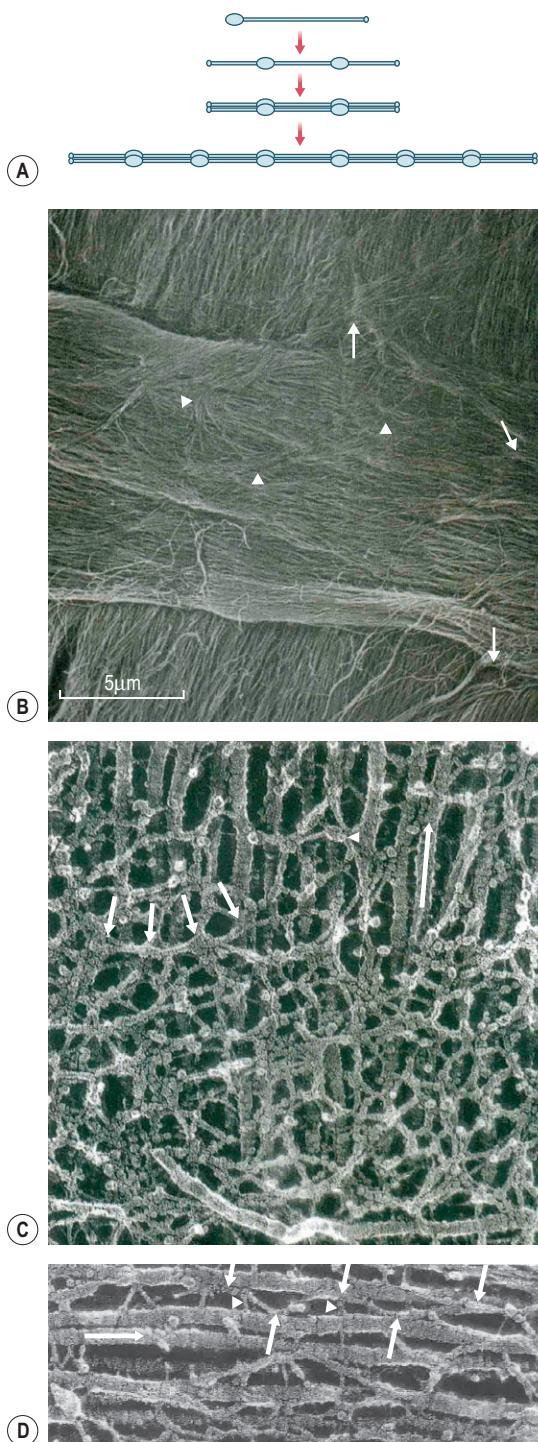

Figure 4.8 (A) Diagram of a type VI collagen molecule showing how it assembles into filaments by aggregating into repeating tetramers of type VI molecules with a periodicity of 100 nm. (B) Low-magnification ($\times 6200$) SEM showing bundles of (type VI) collagen filaments extending between lamellae (arrows) and a loose meshwork of collagen filaments on the posterior surface of a corneal lamella where an adjacent lamella crosses it (arrowheads). Bar = 5 μ m. (From Komai Y, et al. Invest Ophthalmol Vis Sci 1991; 32: 2244–58.) (C) High-magnification ($\times 115,000$) quick-freeze, deep-etched electron micrograph showing a loose meshwork of interlamellar beaded (type VI) filaments with a periodicity of 100 nm (thick arrows) that appear to bind to collagen fibrils (long arrow) by their beads (arrowhead) and bridge fibrils from separate lamellae together. (D) Very-high-magnification ($\times 185,000$) quick-freeze, deep-etched electron micrograph of intralamellar collagen fibrils (long arrows) with beaded (type VI) filaments (thick arrows) criss-crossing between fibrils in the interfibrillar space and projecting three finger-like structures (FACIT collagens) (arrowheads), which both appear to function in joining neighboring fibrils together. (C and D are from Hirsch M, et al. Exp Eye Res 2001; 72:123–35.)

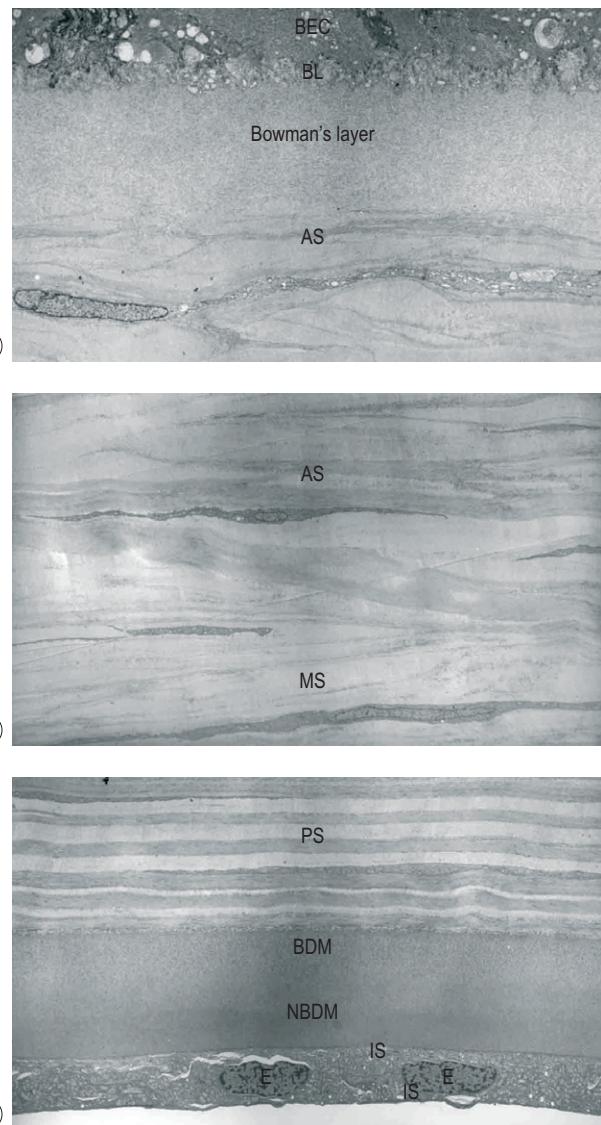

Figure 4.9 (A) The acellular Bowman's layer and anterior-most portion of the stroma proper are shown. The type I fibrils and interweaving lamellae in this region branch extensively and some insert into the posterior surface of the Bowman's layer. This arrangement causes an anterior corneal mosaic pattern to occur on the anterior corneal surface after applying digital pressure through the eyelid and instilling fluorescein. (B) The anterior third of the stroma proper has predominantly oblique lamellar orientation and extensive vertical lamellar branching and interweaving. (C) The posterior third of the stroma proper along with Descemet's membrane and endothelium is shown. The parallel-oriented, orthogonal arrangement of lamellae in this region of corneal stroma is clearly apparent. Although some collagen fibrils randomly insert into Descemet's membrane, no interweaving or significant attachment occurs in this region of the cornea. BEC = basal epithelial cells. BL = basal lamina. AS = anterior stroma. MS = mid-stroma. PS = posterior stroma. BDM = banded portion of Descemet's membrane. NBDM = non-banded portion of Descemet's membrane. E = endothelial cells. IS = intercellular space of the endothelium. (TEM $\times 4750$).

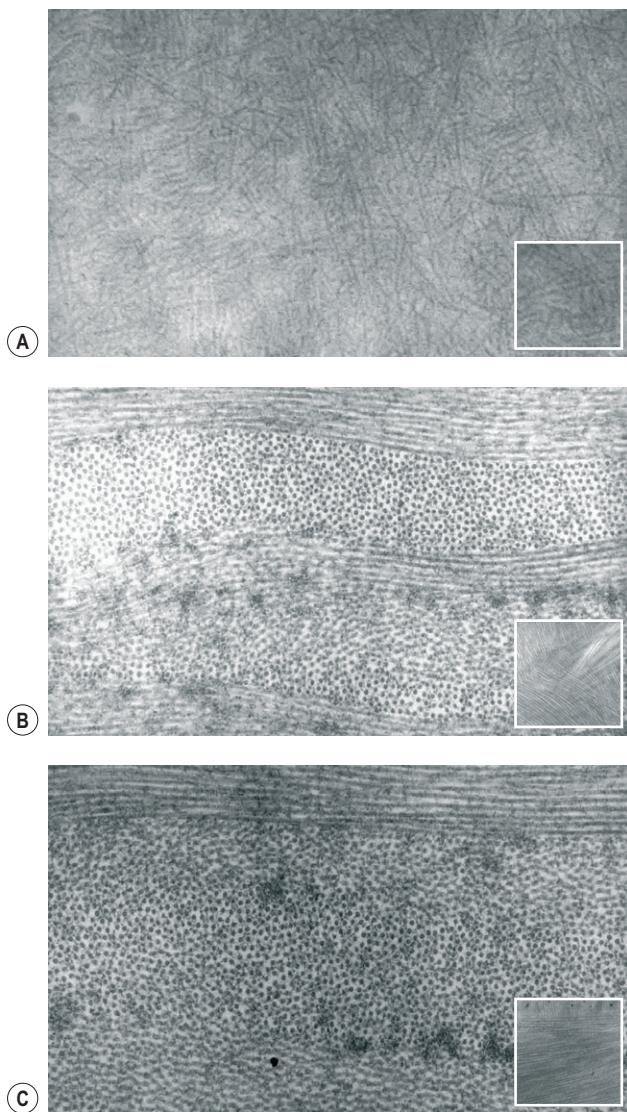

Figure 4.10 (A) The acellular Bowman's layer in cross-section (main photo) and tangential section (inset). Notice the random directionality of the 22 nm diameter collagen fibrils in Bowman's layer. (B) The transition zone between the anterior third and mid-third of the stroma proper in cross-section (main photomicrograph) and tangential section (inset). The thin and more obliquely oriented lamellae in this region of the corneal stroma and its lattice-like arrangement of 25 nm diameter type I collagen fibrils are shown. (C) The posterior third of the stroma proper in cross-section (main photomicrograph) and tangential section (inset). The thick and parallel-oriented lamellae in this region of the cornea stroma and its lattice-like arrangement of 25 nm diameter collagen fibrils are shown. Compare the orthogonal nature of crossing lamellae (inset) to that in the inset B. (TEM $\times 72,500$).

stroma. Subsequently, they remain in the cellular stroma throughout life as modified fibrocytes, where they maintain the extracellular matrix of the corneal stroma. Keratocytes can become metabolically activated or fibroblastic again if the corneal stroma is wounded. The adult human corneal stroma has approximately 2.4 million keratocytes communicating with each other through gap junctions present on their long dendritic processes (Figs 4.11A & 4.12A,B).^{97,98} In adulthood, keratocytes occupy 10 percent of the stromal volume, decreasing from 20 percent in infancy, and on

two-dimensional, cross-sectional views appear to be sparse, flattened, and quiescent (scant intracytoplasmic organelles) cells lying between corneal lamella (Fig. 4.11B).^{73,99} In actuality, keratocytes are three-dimensional, stellate-shaped cells composed of a 15 to 20 μm diameter cell body with numerous dendritic processes that extend up to 50 μm from the cell body. Tangential sections of the normal cornea suggest that these cells more densely populate the stroma than originally thought and are more metabolically active in the resting state than initially presumed since in tangential section an abundance of cytoplasmic organelles are commonly seen (Fig. 4.11C,D).¹⁰⁰

Tangential sections show that the anterior stromal keratocytes contain twice the number of mitochondria as the posterior two-thirds of the stroma, which correlates with the higher oxygen tension of the anterior stroma. It also has been demonstrated that a higher stromal cell density occurs in the anterior stroma than in the mid- or posterior stroma (Fig. 4.12A), whereas a higher cell volume-to-extracellular matrix ratio occurs in the posterior stroma compared to the anterior- or mid-stroma.^{19,26,99} These views also show that in all levels the keratocytes are highly spatially ordered as they turn in a clock-wise direction like a cork-screw. In vivo confocal microscopy of normal human corneas has shown stromal cell densities averaging around 20,000 keratocytes/ mm^3 with a focal zone of increased cell density directly under Bowman's layer, averaging 35,000 keratocytes/ mm^3 in the anterior-most layer that gradually tapers to 20,000 keratocytes/ mm^3 over the initial 60–100 μm in depth (Fig. 4.12C).^{19,26} Confocal microscopy also has shown that stromal cell density decreases with age at a rate of approximately 0.5 percent per year of life with the anterior stroma declining 0.9 percent per year, mid-stroma 0.3 percent per year, and posterior stroma 0.3 percent per year.

Studies using immunohistochemistry or electron microscopy suggest that not all the cells in the corneal stroma are actually keratocytes, but some are one of three types of bone marrow-derived immune cells: "professional" dendritic cells, "non-professional" dendritic cells, and histiocytes (Fig. 4.13).^{100–102} Recent studies also found evidence of a small resident subpopulation of adult stromal stem cells, also known as keratocyte progenitor cells, in the corneal stroma, primarily in the periphery of the corneal stroma near the limbus.^{103,104} The immune cells appear to play a pivotal role in the induction of immune tolerance versus immune initiation in cell-mediated immunity, and the stromal histiocytes have a role in innate immunity as phagocytic effector cells. The presence of adult stromal stem cells helps explain how the slow replacement and renewal of keratocytes occurs after injury, surgery (e.g. epikeratophakia or penetrating keroplasty [PK]), or toxicity to the central corneal stroma (e.g. mitomycin C).

Proteoglycans

Proteoglycans make up the third major component of the corneal stroma's dry weight. They are water-soluble glycoproteins made up of a core protein with a covalently attached anionic polysaccharide side chain called a glycosaminoglycan (GAG). The core proteins are non-covalently attached to collagen fibrils uniformly throughout the tissue, whereas the GAG side-chains extend into the interfibrillar space where it acts as a pressure-exerting polyelectrolyte gel.^{105–107}

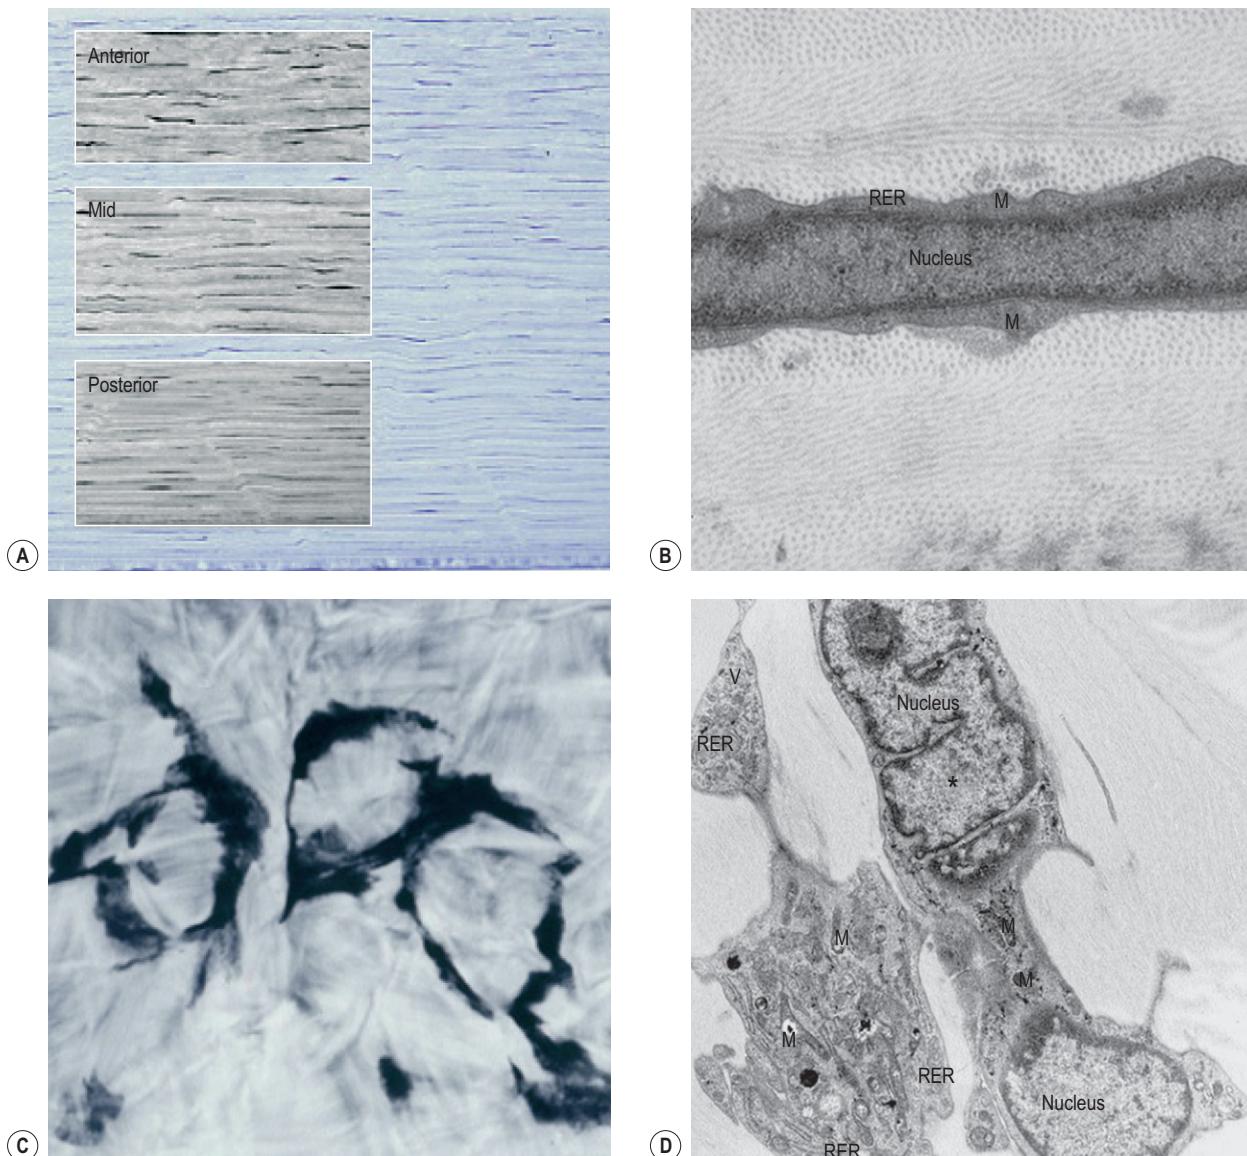

Figure 4.11 Light and TEM photomicrographs showing in cross-section and tangential-section the keratocytes in the stroma. **(A)** Cross-sectional light microscopy view shows that keratocytes are primarily obliquely aligned to corneal surface in the anterior-third of cellular corneal stroma or are aligned parallel to the corneal surface in the posterior two-thirds. **(B)** Cross-sectional TEM view shows that keratocyte nuclei occupy most of the area of the keratocyte seen in this perspective with only a thin rim of surrounding cytoplasm that contains only small numbers of cytoplasmic organelles. **(C)** Tangential-section light microscopy view shows that keratocytes are arranged in a circular fashion. **(D)** Tangential-section TEM view shows that the supposedly quiescent keratocytes may actually be more active in the base-line state than initially thought as an extensive amount of cytoplasmic organelles can be seen in this view. M = mitochondria, RER = rough endoplasmic reticulum, V = vacuoles, * = main portion of nucleus that contains nucleolus. (Modified from Muller LJ et al. Invest Ophthalmol Vis Sci 1995; 36:2557–67.)

The cornea collapses to approximately 20 percent of its original volume if the proteoglycans in the corneal stroma are precipitated out with cetylpyridinium.¹⁰⁵ It has become apparent that the primary functions of proteoglycans are to provide tissue volume, maintain spatial order of collagen fibrils, resist compressive forces, and give viscoelastic properties to the tissue as well as having a secondary role in regulating collagen fibril assembly.¹⁰⁵ Corneal proteoglycans previously were referred to as extrafibrillar amorphous ground substance since their water-soluble state made it difficult to fully delineate them with light and electron microscopy (Fig. 4.14A). It was not until an electron-dense,

cationic dye called cupromeric blue and a critical electrolyte concentration of 0.1 M MgCl₂ were used in combination to specifically stain for the sulfate-ester groups on corneal proteoglycans that the shape, size, arrangement, and location of this material were observed with light and electron microscopy (Fig. 4.14B).¹⁰⁸

Since that discovery, it has become apparent that corneal proteoglycans are not amorphous, but rather tadpole-shaped molecules composed of a 10–15 nm diameter globular core protein with a covalently attached 7 nm wide × 45–70 nm in length. The latter of which is where GAG sidechain attaches to. They are arranged in the corneal stroma perpendicular to

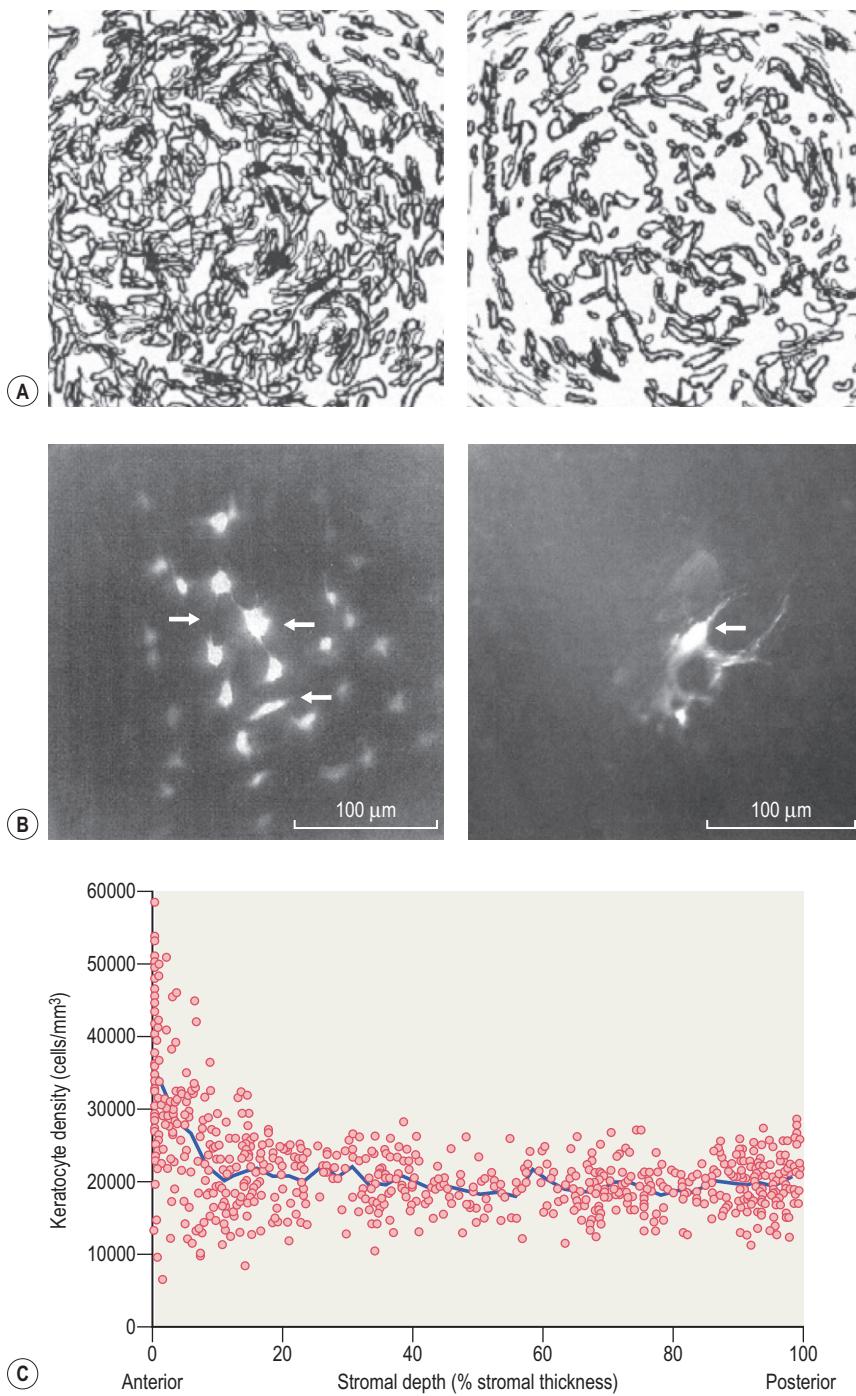

Figure 4.12 (A) Reconstruction of keratocyte outlines seen in tangential-section in the anterior and posterior third of the corneal stroma proper. (Modified from Muller LJ et al. Invest Ophthalmol Vis Sci 1995; 36:2557–67.) (B) Fluorescent dye spreading between many adjacent keratocytes in rabbit (center-left) and human corneas (center-right), which demonstrates the intimate importance of gap junctions in communication of keratocytes with one another. (From Watsky MA. Invest Ophthalmol Vis Sci 1995; 36:S22.) (C) Mean stromal cell density associated with depth in the corneal stroma is shown. The highest zone of increased cell density was closest to the Bowman's layer. Perhaps this is due to baseline, normal epithelial-stromal interactions. (From Patel SV et al. Invest Ophthalmol Vis Sci 2001; 42:333–9.)

collagen fibrils with a constant spacing of around 65 nm between each other along the collagen fibrils. Their core proteins non-covalently bind to collagen fibrils in specific gap zones along the peripheral portions of the collagen fibril. The core proteins with dermatan sulfate side-chains bind to 'd' and 'e' gap zones and those with keratan sulfate side chains bind to 'a' and 'c' gap zones.¹⁰⁹ GAGs are highly negatively charged, stiff polymers that extend into the interfibrillar space and form antiparallel duplexes with adjacent GAG side-chains (Fig. 4.14C), thereby, linking different next-nearest-neighbor collagen fibrils together by forming dumbbell-like structures. The genes that produce the core

proteins have been cloned and four types of corneal stromal proteoglycan core proteins have been identified: decorin, lumican, keratocan, and mimecan.¹¹⁰ Decorin contains a single dermatan sulfate GAG side-chain (Fig. 4.14D), while lumican and mimecan have a single keratan sulfate GAG side-chain and keratocan has three keratan sulfate GAG side-chains (Fig. 4.14D). Thus, there are four known types of proteoglycan core proteins and only two types of GAGs, keratan sulfate (60 percent) and dermatan sulfate (40 percent), found in the human corneal stroma. GAGs are polymers of repeating disaccharide units of galactose and N-acetylglucosamine or iduronic acid and N-acetylgalactosamine, respectively.¹⁰⁹

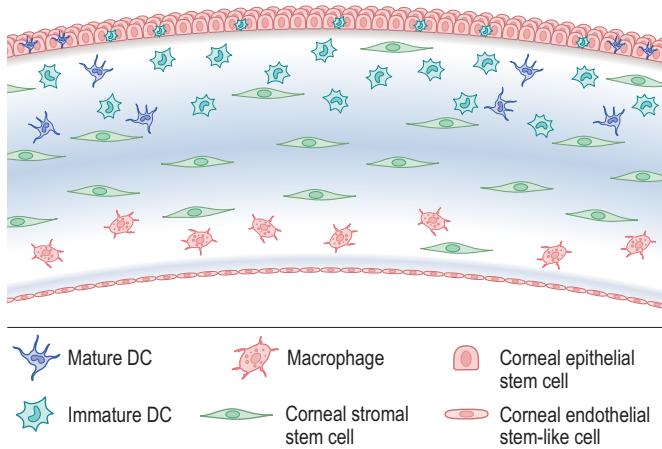

Figure 4.13 The mouse cornea suggests that 5–10 percent of the cells in the cellular corneal stroma are actually one of three types of bone marrow-derived immune cells. The anterior-third of the cellular corneal stroma contains professional (MHC-positive) dendritic antigen-presenting cells in periphery of the cornea, while non-professional (MHC-negative) dendritic cells are present in both the periphery and center of the anterior cornea. The posterior-most regions of the cellular corneal stroma appear to contain macrophages in the periphery and center of the cornea. (Modified from Hamrah P et al. Invest Ophthalmol Vis Sci 2003; 44:581–9.)

Because the core protein tail and their associated GAG side-chains are post-translationally added to core proteins in the Golgi apparatus, there seems to be some flexibility in how long or how sulfated they can become depending on the function of the connective tissue producing them. The human cornea is unique in that the core protein tail and their associated GAG sidechains are fibril-associated and small in length (KS ~45 nm and DS ~70 nm) with a higher amount being over-sulfated than in other connective tissues. A comparative study of corneas from 12 mammalian species suggests that dermatan sulfate is the preferred proteoglycan in oxygen-rich environments, such as in the thin cornea of mice, or is seen predominantly in the anterior portion of the thicker cornea of mammals, such as humans or rabbits. Keratan sulfate is a functional substitute produced through an alternate metabolic pathway in thicker corneas, especially in the posterior portion where oxygen levels may drop precipitously.¹¹¹ Functionally, this duality is quite useful because dermatan sulfate appears to be more efficient at holding water; it absorbs less water than keratin sulfate, but holds most of it in a tightly bound, non-freezable state.¹¹² This is consistent with the fact that dermatan sulfate is more abundant in the anterior corneal stroma in humans, which is the region of highest oxygen tension and most affected by evaporation. In contrast, keratan sulfate is more abundant in the posterior corneal stroma (Fig. 4.15). This is the region of lowest oxygen tension, least affected by evaporation, and the area where the need for loosely bound water is required for transport across the endothelium via the metabolic pumps.

Corneal nerves

The epithelium of the cornea is the most richly innervated tissue of the body with about 16,000 nerve terminals/mm² (~2.2 million nerve endings), about 300–400 times more dense than skin.^{113–115} Most of the nerve fibers in the cornea are sensory in origin, responding to mechanical, chemical,

and temperature stimuli, and are derived from the ophthalmic branch of the trigeminal nerve (CN III₁) (Fig. 4.16A).¹¹⁶ Refer to Chapter 16 (Sensory innervation of the eye) for full details of the innervation pathway of the cornea. Although all mammalian species have been found to receive variable proportions of nerve fibers in the cornea from the sympathetic and parasympathetic autonomic nervous system, human corneas appear to be on the extreme end of this spectrum as their corneas have a very small proportion of their nerve fibers derived from the autonomic nervous system.¹¹⁶

Electrophysiological studies have shown that the cornea's receptive nerve field primarily is composed of polymodal nociceptors (70 percent) followed by mechano-nociceptors (20 percent) and then cold-sensitive nociceptors (10 percent).¹¹⁷ Using in vivo laser confocal microscopes, one can only evaluate morphologically the corneal nerves from the main nerve trunks up to sub-basal plexus (SBP) as the resolution and contrast of these images is not capable of visualizing the final nerve branches and free nerve terminals in the corneal epithelium.¹¹⁸

Since corneal nerve fibers ultimately terminate in the brainstem, it appears that interneuron intermediate pathways must relay the information to the sensation areas of cerebrum. Additionally, there must also be intermediate relays to efferent systems that trigger the reflex pathways of involuntary blinking via orbicularis motor innervation from CN VII and reflex tearing via parasympathetic innervation of lacrimal gland. The intricate central nervous system (CNS) details of these specific pathways are currently unknown.

Corneal sensitivity is a valuable clinical measure of corneal health since corneal nerves directly maintain the health of corneal epithelium through direct trophic factors as well as serve a protective role in warning the host of possible dangers to the normal healthy state and maintain an adequate basal tear secretion rate.^{116,119} It is usually tested clinically in a semi-quantitative fashion with a Cochet and Bonnet esthesiometer, which is a thin (0.12 mm diameter), flexible, nylon filament of variable length (0–6 cm).^{119–121} When the filament is long, it applies very little pressure to the corneal surface because it bends easily, while when short it applies a proportionally higher pressure before bending. The length is converted into pressure using a conversion table with a range of touch pressures between 11 and 200 mg/mm². Corneal sensitivity is defined as the reciprocal of corneal touch threshold and it can be evaluated subjectively by asking the patients when they feel touch upon the cornea or objectively when a reflexive blink response is triggered. Refer to Chapter 16 for full details on the subjective and objective threshold in normal healthy corneas and those with disease or after surgery.

Corneal sensation also variably decreases with corneal disease (e.g. herpes simplex keratitis, diabetes, corneal dystrophies, keratoconus), following surgical procedures on the anterior segment of the eye and sometimes the posterior segment (e.g. panretinal photocoagulation), after application of certain topical medications (e.g. anesthetics, non-steroidal anti-inflammatory drugs), and even after contact lens wear.^{119,122} As nerve regeneration occurs at the rate of approximately 1 mm per month, it may take up to 3–12 months or longer for corneal re-innervation and sensation to maximally recover, depending on the type and degree of

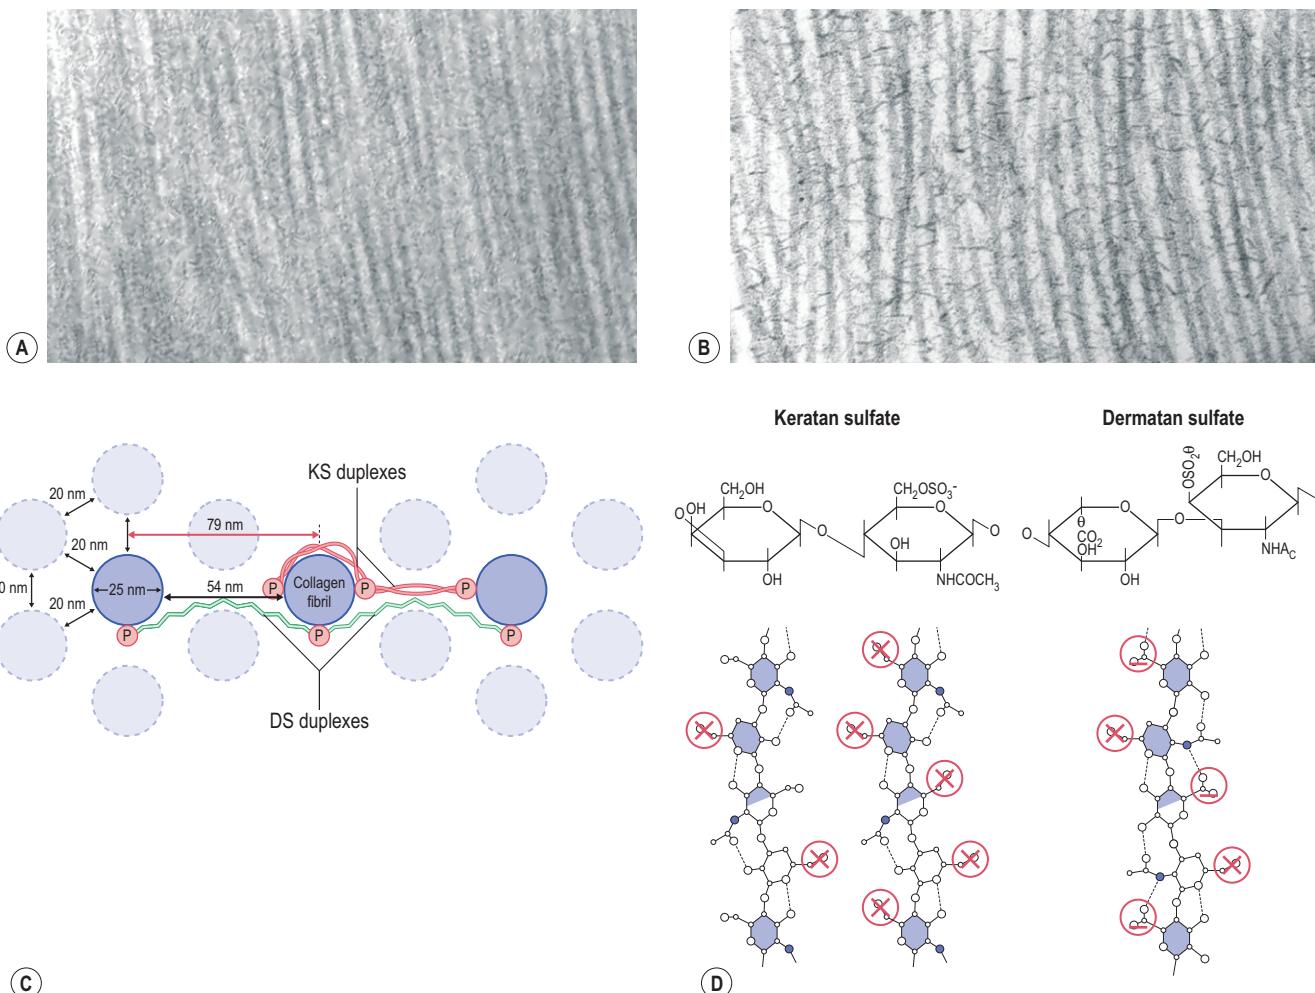

Figure 4.14 Tangential-section TEM views ($\times 90,000$) of longitudinally running type I corneal stromal collagen fibrils in a lamellae without (A) and with (B) cupromeric blue staining. Notice the scattered “amorphous ground substance” in the interfibrillar spaces in (A), while in (B) duplexes of proteoglycans are clearly seen bridging next-nearest neighbor collagen fibrils. (C) Diagram of how proteoglycans attach along the periphery of type I fibrils via their core proteins (P) and how the core protein tail/GAGs duplex in an anti-parallel fashion in the interfibrillar space between next-nearest neighbor collagen fibrils. (D) Diagram of the polymer backbones of keratan sulfate and dermatan sulfate. The top portion shows the primary structure of the repeating disaccharide units of keratan sulfate (top left) and dermatan sulfate (top right). The bottom portion of the diagram shows the secondary structures of each proteoglycan. In the human cornea, ~50 percent of keratan sulfate is in the normal-sulfated state (left), while the other ~50 percent is in the over-sulfated state (center). All three displayed proteoglycan polymers have similar backbones and, therefore, form similar secondary structures of a two-fold helix (right). Anionic charges = sulfate esters (X) and carboxylic acid (–). (C and D are modified from Scott JE. Biochem Soc Trans 1991; 19:877–81.)

surgical injury.¹¹⁹ After maximal recovery, the sensitivity in the portion of the cornea involved by the procedure often is variably less than that which was present prior to surgery, which means there is a potential long-term as well as short-term neurotrophic keratitis.

It has been recently discovered that after corneal nerve injury, microneuromas can develop during the regeneration process.^{117,123} These microneuromas, as well as injured corneal nerves themselves, exhibit altered functional properties where responsiveness to normal stimuli is impaired, yet paradoxically display abnormal intrinsic electrical excitability (i.e. spontaneous impulses or even abnormal responsiveness to normally minimal stimuli).¹¹⁷ Overall, this may produce hyperalgesia and/or dyesthesia, which may continue long-term after surgery despite some attenuation. These neuropathic pain impulses are often perceived by the patient as dryness, foreign body sensation, and irritation

after surgery, yet are not actually due to actual dryness or irritation of the cornea. These undesired, unpleasant sensations may best respond to ion channel antagonists rather than dry eye lubricating medications.¹²³

The mechanisms by which corneal nerves maintain the ocular surface and promote healing after eye injuries are currently under active research in several laboratories. Corneal nerves secrete neuropeptides, such as substance P and calcitonin gene-related protein, and neurotransmitters, such as acetylcholine, vasoactive intestinal polypeptide, and neurotensin, which are believed to be important in corneal epithelial function and proliferation.^{116,117}

Corneal stromal wound healing

The first published report specifically addressing the cellular reactions in the corneal stroma after injury appeared in 1958.¹²⁴ It described the morphologic changes of stromal

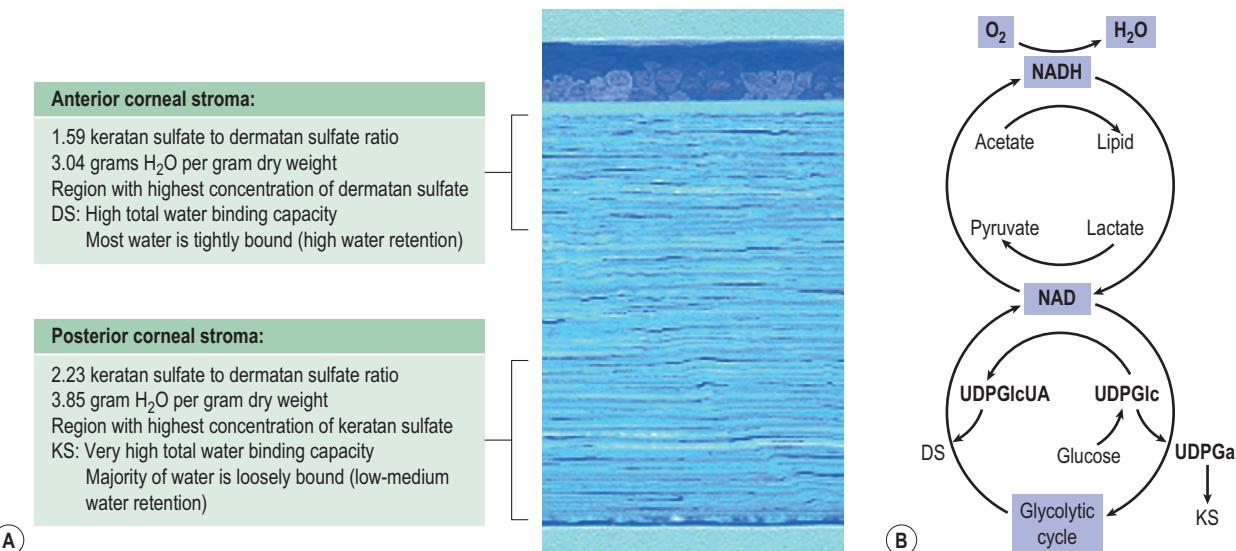

Figure 4.15 (A) The regional differences in the corneal stroma for the proportion of the two types of corneal GAGs and the water-absorbing properties in these regions are shown. **(B)** Diagram of the metabolic pathways for dermatan sulfate and keratan sulfate production. The supply of oxygen is the primary factor determining whether dermatan sulfate is made through an aerobic pathway or whether keratan sulfate is made through an anaerobic alternative pathway. (Modified from Scott JE. TIBS 1992; 17:340–3.)

cells after different types of trauma and found that stromal cells lose their interconnecting, dendritic processes immediately after injury with many cells subsequently developing signs of degeneration. That report also described the appearance of morphologically unique, spindle-shaped corneal fibroblastic cells invading into the wound region during later stages of stromal healing. Since that time, many excellent animal model corneal wound healing studies have further addressed the changes in the extracellular matrix and the stromal cells after stromal injury.^{125–133} They suggest that corneal stromal injury is immediately followed by keratocyte apoptosis in the zone around the site of stromal injury with a subsequent influx of transient mixed acute and chronic inflammatory cells, proliferation and migration of surviving keratocytes, and finally differentiation of the keratocytes into transiently metabolically activated cell types called activated keratocytes. This latter cell type is functionally important because it synthesizes and deposits the extracellular matrix of the stromal scar, while also degrading and remodeling the damaged cellular and extracellular tissues around the wound. Epithelial injury alone can also cause transient cellular injury to the underlying stroma presumably from exposure of stroma to tear-related factors, resulting in apoptosis, proliferation, and differentiation into migratory keratocytes as well as resulting in some anterior stromal edema.^{134–136} It, however, does not appear to cause differentiation into activated keratocytes, hypercellularity, differentiation into myofibroblasts, or stimulate extracellular matrix production – all of which are seen with corneal stromal injury whether by incision or excision.^{134–136} Myofibroblasts are characterized by the intracellular cytoplasmic appearance of α -smooth muscle actin, which helps impart contractile properties to the cell.¹³¹

A number of studies have looked into the expression of cytokines and growth factors in normal and injured corneas.^{137,138} These studies tried to assess the relative

importance of each specific factor in cornea wound healing, since it was known clinically and experimentally that epithelial–stromal interactions increase the number of proliferative and migratory keratocytes within the stromal wound compared to deeper corneal stromal injury, some of which differentiated beyond the activated keratocyte stage into myofibroblastic cell type.^{133,139–142} Some studies focused even more specifically on strictly epithelial or tear-related cytokines or growth factors since the epithelium and aqueous tears were found to be a major source of cytokines and growth factors.^{143–147} The major cytokines and growth factors studied to date include epithelial growth factor (EGF), fibroblast growth factor (FGF), interleukin-1, nerve growth factor (NGF), transforming growth factor-beta (TGF- β), insulin, retinol, and LPA. TGF- β is currently thought to be the most important growth factor of this group in regard to stimulating a fibrotic reparative stromal scar phenotype.^{130,139,142,147,148} A recent study, however, has shown that local cytokine and growth factor-related influence on normal corneal stromal wound repair is predominantly an early wound healing phenomenon as cell–matrix interactions seem to take over in the later stages of wound healing.¹⁴⁷ For example, integrity or return of a complete epithelial cell basement membrane after stromal injury seems to regulate epithelial–stromal interactions long-term as it decreases the production and, more importantly, the release of TGF- β from epithelial cells into the stroma.¹⁴⁷ One gap in this area of research is how mechanotransduction pathways (mechanical load-induced intracellular signals) fit into this scheme, particularly in maintaining myofibroblast differentiation long-term and thus corneal haze. Other cytokines and growth factors of this group were also found to have some minor complementary or even competing roles with TGF- β , and in other cases they had no role at all in corneal wound healing. For example, NGF is complementary to TGF- β as it too is known to stimulate myofibroblastic

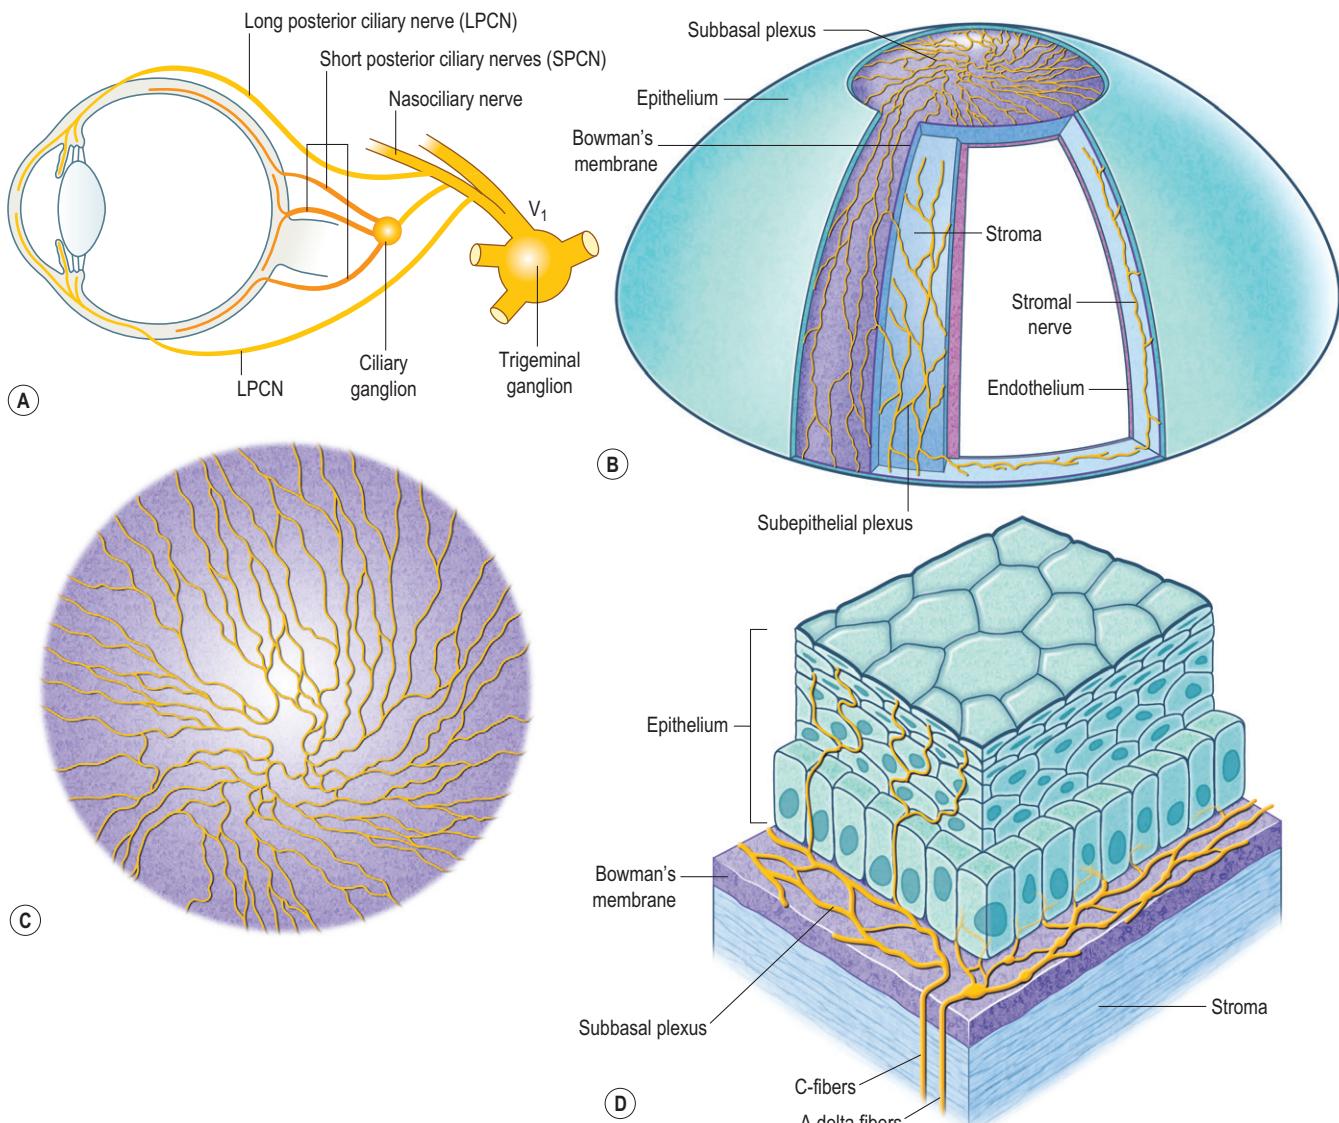

Figure 4.16 (A) The nerves of the cornea and sclera are mixed (motor, sensory, and autonomic) and come from the nasociliary branch of the 1st division of the Vth cranial nerve, which branch to form two long (LPCN) and several short posterior ciliary nerves (SPCN). The SPCN supply the posterior sclera, whereas the LPCN supply the cornea and equatorial and anterior sclera. The nerve supply of the cornea is the richest in the body and the sclera also has numerous nerves, commonly with many free nerve terminal endings found in the most vascular portions of the episclera, presumably to regulate blood flow in the anterior segment and to influence aqueous humor outflow. (Modified from Watson PG, Hazelman B, Pavesio C, Green WR. The sclera and systemic disorders, 2nd edn. Edinburgh, UK: Butterworth Heinemann, 2004). (B) and (C) Distribution of corneal nerves in the stroma including the subepithelial plexus (SEP) and the sub-basal plexus (SBP). (Modified from Muller LJ et al. Exp Eye Res 2003;76: 521–42; Patel DV, McGhee CN, Patel DV, McGhee CJN. Invest Ophthalmol Vis Sci 2005; 46(12):4485–8). (D) The architecture of the nerve bundles in the SBP (arrow) contain both straight and beaded fibers. The straight C fibers branch and turn upwards to extend into the epithelium. (Modified from Guthoff RF, Wiens H, Hahnel C et al. Cornea 2005; 24(5):608–13.)

cellular transformation independent of TGF- β , but it does so without enhancing keratocyte proliferation or extracellular matrix deposition.¹⁴⁶ In another example, all-trans retinol (vitamin A), which is reflexively secreted in the aqueous tears from its storage location in the lacrimal gland, has a completely different role than wound healing as it maintains the moist, mucosal ocular surface phenotype via gene transcription regulation; thus, it ultimately controls the rate of ocular surface cell proliferation and differentiation (i.e. prevents keratinization and squamous metaplasia).^{149,150} Once activated, keratocytes exhibit a wide range of cellular responses,

including increased tritiated thymidine uptake (indicating increased proliferation); initiation of protease and collagenase activity; phagocytosis; interferon, prostaglandin and complement factor 1 production; and fibronectin, collagen, and proteoglycan secretion.^{130,141,151–159}

Human studies of stromal wound healing concur with animal studies on most issues with the following notable differences: adult human corneas heal less aggressively, more slowly, and not as completely as animal corneas.^{62,133,160–163} However, both animal and human studies show that corneal stromal wounds heal in two distinct

Box 4.4 Wound healing variability after common ophthalmic surgeries

The location of scar types along with the variable degree of wound healing responses in the human cornea is best exemplified when one reviews published human histopathology studies that describe findings in corneas that have had common ophthalmic procedures such as cataract extraction (CE), PK, radial keratotomy (RK), astigmatic keratometry (AK), PRK, or LASIK (Fig. 4.17). It is also apparent from these cases that acellular barrier layers, like Bowman's layer, are not reformed if damaged or excised, whereas acellular basement membranes, like the epithelial basement membrane and Descemet's membrane, can be regenerated.¹⁶⁶ Sutured and unsutured clear corneal CE wounds are corneal stromal incisions constructed at oblique angles to the corneal surface so that they self-seal. They usually heal with well-aligned external wound margins and wound edges, which results in a small (50–75 µm in depth) subepithelial zone of hypercellular fibrotic stromal scarring and a remaining deeper zone of hypocellular primitive scarring (Fig. 4.17A).⁶²

Occasional small epithelial plugs are found in the external wound of unsutured clear corneal cataract wounds and sometimes Descemet's membrane is found partially detached or poorly re-aligned along the internal wound margin so that stromal ingrowth occurs. In marked contrast, limbal and scleral tunnel CE incisions heal because fibrovascular granulation tissue from the episclera completely grows into the wound by 15 days after surgery with remodeling up to 2.5 years after surgery (early wound repair mechanisms in vascularized tissue are controlled by bioactive substances released by platelets at the wound site, such as platelet-derived growth factor and TGF-β, as opposed to epithelial-derived factors, such as TGF-β, seen in the avascular cornea).^{147,169–171} PK wounds heal similarly to sutured clear corneal cataract wounds with the notable differences of having significant wound compression because of the oversized nature of the donor button (usually 0.25–0.5 mm) and wound edge mismatch caused by the irregular, asymmetric nature of the trephine wound found between donor and host wound edges. Additionally, a high percentage of PK cases have overriding external or internal wound edges with Bowman's layer or Descemet's membrane incarceration, which serves to cause weak areas in the hypercellular fibrotic scar or regenerated Descemet's membrane.^{166,167,172,173}

Although of partial thickness (70–95 percent depth) and being constructed perpendicular to the corneal surface, RK and AK incisions heal similarly to unsutured clear corneal cataract wounds.^{174–178} The most notable difference from unsutured CE wounds is the more commonly present and more widely variable degree of external wound gaping found in these corneas, which commonly leads to epithelial ingrowth or plugging that rarely goes away long-term (Fig. 4.17B).¹⁷⁸ PRK heals entirely under the influence of epithelial-stromal interactions. Therefore, a disk-shaped hypercellular fibrotic stroma scar is produced (Fig. 4.17C), which usually is 12–20 percent in thickness of the amount initially ablated.^{179,180} In contrast, LASIK heals similar to that of unsutured clear corneal cataract incisions (Fig. 4.17D). A sub-epithelial zone of hypercellular fibrotic scarring occurs at the flap wound margin and the remainder heals by producing a hypocellular primitive stromal scar usually with a thickness around 5–10 percent of the amount initially ablated.^{181–183} However, a notable difference from unsutured CE wounds was that approximately 50 percent of the LASIK corneas were found to have at least some microscopic epithelial plugging present.

phases: (1) an active phase – results in the production of a stromal scar over the first six months after injury in humans, and (2) a remodeling phase – improves corneal transparency and increases wound strength. This 2nd phase occurs up to 3–4 years after injury in humans. Overall, the long-term result in human corneas is the production of a hypercellular fibrotic stromal scar in wound regions where epithelial-stromal interactions occur and a hypocellular primitive stromal scar in wound regions where keratocyte injury pathways occur. These two histological wound types have functional differences as the hypercellular fibrotic stromal scar is strong, but can look clinically hazy because of myofibroblastic cells populating this scar type.^{69,131} In contrast, the hypocellular primitive stromal scar is transparent, but it is very weak in tensile and cohesive strength and serves as a potential space for fluid, inflammatory cells, and microbes.¹⁶⁴ An additional variable to consider in this scheme is the fact that more precisely re-aligned wounds, such as sutured and unsutured wounds with minimal gaping and no epithelial cell plugging, heal better than poorly aligned wounds, such as wounds with wide wound gaping, epithelial plugging, or incarceration of Bowman's layer, Descemet's membrane, or uvea.^{164–167}

Barrier properties

Low-permeability barrier: the corneal epithelium

The external surface of the human cornea is covered by a stratified squamous epithelium (see Fig. 4.1D).^{1,2} Unlike other epithelial surfaces, the corneal epithelium is specialized to exist over a moist, transparent, refractive, avascular surface and thus it is smooth and non-keratinized. The corneal epithelium is composed of 4–6 cell layers about 50 µm in total thickness across the entire anterior corneal surface (Fig. 4.18). It is continuous with the epithelium of the limbus (see Fig. 4.3B). The basal epithelial cells actively secrete a basement membrane, around 90 nm thick at birth, composed of type IV collagen fibrils, laminin, heparin sulfate, and fibronectin. The corneal epithelial basement membrane, or basal lamina, increases in thickness with age measuring around 300 nm thick in late adulthood.²³ By electron microscopy, the basal lamina appears to be composed of two distinct layers: a 20–30 nm thick more anterior lamina lucida and a 30–60 nm thick more posterior lamina densa. Its function is similar to most basement membranes in that it serves as a scaffold for epithelial cell movement and attachment.

The cytoplasm of all epithelial cells contains mainly cytoskeletal intermediate filaments and has sparse cytoplasmic organelles. This aids in maintaining transparency. The predominant cytoplasmic protein is keratin, while actin filaments and microtubules are the other major ones. The basal cell layer stores large glycogen granules as a source of metabolic energy for times of stress during hypoxia or wound healing. The epithelial cells are held together by desmosomes, while the basal surface of the epithelium adheres to the basal lamina and underlying Bowman's layer through an anchoring complex composed of hemidesmosomes, type VII collagen anchoring fibrils, and anchoring plaques (Fig. 4.19). The epithelial cells differentiate from the basal layer to form one to three mid-epithelial layers of wing cells and finally to form one to two superficial squamous cell layers

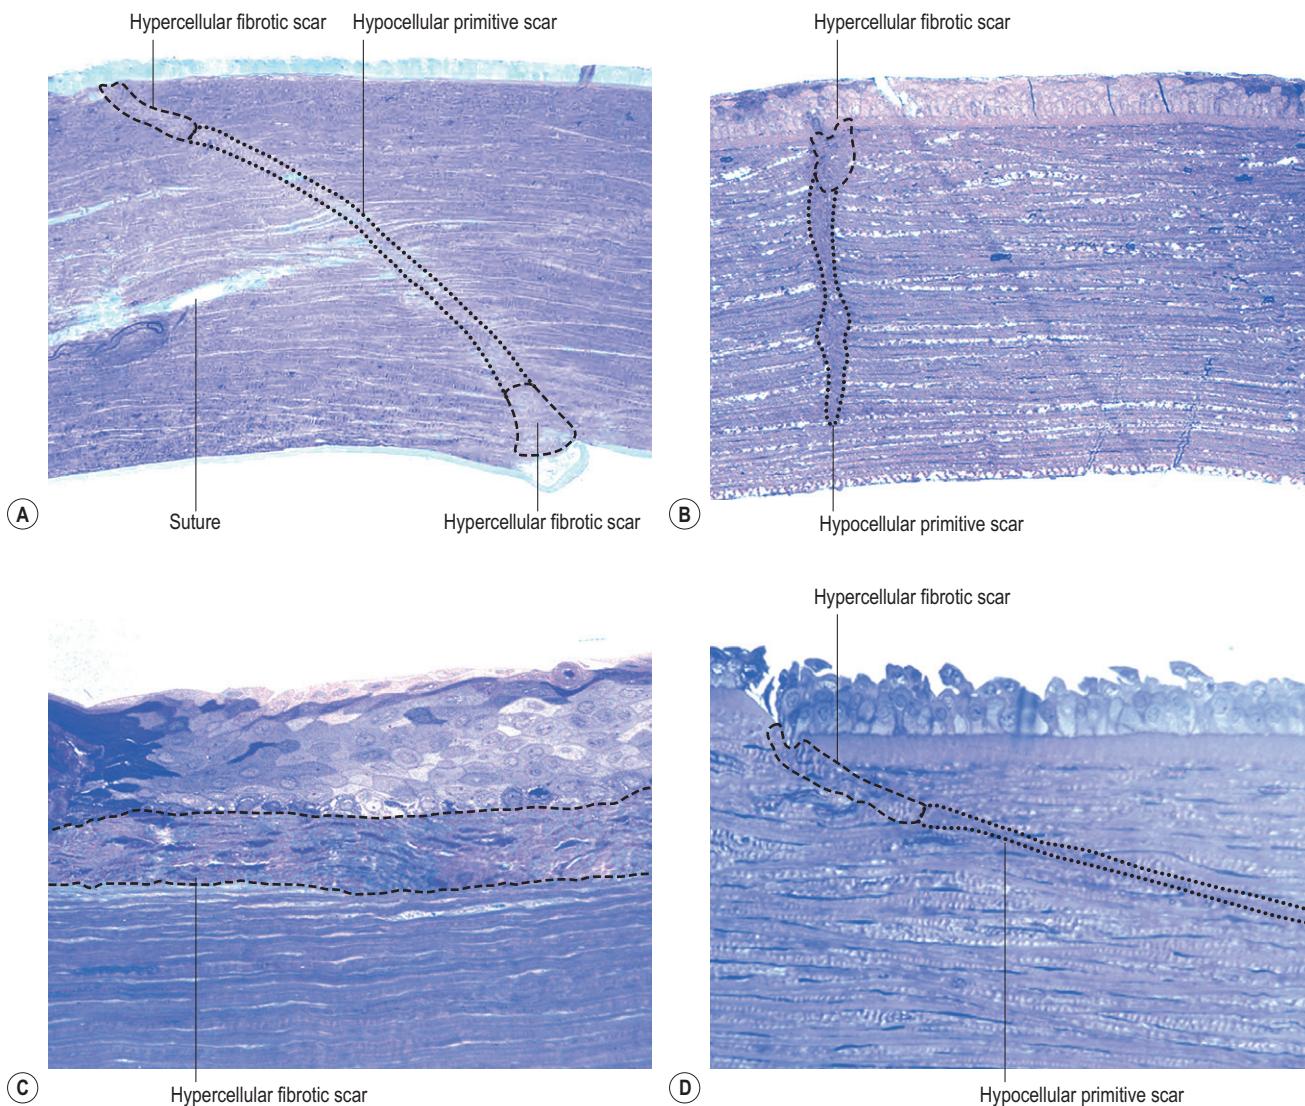

Figure 4.17 Long-term wound healing findings of corneas that had undergone sutured, temporal, clear-corneal cataract extraction surgery (**A**), astigmatic keratotomy (**B**), photorefractive keratectomy (**C**), and laser in situ keratomileusis (**D**). All corneas shown are greater than 4 years after surgery. (toluidine blue $\times 15$ for A, $\times 25$ for B, and $\times 100$ for C and D). (Modified from reference 62.)

(Fig. 4.18). The most superficial squamous cells at the external surface form a high-resistance ($8\text{--}16 \text{ k}\Omega \cdot \text{cm}^2$) barrier to the external environment since they are all surrounded by a continuous band of apical zonula occludens tight junctions at their peripheral intercellular margins (Fig. 4.20).^{184,185}

Zonula occludens tight junctions are characterized by fusion of the adjacent cell membranes resulting in obliteration of the intercellular space over variable distances and are made up of the tight junction proteins ZO-1, JAM-A, occludin, and claudin-1, as well as some other claudin subtypes.¹⁸⁶ This barrier prevents the movement of ions and thus fluid from the tears into the stroma, reduces some evaporation, and protects the cornea from infectious pathogens. A clinical test to determine if this barrier is disrupted uses the vital dye fluorescein, which is topically instilled on the external surface of the cornea and stains the corneal surface if there is a breakdown in the epithelial tight junctions. The apical surface of the corneal epithelium has microplicae and

microvilli (Fig. 4.18) that are covered with a wettable, smooth glycocalyx layer, consisting of membrane-associated mucins (Fig. 4.20), MUC 1, MUC 4, and MUC 16.¹⁸⁷⁻¹⁸⁹ These mucins are produced by surface epithelial cells and conjunctival goblet cells forming a $1.0 \mu\text{m}$ thick mucinous layer of the tear film.^{2,190} The healthy total tear film typically measures $7 \mu\text{m}$ in thickness and contains three layers: mucinous, aqueous, and lipid layers (Fig. 4.20B). Recently, the aqueous layer of the tear film has also been found to contain other membrane-spanning, gel-forming mucins, MUC 5AC and 2, along with lysozyme, immunoglobulin A, transferrin, defensin, and trefoil factor.¹⁸⁹ Overall, the tear film functions in maintaining a healthy ocular surface by preventing evaporation, friction during eye blinking, and ocular infections. It also is of paramount importance in forming a moist, smooth optical surface on the cornea required for clear vision. Deficiencies in the components of tear film potentially can cause ocular surface disease. For example, loss of the lipid layer,

which is produced by the meibomian glands, results in the condition of evaporative dry eye disease due to increased evaporative loss from the anterior corneal surface (from the normal baseline rate of $3 \mu\text{l}/\text{hr cm}^2$ up to a maximum of $40 \mu\text{l}/\text{hr cm}^2$).¹⁹¹ In another example, loss of the aqueous layer, which is produced by the lacrimal glands, results in the condition of aqueous tear-deficiency dry eye disease. For more information about dry eye disease including the pathophysiology, classification, diagnosis, and management, see references or refer to Chapter 15.¹⁹²⁻¹⁹⁴

The corneal epithelium is in a state of constant renewal as the most superficial squamous cells are continuously shed into the tear film. It is estimated that the cell layers of the corneal epithelium turn over every 7–10 days. The epithelial surface is maintained by basal epithelial cells, which can usually undergo mitosis one time resulting in two daughter cells that are found anterior to the basal cell layer, resulting into two wing cells and eventually into two squamous cells (Fig. 4.21).¹⁹⁵⁻¹⁹⁷ A delicate balance of shedding followed by proliferation is critical in maintaining a smooth and uniform epithelial surface. The shedding step is primarily induced by friction that occurs from involuntary or voluntary eyelid blinking, which happens on average every 7 seconds or 6–15 times/minute. The signal for basal epithelial cell proliferation probably comes via the gap junctions, especially in the basal cell layer since they express the gap junction protein connexin 43.^{187,198} In addition to basal epithelial cell mitosis (vertical proliferation), the corneal epithelium is maintained by migration of new basal epithelial cells into the cornea from the limbus (horizontal proliferation). The cells migrate centripetally at a rate of approximately $120 \mu\text{m}/\text{week}$ and originate from a subpopulation of proliferative limbal progenitor epithelial cells (Fig. 4.21).¹⁹⁹⁻²⁰¹ It appears that the

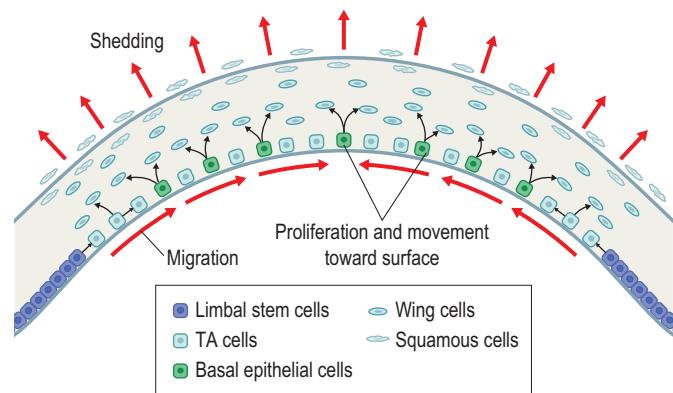

Figure 4.21 The basal epithelial cells of the cornea, which undergo vertical proliferation (both daughter cells move into the middle layers of the epithelium) are continually replenished by a stem cell population that resides in basal layer of the limbus. The transient amplifying (TA) basal epithelial cells, which are two horizontal progeny from the stem cells, migrate forward from the limbus to the periphery of the cornea and commonly to reach the center of the cornea. The TA undergo mixed (one daughter cell retained in the basal cell layer and the other moves into the middle layers of the epithelium) proliferation. The final or terminal cell cycle of mitosis is the vertical proliferation step, where the two daughters continually move toward the surface eventually being shed in the tear film. (Modified from Thoft RA et al. Invest Ophthalmol Vis Sci 1983; 24:1442)

corneal epithelium is maintained by a balance among the processes of limbal cell horizontal proliferation and migration, basal corneal epithelial cell horizontal migration and vertical terminal proliferation, and shedding of superficial squamous corneal epithelial cells.^{201,202} This concept has been coined the X, Y, Z hypothesis by Thoft, where X (basal

corneal epithelial cell proliferation) + Y (limbal cell proliferation) = Z (epithelial cell loss on the anterior surface from eyelid blinking).²⁰³ When this equilibrium is disrupted, corneal epithelial cell wound healing typically begins. After injury, these processes typically return to equilibrium with a degree of flexibility. For instance, after epithelial and stromal injury, if a stromal deficit occurs (e.g. a healed corneal ulcer) then the epithelium can still maintain a smooth anterior corneal surface either by developing elongated hypertrophic basal epithelial cells in mild defects and/or by developing epithelial hyperplasia (> 6 cell layers) in moderate to severe defects.²⁰⁴

The subpopulation of limbal basal progenitor epithelial cells are called adult corneal epithelial stem cells.^{201,205} Epithelial stem cells have the characteristics of being undifferentiated, slow cycling, and extremely long lived with a high proliferative potential. They are an excellent source for corneal epithelial cell reconstruction. The stem cells are located in a well-defined, protective niche microenvironment called the palisades of Vogt (see Fig. 4.3B), and are controlled via delicate regulatory mechanisms.^{206–208} The progeny of these epithelial stem cells are referred to as transient amplifying (TA) cells, which are the basal epithelial cells of the limbus or peripheral cornea that migrate centripetally (Fig. 4.21). These TA cells divide more frequently than stem cells and undergo mixed (horizontal or vertical) proliferation. They do, however, have a finite proliferative potential, usually replicating at least twice, which is in marked distinction to the stem cells from which they are derived. Once TA cells reach the end of their proliferative capacity, usually when near the center of the cornea, they become basal epithelial cells, which terminally differentiate just once into two daughter wing cells (vertical proliferation). Limbal stem cell theory forms the basis for several surgical procedures using transplanted or cultured limbal stem cells to restore vision in patients with limbal stem cell deficiency.^{209,210}

Finally, it has been shown in both animal and human specimens that the corneal epithelium is devoid of melanocytes, but does contain immune cells (see Fig. 4.13). The basal epithelial cell layer of the peripheral cornea along with the limbus and conjunctiva appear to have a subpopulation of cells that are bone-marrow-derived immune surveillance cells with high constitutive expression of major histocompatibility complex (MHC) type II antigen and co-stimulatory molecules.²¹¹ This type of immune cell has previously been termed a Langerhans cell, which functions as a "professional" antigen-presenting cell with an extraordinary capacity to initiate T-cell lymphocyte-dependent responses.^{212,213} The functional steps of this cell type include the up-take and processing of antigens and migration out of the cornea to lymph nodes where they stimulate naïve T-lymphocyte-mediated immune responses by presenting antigens and overexpressing co-stimulatory molecules. Recently, the central corneal epithelium also has been found to have a similar subpopulation of immune cells that are apparently all "immature" Langerhans cells because their constitutive expression of MHC type II antigen and costimulatory molecules is low.²¹⁴ These "immature" Langerhans cells or "non-professional" antigen-presenting cells under certain circumstances, such as inflammation or trauma, may develop the requisite signals for T-cell priming.²¹⁴

High-permeability barrier: the corneal endothelium

The primary function of the corneal endothelium is to maintain corneal transparency by regulating corneal hydration and nutrition through a "leaky" barrier and metabolic pump function first described by David Maurice.⁷² The "pump-leak" hypothesis basically suggests that an equilibrium is needed in the amount of passive fluid flow into the cornea and energy expended pumping out excess fluid for maintenance of corneal transparency and relative dehydration of the corneal stroma. Secondarily, it is also known to secrete an anteriorly located basement membrane called Descemet's membrane and a posterior-located glycocalyx layer.¹

The endothelium of the infant cornea is composed of a monolayer of approximately 500,000 neural-crest-derived cells, each measuring around 6 µm in thickness by 20 µm in diameter, or covering a surface area of 250 µm² (Figs 4.22A & 4.23A).^{6,215} The cells lie on the posterior surface of the cornea and form an irregular polygonal mosaic. The tangential apical or inner surface of each corneal endothelial cell is uniquely irregular, usually uniform-in-size to one another, and typically six-sided hexagons. The hexagon is the most energy-efficient geometric shape in order to cover a surface completely without leaving gaps; thus, minimizing intercellular boundary exposure to the aqueous humor.^{215,216} They abut one another in an undulating, interdigitating fashion with a 20 nm wide intercellular space between each other, which serves to increase the internal surface area of the lateral cell membranes, making the length of the intercellular space sometimes at least ten times the width of the cell itself (Fig. 4.22A,B).^{44,217} This is clearly seen on the endothelium's tangential basal or outer surface as corneal endothelial cells form an extremely complex jig-saw shape here as opposed to the six-sided hexagon on the inner surface.²¹⁸ The intercellular space is known to contain apical macula occludens tight junctions and lateral gap junctions (Fig. 4.22C,D); thereby forming an incomplete barrier with a preference to the diffusion of small molecules (Fig. 4.23B,C). The corneal endothelial cells have numerous cytoplasmic organelles, particularly mitochondria, and thus have been inferred to have the second highest aerobic metabolic rate of all the cells in the eye next to the retinal photoreceptors (Fig. 4.22B).⁶

At birth, the central endothelial cell density (ECD) of the cornea is around 5000 cells/mm².²¹⁵ Postnatally, the corneal endothelium of primates and higher mammals including humans, mature and lose most of their proliferative capacity, whereas lower mammals do not lose this proliferative capacity and thus can regenerate a normal endothelial cell monolayer after injury or disease as compared to humans. Because the human corneal endothelium has very limited innate *in vivo* proliferative capacity due to contact inhibition, high aqueous humor concentrations of TGF-β, and age-related gradual cellular senescence, particularly in the central regions of the cornea in part through the activity of the cyclin-dependent kinase inhibitor p21, there is a well-documented decline in central ECD with age that typically involves two phases: a rapid and a slow component.^{24,25,219–221} In fact, recent studies suggest that an adult stem cell population of corneal endothelial cells exists near Schwalbe's line of the limbus, which is a transition zone between the

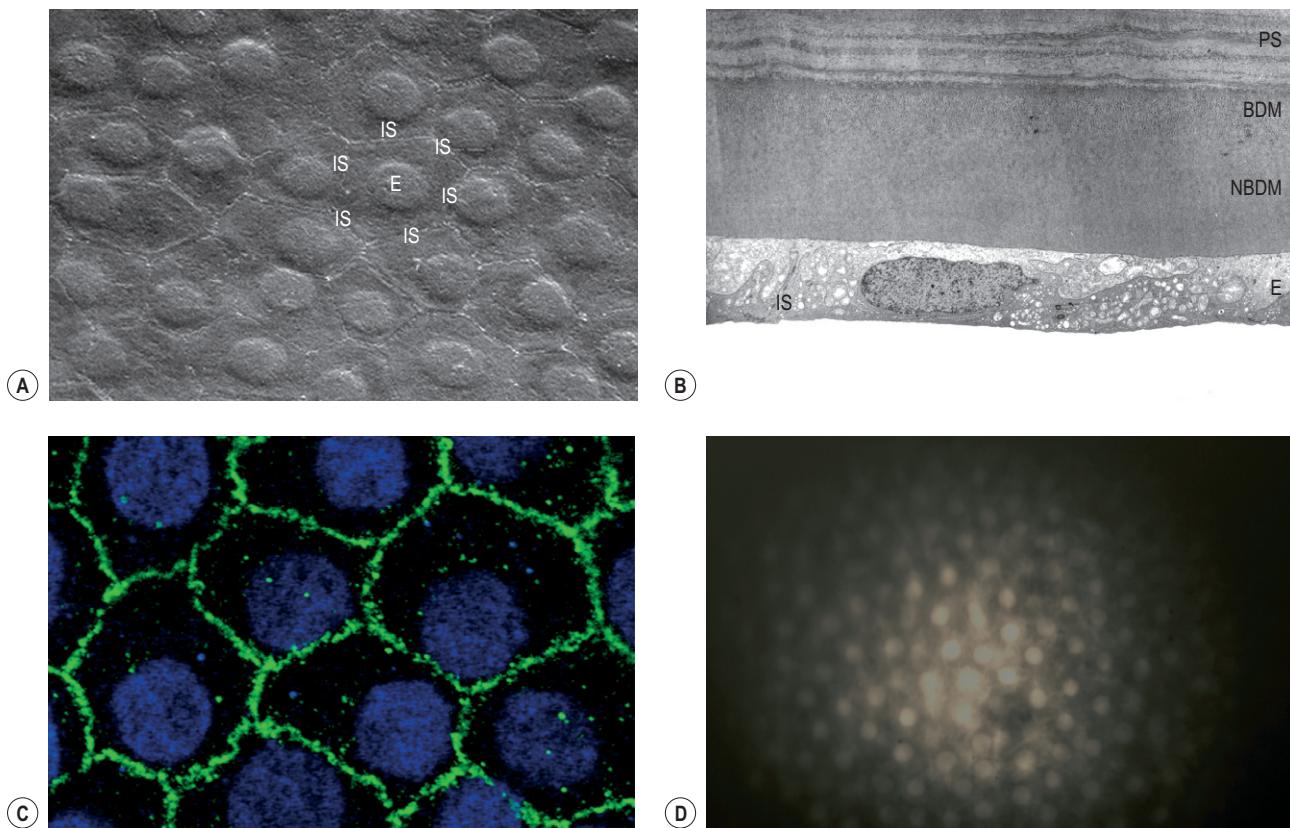

Figure 4.22 (A) Scanning electron micrograph ($\times 1000$) of the posterior surface of the corneal endothelium from a 65-year-old patient with healthy corneas. Note how the hexagonal endothelial cells form a uniform monolayer with small 20 nm intercellular spaces between adjacent endothelial cells. E = endothelial cells. IS = intercellular space. (B) Transmission electron micrograph ($\times 4750$) of the posterior corneal stroma, Descemet's membrane, and corneal endothelium from a 65-year-old patient with healthy corneas. PS = posterior stroma. BDM = banded portion of Descemet's membrane. NBDM = non-banded portion of Descemet's membrane. E = endothelial cells. IS = intercellular space. (Courtesy of Mitchell A. Watsky, PhD.)

trabecular meshwork and the corneal endothelial periphery, and proliferates in a limited fashion, particularly after injury.^{222,223} Due to corneal growth and developmentally selective cell death, during the fast component, the central ECD decreases exponentially to about 3500 cells/mm² by age 5 and 3000 cells/mm² by age 14–20 (Fig. 4.24A).^{25,221} Thereafter, a slow component occurs where central ECD decreases to a linear steady rate of 0.3–0.6 percent per year, resulting in central ECDs around 2500 cells/mm² in late adulthood (Fig. 4.24A).^{24,25,221} Because the corneal endothelium maintains its continuity by migration and expansion or thinning of surviving cells to cover a larger surface area, it is not surprising that the percentage of hexagonal cells decreases (pleiomorphism) and the coefficient of variation of cell area increases (polymegathism) with age.²²¹

When reviewing normal physiologic variability of the corneal endothelium, realize that these average central ECDs are primarily from Caucasian US populations. Several studies reveal that important ethnic differences exist as Japanese, Filipino, and Chinese corneas have been found to have higher central ECDs than Caucasians at all ages, while Indian

corneas have lower central ECDs (Table 4.2).^{224–227} It is hypothesized that this ethnic variance of central ECDs may be predominantly due to population differences in mean corneal diameter and thus mean endothelial surface area between these groups (Japanese, Caucasian, and Indian horizontal corneal diameters averaged 11.2, 11.7, and 12.0 mm, respectively), but genetic and environmental factors cannot be excluded and thus need further study. Additionally, these data apply only to central ECD since a recent study has shown that higher ECDs can typically be found in the periphery of the cornea (Figs 4.23A & 4.24B).²²⁸ This finding has been previously reported, but the recent study was the only one that was thorough enough in detail to document how the variance applies to the entire posterior corneal surface.^{229–232} Therefore, it appears that total corneal endothelial cell numbers and ECDs decrease on average about 50 percent from birth to death in normal subjects without causing corneal disease or pathology. Because corneal decompensation typically doesn't occur until central ECDs reach 500 cells/mm² (Fig. 4.25A,B), which is a 90 percent decrease in central ECD from birth or an 80 percent decrease

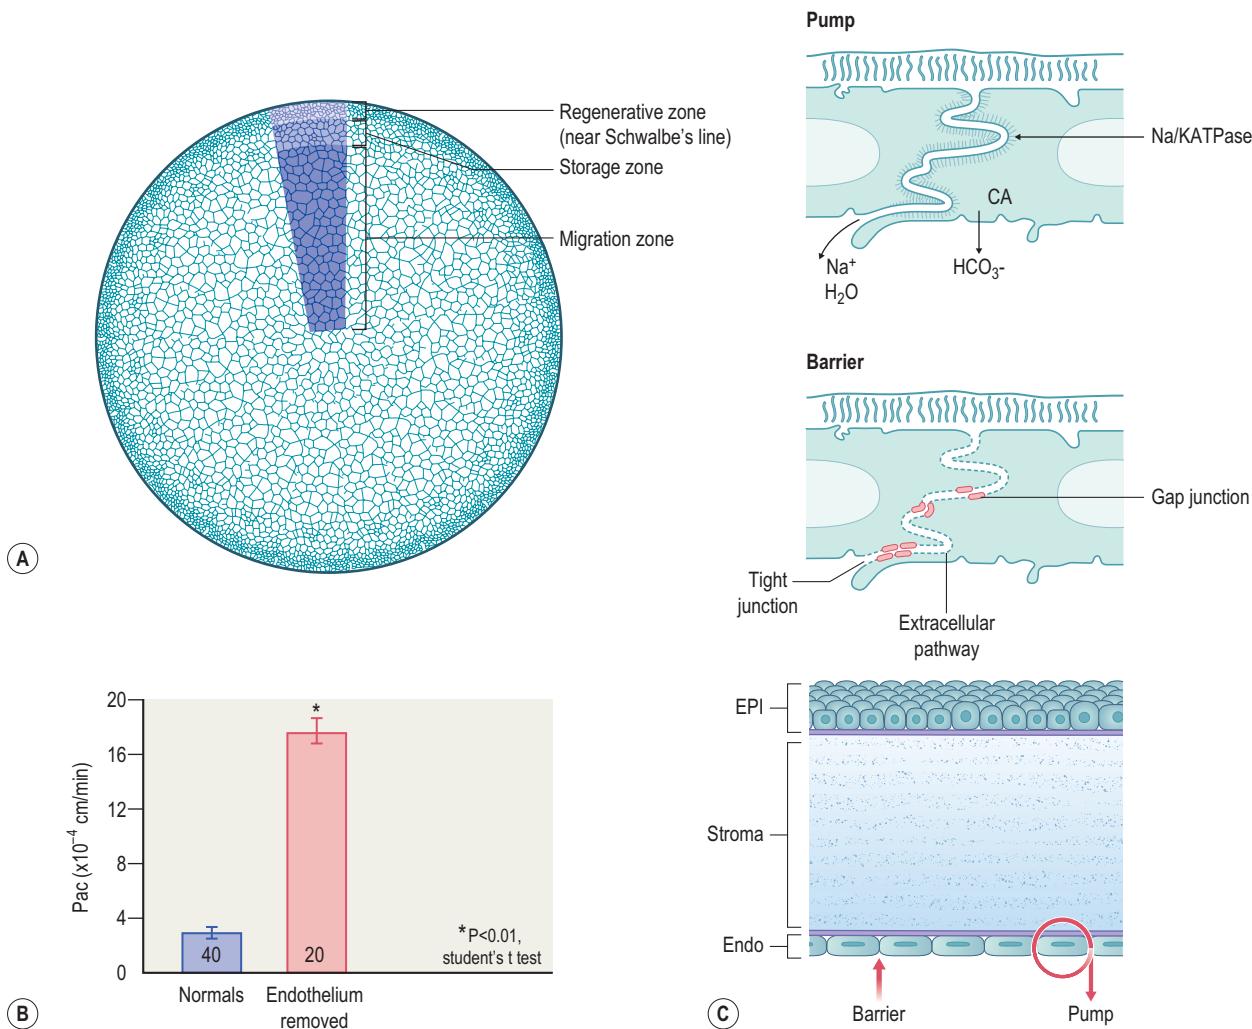

Figure 4.23 (A) The normal barrier function of corneal endothelium is due to endothelial cells covering the entire posterior corneal surface without gaps and the focal, discontinuous tight junctions in its apical intercellular space. (B) shows the normal permeability of the human endothelial cell monolayer to carboxyfluorescein (2.26×10^{-4} cm/min) compared to that without endothelium (12.85×10^{-4} cm/min), which resulted in a six-fold increase in permeability. (Modified from Watsky MA et al. Exp Eye Res 1989; 49:751–67). (C) The opposing forces of the leaky corneal endothelial barrier and the metabolic pump sites are shown. When the leak rate equals the metabolic pump rate, the corneal stroma is 78 percent hydrated and the corneal thickness and transparency is maintained. (Modified from Waring GO et al. Ophthalmol 1982; 89:531).

from healthy adulthood levels, there appears to be plenty of cellular reserve remaining after an average human lifespan of 75–80 years of life.^{25,221} Estimates suggest that healthy, normal human corneal endothelium should maintain corneal clarity up to a minimum of 224–277 years of life – if humans could live that long.²⁵

Leaky barrier function

The barrier function of the corneal endothelium is dependent upon a sufficient number of endothelial cells to cover the posterior surface of the cornea (Fig. 4.23A) and intact macula occludens tight junctions (Fig. 4.23B,C) between the endothelial cells resulting in a low electrical resistance ($25 \Omega \cdot \text{cm}^2$) barrier to the aqueous humor flow. Macula occludens tight junctions are characterized by partial obliteration of the intercellular space and partial retention of a

10 nm wide intercellular space.²¹⁷ Clinically, the barrier function of the cornea can be assessed by using the specular microscope or the confocal microscope to measure ECD, and fluorophotometry to measure permeability.²³³ In healthy human corneas, this barrier prevents the bulk flow of fluid from the aqueous humor to the corneal stroma, but it does still allow moderate diffusion of small nutrients, water, and other metabolites to cross into the stroma through the 10 nm wide intercellular spaces.⁴⁴

The leakiness of the endothelial barrier may initially seem inefficient and counterproductive; however, most nutrients for all layers of the cornea come from the aqueous humor. Thus, leakiness of the endothelial cell monolayer is essential for corneal health due to the fact that the cornea is avascular and contains no lymph vessels or other channels for bulk fluid flow. Despite the loss of endothelial cells that occurs with aging, there appears to be no significant increase in the

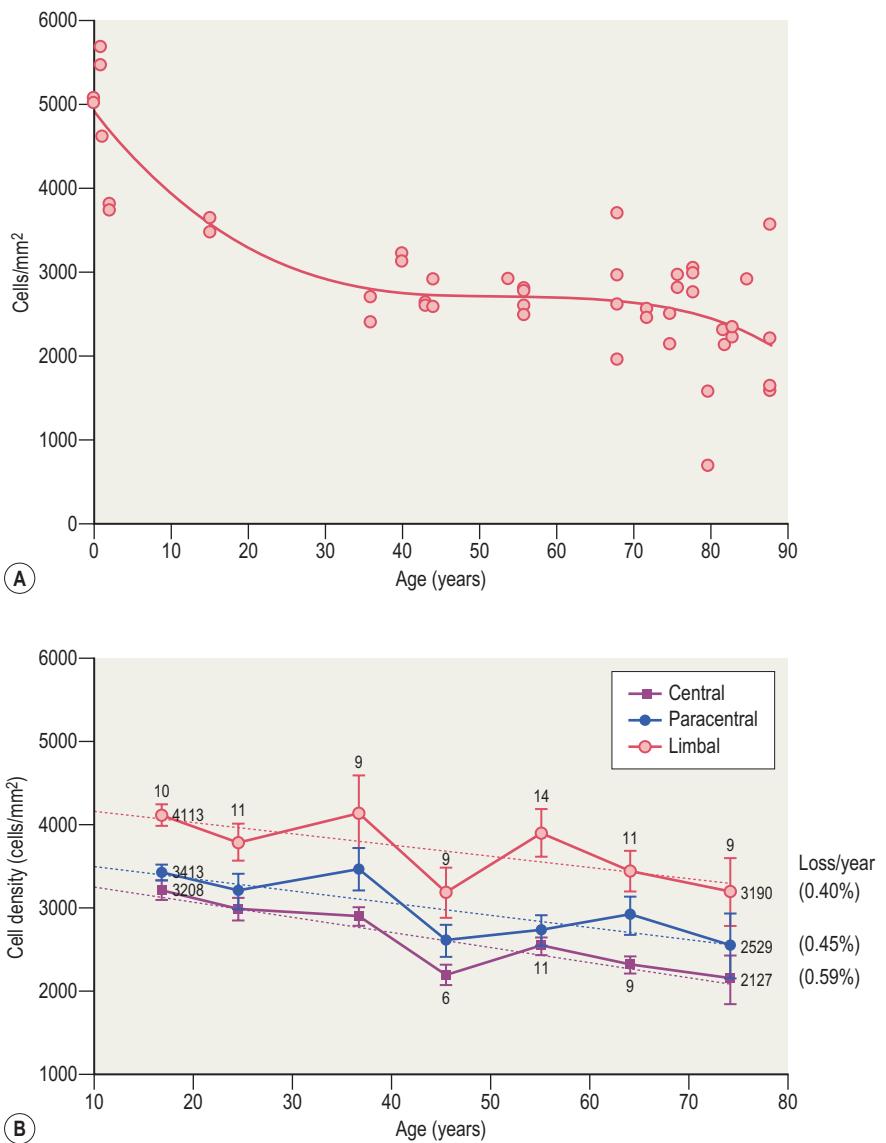

Figure 4.24 (A) Scatterplot with best fit curve showing the average central corneal endothelial cell density (ECD) for normal, healthy eyes of different ages. (From Williams KK et al. Arch Ophthalmol 1992; 110:1146–9.) (B) Graph illustrating the central, paracentral, and peripheral corneal ECDs for healthy, normal subjects of different ages. (From Edelhauser HF. Cornea 2000; 19:263–73; and Edelhauser HF. Invest Ophthalmol Vis Sci 2006; 47:1755–67.)

permeability of normal, healthy aged corneas.^{234,235} Only when the endothelial cell junctions are disrupted does permeability increase, usually up to a maximum of 6-fold higher than baseline (Fig. 4.23B).²³⁴ Corneal endothelial permeability does, however, gradually increase as central ECD decreases below 2000 cells/mm², but compensatory metabolic pump mechanisms keep the cornea at its normal dehydrated state until a central ECD of 500 cells/mm² is reached.

A number of factors are known to acutely affect the barrier function of the endothelium including reversible disruption of cell junctions during irrigation with calcium-free solutions or glutathione-restricted solutions, mechanical damage during intraocular surgery, or chemical injury due to introduction of non-physiologic or toxic solutions into the anterior chamber. Fortunately, the remaining viable cells are oftentimes able to migrate and re-cover the posterior corneal surface by spreading out over a larger surface area, re-establishing the intercellular cell junctions. Thus, the barrier function of the corneal endothelium is efficiently restored.

Metabolic pump function

In the early days of corneal transplantation, it was observed that when donor corneas were refrigerated, corneal thickness increased and transparency decreased.²³⁶ When the cornea was brought back to its normal temperature of 35°C, a temperature reversal occurred during which the cornea returned to its normal thickness and regained clarity. In vitro perfusion studies of the cornea showed that temperature reversal can take place in the absence of the epithelium, leading to the conclusion that active metabolic processes in the endothelium are responsible for maintaining corneal dehydration.²³⁶ Subsequent studies demonstrated that transporters, located primarily in the endothelial cell's basolateral cell membrane transport ions, principally sodium (Na^+) and bicarbonate (HCO_3^-), out of the stroma and into the aqueous humor (Fig. 4.23C).^{236,237} An osmotic gradient is created and water is thus osmotically drawn from the stroma into the aqueous humor. This osmotic gradient can be maintained only if the endothelial barrier is intact. A major transport protein found to be essential for endothelial metabolic pump function is

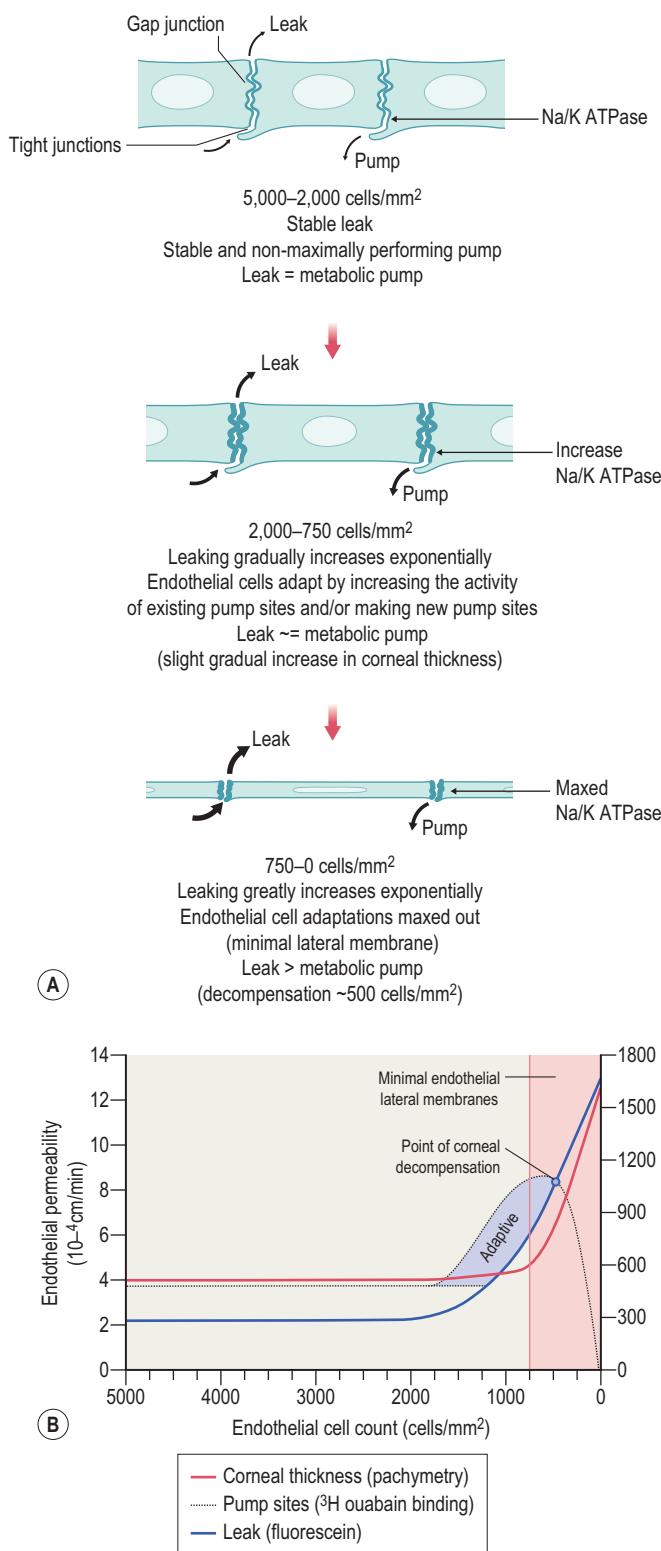

Figure 4.25 (A) and (B) The relationship between central ECD, barrier function, metabolic pump sites, and pachymetry is shown. Note that the pump sites are not all maximally used in the normal state (5000–2000 cells/mm²). With increased permeability (2000–750 cells/mm²), there is an adaptive phase in which the endothelial cells can maximally use all their pump sites or can make more pump sites to offset the leak up to a certain point. When the surface area of the corneal endothelial cell's lateral membranes becomes too small (750–0 cells/mm²), these adaptations max out and eventually decline. The point where endothelial cell pump site adaptations intersect with permeability (500 cells/mm²) is typically when corneal decompensation occurs. (Modified from Dawson DG et al. In: Duane's Foundation of Clinical Ophthalmology on CD-ROM. 2006v. 2 c. 4:1–76.)

Na^+/K^+ -ATPase.^{238,239} The number and density of Na^+/K^+ -ATPase sites have been quantified using [^3H]-ouabain, which binds specifically in a 1-to-1 ratio to Na^+/K^+ -ATPase pump sites.²⁴⁰ These studies have shown that approximately 3 million Na^+/K^+ -ATPase pump sites are present in the basolateral membrane of a single corneal endothelial cell. This corresponds to an average pump site density of 4.4 trillion sites/mm² along the lateral plasma membrane of an intact endothelial cell.²⁴⁰ Clinically, the metabolic pump function of the corneal endothelium can be assessed *in vivo* using pachymetry to measure how quickly the corneal thickness recovers after being purposefully swollen by wearing an oxygen-impermeable contact lens or, secondarily, by measuring the degree of diurnal fluctuation in corneal thickness.^{233,241}

A number of factors are known to alter endothelial pump function including pharmacologic inhibition of Na^+/K^+ -ATPase, decreased temperature, lack of bicarbonate, carbonic anhydrase inhibitors, and a chronic reduction in ECD from mechanical injury, chemical injury, or disease states. Fortunately, with regard to the latter, compensatory metabolic pump mechanisms prevent corneal edema from occurring to a certain degree when central ECDs are between 2000 and 750 cells/mm² (Fig. 4.25A, B). This occurs by either increasing the metabolic activity of pump sites already present, which requires more ATP production by the cell, and/or by increasing the total number and density of pump sites on the lateral membranes of endothelial cells.²⁴⁰ A similar phenomenon occurs in the proximal tubule of the human kidney to adjust for an increased salt load. For example, in Fuchs' endothelial dystrophy, the cornea has been found to remain clear and of normal thickness despite having focal areas of very low ECD and increased endothelial monolayer permeability to fluorescein.²⁴² Apparently, this occurs because the metabolic activity and density of the Na^+/K^+ pump sites increase in adjacent healthier areas to compensate for the focal areas of increased permeability.²⁴² The point at which compensatory mechanisms ultimately fail is when the central ECD reaches approximately 500 cells/mm² or less.^{215,243} At this low ECD, the permeability has increased to a point where the endothelial cells are spread so thin that they do not have enough room on their lateral cell membranes for more metabolic pump sites and all the existing pump sites are maximally active (Fig. 4.25A, B). At this point, the metabolic pump fails to balance the leak and corneal edema results.

A summary of the entire corneal endothelial cell transport system was recently reviewed by Bonanno.²⁴⁴ When the corneal endothelial barrier and metabolic pump are functioning normally, the corneal stroma has a total Na^+ concentration of 179 mM (134.4 mM free and 44.6 mM bound to stromal PGs), while the aqueous humor has a total Na^+ concentration of 142.9 mM (all free).²⁴⁵ Therefore, after accounting for chloride activity and stromal imbibition pressure, an osmotic gradient of +30.4 mmHg exists causing water to diffuse from the stroma into the aqueous humor.

Corneal edema

Corneal edema is a term often used loosely and non-specifically by clinicians, but it literally refers to a cornea that is more hydrated than its normal physiologic state of 78 percent water. The Donnan effect states that the swelling

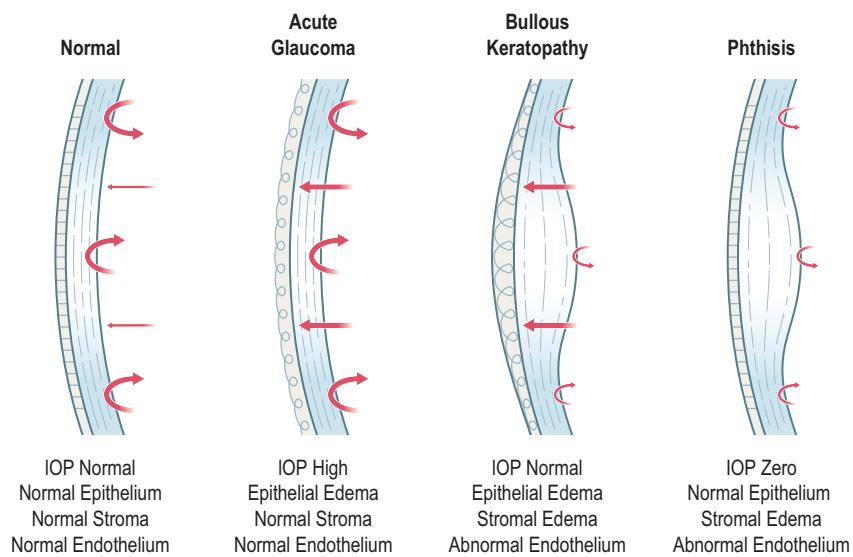

Figure 4.26 The delicate balance between stromal swelling pressure, endothelial barrier, metabolic pump function, and intraocular pressure are illustrated. Usually if endothelial cell pump function fails and IOP remains at normal physiologic levels, both stromal and epithelial edema occur (center right). Only when IOP increases above the swelling pressure of the stroma and the endothelium functions normally, does epithelial cell edema occur by itself (center left); and only when IOP is around zero and the endothelium functions abnormally, does stromal edema occur by itself (farther right). (Modified from Hatton MP et al. *Exp Eye Res* 2004; 78:549–52.)

pressure in a charged gel, like the corneal stroma, results from ionic imbalances. The fixed negative or anionic charges on the corneal stromal proteoglycan GAG side-chains have a central role in this effect. The anti-parallel GAG duplexes (tertiary structure) produce long-range electrostatic repulsive forces that induce an expansive force termed swelling pressure (SP). Because the corneal stroma has cohesive and tensile stiffness (elasticity) that resists expansion, the normal SP is around +55 mmHg.^{246,247} If the stroma is compressed as occurs with increasing IOP or mechanical appplanation or is expanded as occurs with corneal edema, the SP will correspondingly increase or decrease. Conversely, the negatively charged GAG side-chains also form a double-folded helix in aqueous solution (secondary structure) that attracts and binds Na⁺ cations, resulting in an osmotic effect, leading to the diffusion and subsequent absorption of water. Thus, the central corneal thickness is maintained at an average value of 544 µm because the fixed negatively charged proteoglycans induce a constant swelling pressure through anionic repulsive forces, yet it still tends to imbibe more water via its cationic attractive forces.¹⁰⁵

Under normal circumstances, the negative pressure drawing fluid into the cornea, called the imbibition pressure (IP) of the corneal stroma, is approximately -40 mmHg.²⁴⁸ This implies that the negative charges on corneal proteoglycan GAG side-chains are just over one-quarter saturated or bound with Na⁺, and that the remaining unbound proportion is still available to bind more Na⁺ and absorb more water if given the opportunity. Normally, the highly impermeable epithelium and the mildly impermeable endothelium keep the diffusion of electrolytes and fluid flow in the stroma to such a low level that the endothelium's metabolic pumps can maintain stromal hydration in the normal range of 78 percent without significant effort. Although IP = SP when corneas are in the ex vivo state, IP is lower than SP in the in vivo state because the hydrostatic pressure induced by intraocular pressure (IOP) must now be accounted. This is best represented by the equation IP = IOP – SP and explains why the hydration level of a patient's cornea is not only dependent on having normal barrier function, but also on having a normal IOP.²⁴⁸ Therefore, a loss

of corneal barrier function, an IOP ≥ 55 mmHg, or a combination of the two typically results in the clinical appearance of corneal edema (Fig. 4.26).^{23,249,250}

The topic of corneal edema is important for clinicians to understand because it affects the function of the corneal stroma and the epithelium. With minor (< 5 percent) hydration changes, the corneal thickness changes with slight to no effect on the refractive, transparency, and mechanical functions of the cornea. For example, during sleep, a diurnal increase in hydration occurs causing on average a 6 ± 3 percent increase in corneal thickness of the cornea (range: 2–13 percent; stromal = 6 percent and epithelial = 8 percent), mainly because of reduced oxygen levels (from 155 to 55 mmHg) caused by eyelid closure and secondarily from decreased evaporative loss (from 3 µl/hr cm² to 0 µl/hr cm²) caused by eyelid closure.^{191,251,252} Upon awakening and eyelid opening, the corneal hydration and thickness reverts back to normal within 1–2 hours.

If the cornea becomes hydrated by 5 percent or more above its normal physiologic level of 78 percent, it begins to scatter significant amounts of light and loses its transparency. Some loss of refractive function may also occur, particularly if the epithelial surface becomes too irregular. Epithelial edema clinically causes a hazy microcystic appearance to occur in the epithelium in mild to moderate cases, significantly decreasing vision and increasing glare. It also can cause the development of large painful, sub-epithelial bullae in severe cases. These changes correlate histopathologically with hydropic basal epithelial cell degenerative changes due to intraepithelial fluid accumulation and the development of interepithelial cellular fluid-filled spaces, known as cysts and bullae. If bullae are chronically present, a fibrocollagenous degenerative pannus will often times form in the subepithelial space decreasing vision further, but, paradoxically, this reduces the pain. In comparison, corneal stromal edema clinically appears as a painless, hazy, thickening of the corneal stroma resulting in a mild to moderate reduction in visual acuity and an increase in glare. At the same time, Descemet's membrane folds commonly appear on the posterior corneal surface. Histopathologically, these changes correlate with the light microscopic findings

of thickening of the corneal stroma in the posterior cross-sectional direction with loss of the normally present artefactual interlamellar stromal clefting.²⁵³ Ultrastructural and biochemical studies have further shown that stromal edema results in an increase in the interfibrillar distance and disruption of the spatial order between collagen fibrils, a decrease in the refractive index of the extracellular matrix, loss of proteoglycans, and, perhaps most importantly, hydropic degenerative changes or cell lysis in the resident keratocyte population.^{250,254–256}

Although depth-related differences in the concentration of the two types of negatively charged proteoglycans may account for the higher hydration levels in the posterior stroma compared to the anterior stroma, it appears that the directional orientation of the collagen fibrils and the degree of lamellar interweaving have the greatest influence on the amount of regional stromal thickening from edema-related swelling.^{106,257} Because the collagen fibrils in the cornea run from limbus to limbus, the corneal stroma highly resists circumferential expansion; however, it can expand anterior-posteriorly, mostly in the posterior direction. The depth-related differences in lamellar interweaving explain why the anterior third of the cornea mildly swells and actually maintains the anterior corneal curvature even when the remaining posterior two-thirds swells up to three times its normal

thickness.²⁵⁰ Because fibrotic corneal scars have random directionally oriented collagen fibrils, they too have been found to resist swelling under edematous conditions.²⁵⁸ Therefore, although it is commonly stated that corneal thickness and interfibrillar spacing increase linearly with increasing hydration of the corneal stroma, this relationship mainly applies to the posterior two-thirds of the corneal stroma.^{247,250}

Finally, while epithelial and stromal edema commonly co-exist together, there are two notable exceptions. As the epithelium has much weaker cohesive and tensile strengths than the corneal stroma, its state of hydration is mainly dictated by IOP levels.²⁵⁹ Conversely, because collagen fibrils in the corneal stroma are anchored at the limbus for 360°, they exert increasing or decreasing cohesive strength on the corneal stroma (i.e. compression or decompression of stromal tissue) as the IOP elevates above or decreases below normal, respectively. This results in the transmission of stromal edema to the epithelial surface in cases of high IOP or into the stroma in cases of low IOP. Therefore, if IOP is ≥ 55 mmHg with normal endothelial barrier and metabolic pump function, epithelial edema usually occurs by itself. In comparison, if endothelial cell dysfunction and hypotony (IOP ~ 0 mmHg) occur together, then stromal edema occurs alone (Fig. 4.26).

Box 4.5 Endothelial cell injury

There are many exogenous stresses that could potentially damage the corneal endothelium (Fig. 4.27). Although accidental trauma and infection are perhaps the most common, they usually are preventable or are difficult to prognosticate since so many variables need to be considered. Several common, more predictable intentional interventions that might stress a person's corneal endothelium are contact lens wear, excimer laser-based keratorefractive surgery, and intraocular surgery.

Contact lenses

Contact lens wear does not cause loss of ECD, but it can cause acute reversible corneal edema and, in the long-term, increased polymegathism and decreased pleomorphism.^{215,260} The corneal endothelium utilizes the same carbohydrate metabolic pathways as the corneal epithelium. However, the transport function of the endothelial cell is higher than that of the epithelial cell due to its high baseline metabolic rate, which requires oxidative activity that is 5–6 times that of the epithelial cell.²⁶¹ Atmospheric oxygen is the primary source of oxygen to the endothelium. Interruption of this oxygen supply by low oxygen transmissibility contact lenses or a low oxygen environment (e.g. eyelid closing) will result in a shift to anaerobic metabolism, a concurrent increase in stromal lactic acid and CO₂ production, and a drop in stromal pH.²⁶² Hypoxia can also stimulate epithelial production of 12(R)HETE, a potent inhibitor of the endothelial Na⁺/K⁺-ATPase pump sites.^{263,264} Acute reversible endothelial changes observed with hypoxia include stromal swelling, endothelial dysfunction, and endothelial blebbing. Chronic hypoxia can eventually lead to irreversible endothelial polymegathism and pleomorphism. In fact, Polse and associates have shown that chronic corneal hypoxia in humans alters the endothelium's ability to reverse induced swelling.²⁶⁵

Surgical injury

Excimer laser-based keratorefractive surgery has been found to induce acute loss of barrier function and reversible endothelial cell

stress (increased polymegathism and decreased pleomorphism) only if performed on a cornea with a residual stromal bed thickness ≤ 200 µm due to the shockwave effect from photoablation. As refractive surgeons rarely or never ablate to this depth due to concerns for the risk of ectasia, there appear to be no short- or long-term endothelial effects from this type of surgery in the current clinical setting.²¹⁵

By comparison, all intraocular surgeries have been found to cause varying degrees of both acute and, perhaps more importantly, chronic damage to the corneal endothelium. Modern small incision cataract surgery (≤ 1.5 mm incisions for microincision cataract surgery [MICS]; ~ 3.5 mm incisions for Kelman phacoemulsification [KPE]) is the preferred technique in the USA, Europe, and other more developed countries as randomized studies have shown that it results in better clinical outcomes compared to larger incision techniques (~ 7 –12 mm incisions for extracapsular cataract extraction [ECCE]).²⁶⁶ However, KPE does cause significant endothelial cell injury due to a number of factors, such as corneal distortion, ricocheting of nuclear fragments, intraocular lens or intraocular instrument contact, and release of free radicals.²⁶⁷ A recent randomized controlled trial showed that KPE caused an exponential reduction in central ECD up to 1 year after surgery with ECD loss averaging 10.5 percent.²⁶⁷ However, no significant changes in polymegathism or pleomorphism were found.²⁶⁷ This fast component period of cell loss is statistically similar to that observed following ECCE, another common surgical alternative technique used for performing cataract surgery, particularly in developing countries, which results in an average 9.1 percent reduction in ECD at 1 year after surgery.²⁶⁷ Long-term slow component cell loss data are currently unknown for KPE as it has not been well studied beyond 1 year postoperatively, whereas ECCE data show that an annual cumulative cell loss rate of 2.5 percent exists from 1 to 10 years after surgery (four-fold higher than normal physiologic annual cell loss rates).^{25,260,267,268} There

Box 4.5 Endothelial cell injury—cont'd

currently is no significant evidence to support MICS over KPE or to support one cataract technique over another (e.g. divide-and-conquer vs. phaco-chop) from an ECD loss standpoint as they all seem to be statistically similar.^{269,270}

Recent data on the two phakic refractive IOL procedures commercially available in the USA, Verisyse (Ophthec, Gronigen, The Netherlands/AMO, Santa Ana, California) and the foldable Visian Implantable Collamer Lens (ICL, Visian ICL 4; STAAR Surgical Co., Monrovia, California), show less acute component damage than standard cataract surgery (Verisyse: ~7 percent ECD loss and Visian ICL: ~3 percent ECD at 1 year after surgery).^{271,272} However, just as with ECCE, a chronic, slow component annual cumulative cell loss rate is found from 1 to 5 years postoperatively, which is approximately 4–5-fold higher than normal physiologic cell loss rates (Verisyse: ~2.7 percent ECD loss/year and Visian ICL: 2.5 percent ECD loss/year between 1 and 5 years after surgery).

Corneal transplantation surgery (e.g. PK) has been found to cause the greatest long-term decrease in central ECDs of all the commonly performed intraocular anterior segment surgeries, perhaps because of the peripheral loss of stem-like cells or the peripheral storage zone (Fig. 4.23A).^{223,228} Long-term longitudinal studies up to 20 years after PK surgery show that ECD loss occurs in two phases: a fast and a slow component.²⁷³ During the fast component, the central ECD decreases exponentially with 36.7 percent ECD loss at 1 year and 8.4 percent ECD loss/year up to 5 years after surgery.²⁶⁶ Thereafter, a slow component occurs where central ECD loss decreases to a linear rate of 4.2 percent ECD loss/year.²⁷³ Concurrently, polymegathism gradually increases and pleomorphism gradually decreases throughout the longitudinal follow-up period.

Over the last decade, surgical techniques for corneal transplantation have changed markedly as techniques such as posterior lamellar keratoplasty (PLK), deep lamellar endothelial keratoplasty (DLEK), Descemet's stripping endothelial keratoplasty (DSEK), Descemet's stripping automated endothelial keratoplasty (DSAEK), and Descemet's membrane endothelial keratoplasty (DMEK), have evolved to take the place of PK for endothelial cell disorders.^{274,275} Currently, the simplest and most efficient technique is DSAEK surgery, which is preferred by patients and surgeons compared to the more traditional full-thickness PK surgery.²⁷⁶ The preferred approach of DSAEK, however, may soon be supplanted by DMEK.^{277,278} One of the major concerns with DSAEK surgery, second only to the high dislocation rate, is how the endothelium survives long-term in these grafts. Surgeons commonly fold the ~8 mm diameter DSAEK graft and insert them through small incisions (~3.5–5 mm incisions) using various grasping forceps, injectors, or insertion devices, and then inject air in the anterior chamber to keep the graft in place for 1 hour to up to 2 days in duration after the surgery. Long-term studies show similar short-term rates of ECD loss (35–39 percent central ECD cell loss at 1 year postoperatively) to those observed after PK.^{279,280}

Finally, there are other surgical adjuvants or new procedures on the horizon that could affect the corneal endothelium. The surgical adjuvant that is currently of most interest is topical mitomycin C (MMC) application, which is applied after excimer laser-based

keratorefractive surface surgery to prevent or treat corneal haze caused by subepithelial scarring. Currently, there appears to be no evidence of short- or long-term ECD loss or keratocyte toxicity, if a single local application of MMC is used at a concentration of 0.02 to 0.002 percent for an exposure duration of 12 s to 2 min.^{281–285} The medical procedure that is currently of most interest is corneal collagen cross-linking with riboflavin and UVA light (CXL), which is a promising treatment option for the disease of corneal ectasia.^{286,287} Currently, no evidence of endothelial cell damage has been found, but most of the studies to date are preliminary, short-term, small in number, and are under strict research protocols.^{23,288,289}

Pharmacologic toxicity

In addition to surgical injury, the corneal endothelium can also be influenced by pharmacologic toxicity.^{215,290,291} Past studies that helped guide the development of intraocular irrigating solutions found that the best were those most similar to aqueous humor in composition. BSS Plus (Alcon Laboratories, Ft Worth, TX, USA) is currently the most physiologically compatible intraocular solution (Table 4.3); BSS is probably the next best alternative (Table 4.3). The main ingredients required for intraocular solutions to be biologically compatible with the corneal endothelium are electrolyte levels matching those in the aqueous humor, glucose as an energy source, bicarbonate as a buffer, and glutathione as an antioxidant/free radical scavenger. Intraocular tissues, particularly the corneal endothelium, require a pH between 6.7 to 8.1 and an osmolality between 270 and 350 mOsm. Furthermore, any medication used intraocularly needs to be at a non-toxic concentration and contain no preservatives. Pharmacologic toxicity to the anterior segment tissues of the eye, including the corneal endothelium, has become better understood through the discovery of a condition known as toxic anterior segment syndrome (TASS).²⁹⁰ TASS is a sterile postoperative inflammatory reaction caused by a non-infectious substance that enters the anterior segment, resulting in toxic damage to intraocular tissues. Most cases are severe, resulting in >50 percent loss of central ECD. The injury typically starts 12–48 hours after cataract or anterior segment surgery and is limited to the anterior segment of the eye. It is always Gram stain and culture negative and usually improves with steroid treatment. The primary differential diagnosis is infectious endophthalmitis.

The possible causes of TASS include intraocular solutions with an inappropriate chemical composition, drug concentration, pH, or osmolality. It can also be caused by preservatives, enzymatic detergents, bacterial endotoxin, oxidized metal deposits and residues, and factors related to intraocular lens processing, such as retained residues from polishing or sterilizing the lenses (Table 4.4).²⁹⁰ Since TASS is an environmental and toxic control issue, it has made anterior segment surgeons and surgical staff more aware that maintaining the health of the corneal endothelium requires a thorough understanding of all medications and fluids used during surgery. Additionally, it has helped all involved in surgical eye care understand the importance of proper cleaning and sterilization of intraocular instruments since most cases of TASS appear to be directly caused by retained detergents or contaminated water sources.

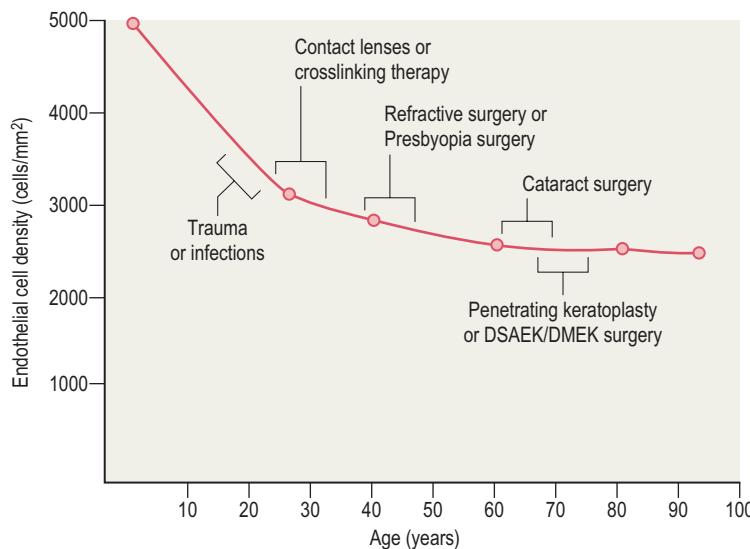

Figure 4.27 The normal decrease in central ECD that occurs with aging is shown. Located along the line graph are major endothelial cell stressors that commonly may occur in a person's lifetime, which potentially could decrease the central ECD greater than normal.

Table 4.3 Composition of aqueous humor compared to various intraocular irrigating solutions

Ingredient	Human aqueous humor	BSS Plus	BSS
Sodium	162.9	160.0	155.7
Potassium	2.2–3.9	5.0	10.1
Calcium	1.8	1.0	3.3
Magnesium	1.1	1.0	1.5
Chloride	131.6	130.0	128.9
Bicarbonate	20.15	25.0	–
Phosphate	0.62	3.0	–
Lactate	2.5–4.5	–	–
Glucose	2.7–3.7	5.0	–
Ascorbate	1.06	–	–
Glutathione	0.002–0.010	0.3	–
Citrate	–	–	5.8
Acetate	–	–	28.6
pH	7.38	7.6	7.4
Osmolarity (mOsm)	304	305	298
Protein	0.135–0.237	–	–

All concentrations are expressed in millimoles per liter or millequivalents per liter of solution.

Basement membrane and glycocalyx

A secondary function of the corneal endothelium is its ability to secrete a basement membrane along its basal surface called Descemet's membrane, which is continuously deposited throughout life (Fig. 4.22B).^{1,6} Although some collagen fibrils from the posterior stroma are embedded in the Descemet's membrane, it really has no major junctional or adhesional complexes to the posterior stroma other than a 0.5 µm thick layer of fibronectin.¹ Descemet's membrane is highly extensible and tough, but less strong and stiff than

Table 4.4 Causes of toxic anterior segment syndrome

1. Irrigating solutions or viscoelastic devices
• Incomplete chemical composition
• Incorrect pH (<6.7 or >8.1)
• Incorrect osmolality (<270 mOsm or >350 mOsm)
• Preservatives or additives (e.g. antibiotics, dilating medications)
2. Ophthalmic instrument contaminants
• Detergent residues (ultrasonic, soaps, enzymatic cleaners)
• Bacterial LPS or other endotoxin residues
• Metal ion residues (copper and iron)
• Denatured viscoelastics?
3. Ocular medications
• Incorrect drug concentration
• Incorrect pH (<6.7 or >8.1)
• Incorrect osmolality (<270 mOsm or >350 mOsm)
• Vehicle with wrong pH or osmolality
• Preservatives in medication solution
4. Contaminated water sources
• Water baths
• Autoclave reservoirs
• Non-sterile or non-pyrogen-free water
5. Intraocular lenses
• Polishing compounds
• Cleaning and sterilizing compounds

the posterior stroma since it is primarily composed of type IV and VIII collagen fibrils as well as the glycoproteins fibronectin, laminin, and thrombospondin. At birth, it averages 4 µm thick.⁶ On electron microscopy, the fetal Descemet's membrane is composed of many wide-spaced, 110-nm banded collagen fibrils (see Fig. 4.22B).²⁹² Postnatally, collagen is gradually added posteriorly to this initial fetal layer throughout life, being notably different in morphology from the fetal layer as it is non-banded and contains small-diameter collagen fibrils that are arranged into a hexagonal lattice (see Fig. 4.22B).²⁹² Typically, at the end of a normal lifespan, Descemet's membrane measures around 10–15 µm thick (4 µm thick banded layer and a 6–11 µm thick non-banded layer). With disease (e.g. Fuchs' dystrophy) or injury (e.g. trauma or surgery), Descemet's membrane may become

focally (corneal guttae) or diffusely thicker than normal from abnormal collagen deposition. This newly deposited abnormal basement membrane is called the posterior collagenous layer of the Descemet's membrane and is classified into one of three types: banded, fibrillar, or fibrocellular.²⁹³ Excess basement membrane deposition is a common strategy used by cells attempting to recover from injury, allowing them to remain attached to a tissue's scaffolding. Finally, the endothelium is also known to secrete a 0.7 µm thick glycocalyx layer on its apical or posterior surface.²¹⁵ Functionally, it is thought that the glycocalyx layer may protect the internal (or posterior) surface membrane of the endothelium.

Mechanical properties

As the cornea is a pressurized, thick-walled, partially woven, unidirectionally fibril-reinforced laminate biocomposite, it represents an excellent compromise between stiffness, strength, extensibility, and therefore toughness to withstand internal and external forces that may stress it, distort its shape, or threaten its integrity.^{1,90,294,295} The biologic behavior of a soft fibrous connective tissue, like the human cornea, usually is much stronger in the direction of its collagen fibrils than perpendicular to it and these fibrils are assembled into various hierarchical structures, which give the tissue anisotropic mechanical properties.^{296–298} Maturity and age-acquired covalent collagen cross-links serve to bolster the stiffness, strength, and toughness of these hierarchical structures, usually without significantly compromising extensibility (Fig. 4.6C). As the biomechanical properties of the cornea are dominated by the stroma, the macro-, micro-, and nano-mechanical behaviors of the cornea is primarily due to the hierarchical structure of essentially four composite-like regions: Bowman's layer, the anterior third of the stroma proper, the posterior two-thirds of the stroma proper, and Descemet's membrane (Fig. 4.28).^{93,299–306} Like most composites, the cornea is biomechanically strong, light in weight (when dehydrated), and has an extraordinary capacity to absorb energy by material destruction due to its fluid-like matrix gel; however, it also has a composite's shortcomings in that its dynamic three-dimensional state of stress is difficult to definitively quantify and its biomechanical failure process is complex since it appears to break down at the nano- and micro-mechanical level.

When a biologic tissue is subjected to force (or load), it typically will deform (elongate, compress, or shear) in the direction of the applied force. The force divided by the cross-sectional area of the applied stress (N/m^2) is called the stress acting on the material, while the degree of deformation in the direction of the applied stress is called strain. The ratio of the stress and strain (i.e. the slope of the stress-strain curve) is called the elastic modulus or Young's modulus of the tissue, which basically describes the stiffness of the material. Stiff materials are needed to transmit forces and are especially crucial in resisting bending or buckling from compression. The strength of a material is defined as the maximum stress it can sustain before breaking. Strong materials are needed to carry a load. The extensibility of a tissue is defined as the maximum strain it can sustain before rupturing. Extensible materials are needed to reversibly change elastic shape instantaneously and then return to its original shape without damage. Toughness is defined as the ability

of the material's micro- and nano-structure to dissipate deformation energy without initiation or propagation of a critical crack. Toughness is a common characteristic of a tissue that deforms to dissipate energy on impact (i.e. not brittle) and/or has natural crack-stopping mechanisms so that it avoids initiation and/or propagation of a critical crack (i.e. work of extension [work per volume or work per unit mass] or work of fracture [work per surface area created]). In essence, toughness describes the characteristics of a tissue's durability and unbreakability. The area under the stress-strain curve or the energy needed to elongate a pre-existing crack both correspond to the toughness of the material, with the former describing crack initiation and the latter crack propagation. Strength and toughness are both highly influenced by internal defects in a tissue's structure or material components, whereas stiffness and extensibility are not.

Corneal stress

The dome-like cornea encounters three types of loads or stresses: transmural pressure, piercing, and crushing. The static net internal pressure constantly stressing the cornea in an outward direction is the IOP (16 ± 3 [S.D.] mmHg above external atmospheric pressure [760 mmHg] and the external resting tension from the eyelids).^{307–309} Additional dynamic stressors that can occur as a result of normal variability or external environmental stress include various causes of increased IOP, such as accommodation (4 mmHg), turning the eyes (10 mmHg), arterial pulsation (1–2 mmHg), diurnal changes (5 mmHg), respiration (5 mmHg), Valsalva maneuver (8 mmHg) and recumbent or inverted positions, external eyelid blinking (normal blinks = 5–10 mmHg; hard squeeze blinks = 50–110 mmHg), eye rubbing (increases IOP [light digital rubbing = 5–20 mmHg; hard knuckle grinding/rubbing, = 25–135 mmHg], induces shear and transverse compression on the corneal stroma, and may actually indent the cornea), or accidental eye impact.^{307–311} An increase in internal pressure causes the cornea's stress behavior to be dominated by transmural longitudinal tension, which is usually very well tolerated since the net vector direction of stress is essentially parallel to the direction of most of the collagen fibrils in the structure. In contrast, external pressure, such as from eye rubbing (back and forth or circular pressure and friction), nocturnal external eye pressure, or direct blunt impact trauma, causes radial compressive stress, circumferential tensile stress, and/or deformation. Since the net vector direction of stress is oblique to the direction of most collagen fibrils in the cornea, external stress is more likely to initiate or propagate internal defects due to fatigue-related damage in the corneal stroma than internal stress. Moreover, eye rubbing's often repetitive or oscillatory ECM shearing and subsequent cellular damage results in both transmural pressure and crush-related injury.

Using a basic understanding of mechanical physics, the cornea should theoretically obey Pascal's Principle, which states that the pressure is the same everywhere inside an enclosed system or vessel at equilibrium in addition to contributions already caused by static fluid pressure. Despite this constant IOP, differences in wall tension exist because according to the Law of LaPlace – the tension in the walls of an enclosed vessel are directly dependent on the pressure in the system and its radius of curvature and inversely

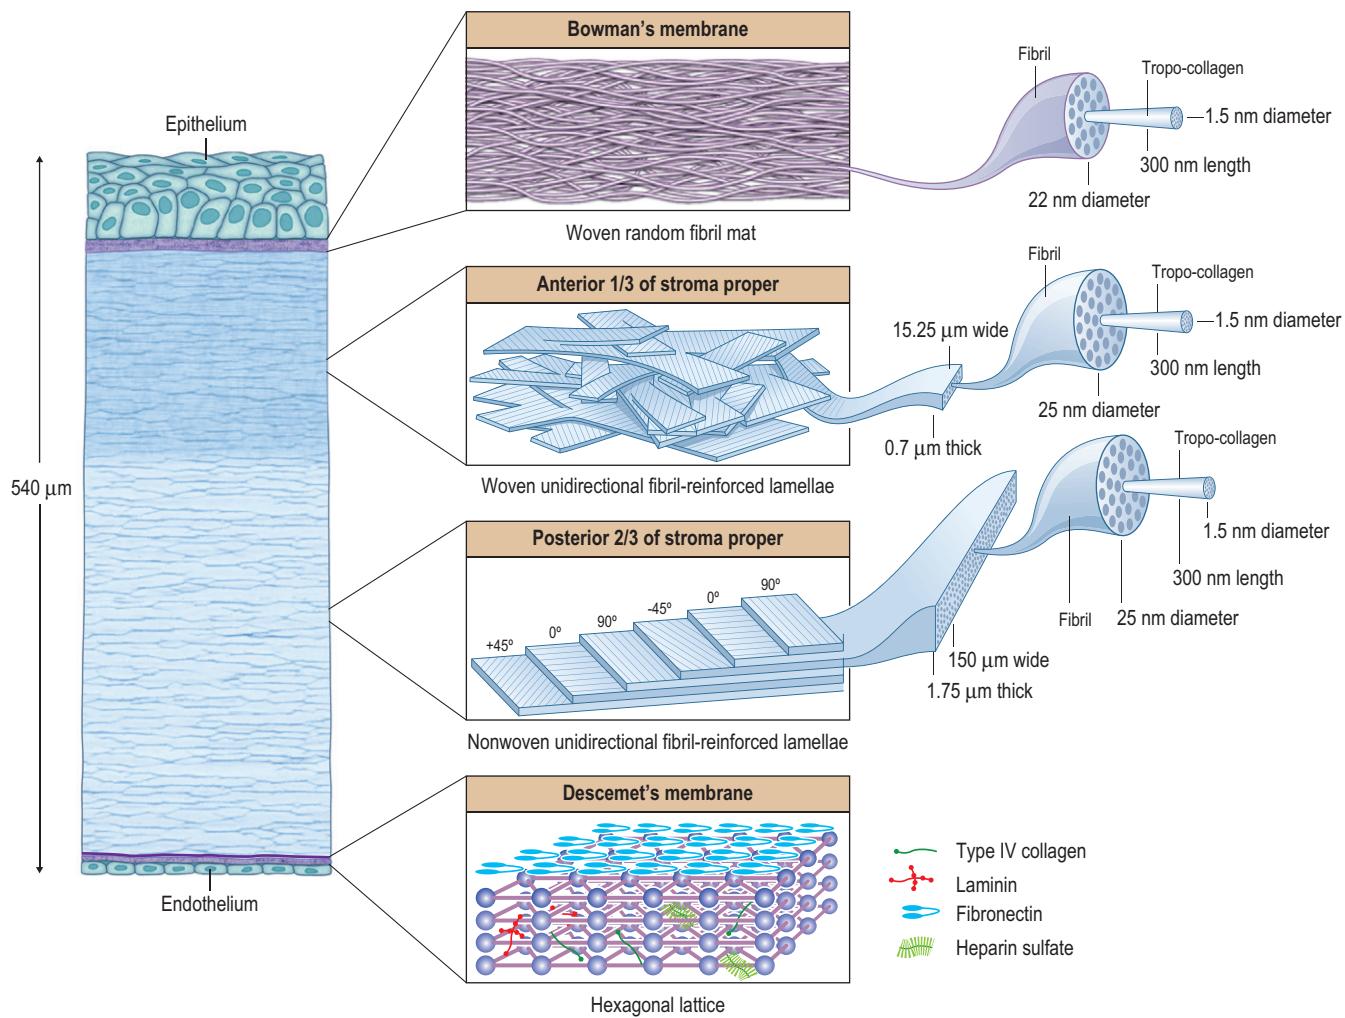

Figure 4.28 The hierarchical structure of the cornea showing that it is basically composed of three composite-like regions. A fourth composite-like region, the Descemet's membrane, is included for completion's sake. The macroscopic to microscopic to nanoscopic features are emphasized (from left to right) to help illustrate the various interactions between the tissue components. The Bowman's layer is essentially a random fibril, woven mat composite, which maximizes multiaxial stiffness and strength. The underlying anterior third of the stroma proper is a lamellar interwoven fabric composed of unidirectionally (UD) fibril-reinforced lamellae. This architectural hierarchy is much more reinforced against z-axis deformations compared to non-woven UD-lamellae. In the human body, it is most similar to that of pericardium, which serves in mechanically preventing aneurysm formation of the heart. The posterior two-thirds of the stroma is essentially a non-woven, UD-fibril-reinforced lamellar composite, which maximizes longitudinal x- and y-axis stiffness and strength, but has weak transverse z-axis stiffness and strength. In the human body, it is most similar to that of the annulus fibrosis of intervertebral disk, which functions efficiently as a cushioning mechanism for the spine, but is prone to chronic biomechanical failure. The UD-orientation of collagen fibrils in each lamellae is important because this arrangement prevents fibril undulation and thus maximizes the initial axial tensile strength of each individual fibril. Descemet's membrane forms a hexagonal lattice. In toto, these composite-like regions characterize the overall stiffness, strength, extensibility, and toughness of the cornea. They also help explain how the cornea biomechanically behaves normally after surgery, disease, or injury.

dependent on the thickness of the vessel wall. For example, in an isotropic, thin-walled (wall thickness to cavity diameter ratio ≤ 0.1) elastic vessel, the Law of Laplace would be simplified to the following equation:

$$T = PR/2t$$

where T equals the radial wall tension or stress of a spherical vessel wall, P equals the internal pressure in the vessel (IOP), R equals the radius of curvature of the wall (the curvature of the posterior corneal surface), and t equals the thickness of the wall in meters (corneal thickness). Unfortunately, the Law of Laplace is not a perfect approximation of stress in the corneal eye wall in the real world since the cornea is actually anisotropic, inhomogeneous, asymmetric, and thick-walled

(Fig. 4.28). Thus, one can see that although the static stress can be approximated (Fig. 4.29A), the dynamic temporal stresses acting upon the corneal eye wall are quite complex and perhaps too difficult to definitively characterize, particularly since they overlap one another in real-time.^{312,313}

Corneal stiffness, strength extensibility, and toughness

The two principal structural characteristics of the human cornea that help maintain its stiffness (rigidity or elasticity), strength (ultimate fracture stress), extensibility (ultimate fracture strain), and toughness (durability or unbreakability) are its thickness and its innate biomechanical properties (hierarchical structure and degree of collagen fibril cross-linking). While corneal thickness can be directly measured accurately *in vivo*, a major difficulty in the field of

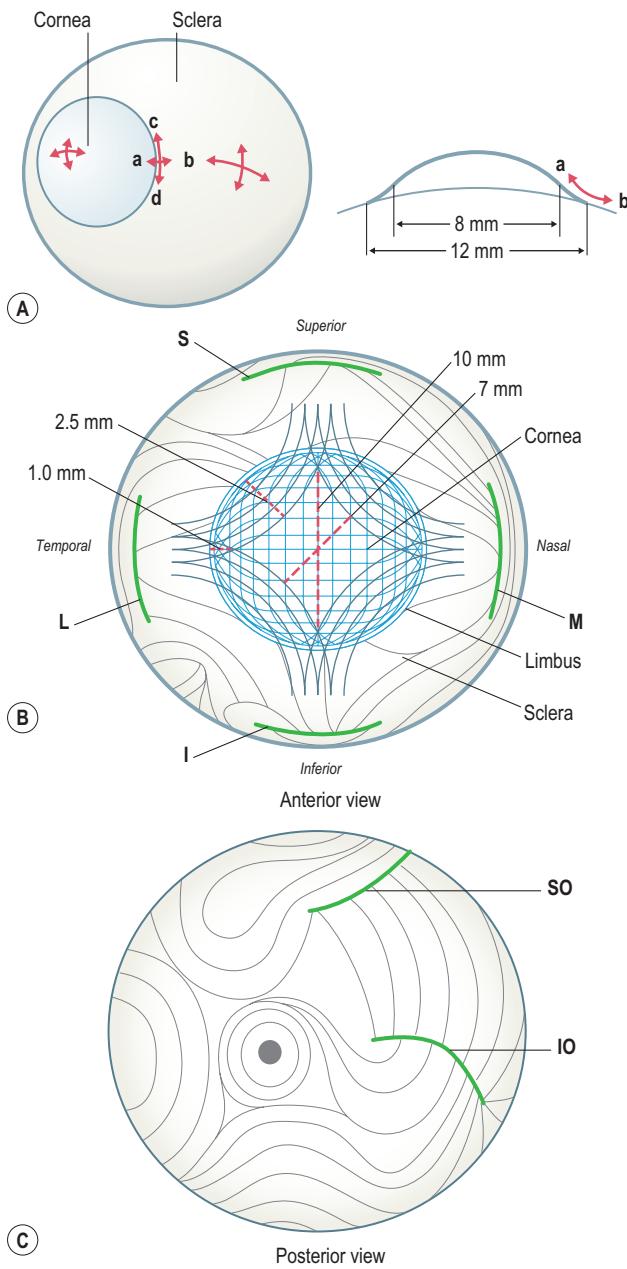

Figure 4.29 The stress on the coats of the eye wall (red lines with double-headed arrows are shown in (A)) and the preferential orientation of the collagen fibrils (solid gray and blue lines) are shown in (B) and (C). (A) The lowest radial stress is in the cornea due to its smaller radius of curvature; the largest radial stress is under the rectus muscle insertion sites or at the equator of the globe due to its large radius of curvature and the fact that these are the thinnest regions of the sclera. The largest circumferential stress is at the limbus due to the sudden change in curvature going from the cornea to the sclera, which doubles the stress in the circumferential direction compared to the radial direction. (B) The central 4–5 mm of the cornea has collagen fibrils that are relatively uniformly directed in either the superior–inferior or the nasal–temporal direction. These fibrils appear to bend in the periphery of the cornea to coalesce and form the circumferential annulus. The diamond-shaped appearance of the central orthogonal collagen fibrils suggests that additional anchoring collagen fibrils come in from the sclera and limbus at one of the principal meridians (inferior, nasal, etc.), then curve within the peripheral cornea to exit an adjacent principal meridian 90° away. Overall, this arrangement would aid in maintaining the peripheral flattening of the cornea and resisting the higher stress in that region of the cornea. It secondarily would not interfere with the central optical zone of the cornea. (C) The preferential direction of the sclera's collagen fibrils is radial in the anterior sclera, particularly in relation to the muscle insertion sites, whereas those at the equator are circumferential and those at the posterior sclera form circular whorls. The deep layers of sclera, which are not shown, form a net- or rhomboid-like layer diffusely throughout all regions of the sclera. (Modified from Meek KM. In: Frazl P, ed. Collagen: structure and mechanics. New York: Springer, 2008:359–96; Aghamohammadzadeh H, Newton RH, Meek KM et al. Structure 2004; 12(2):249–56; and Watson PG, Hazelman B, Pavesio C, Green WR. The sclera and systemic disorders, 2nd edn. Edinburgh, UK: Butterworth Heinemann, 2004.)

ophthalmology has been an adequate actual direct measurement or even an accurate approximation of its innate biomechanical properties.³¹⁴ The current understanding of the cornea's biomechanical properties still mainly relies on ex vivo experiments, primarily strip extensiometry and inflation testing.³¹⁵

The cornea is an important biological mechanotransducer of stress due to its viscoelastic properties (i.e. solids with some characteristics of a fluid), which helps prevent premature biomechanical failure via energy dissipation. The property of viscoelasticity complicates our understanding of corneal biomechanical behavior since it contains both elastic and viscous component properties that overlap one another over time when forming the stress–strain curve. Elasticity is related to time-independent energy storage due to stretching or strain of the flexible domains of collagen molecules (potential energy) and deformation or transfer of energy to the sclera and other portions of the eye due to the rigid

domains of collagen molecules (kinetic energy). In essence, elasticity is a time-independent physical property of a solid that allows the cornea to return to its original shape after stress or, if significantly damaged, to be permanently altered in shape. Viscosity is related to time-dependent energy dissipation due to the sliding of interfibrillar collagen fibrils, filaments, and lamellae past one another in a hydrated proteoglycan matrix (mechanicothermal energy transduction). In essence, viscosity is a time-dependent physical property of a fluid that allows the cornea to deflect some input energy away from its elastic components and it allows the cornea the possibility to reversibly or permanently change its elastic shape with time.

Ex vivo experiments show that the human cornea has J-shaped, non-linear, stress–strain loading and unloading curves. The cornea's stress–strain curves have an immediate elastic response dominated initially by the low strain behavior of its non-collagenous matrix and the act of removing

slack from its collagen fibrils (fibril uncrimping) as well as re-orienting its collagen fibrils to the direction of the stress (fibril recruitment) at the lower part of the J and then later by the high strain behavior of collagen fibrils that are maximally taught and oriented in the direction of stress in the upper part of the J.³¹⁶ Finally, a slower, time-dependent viscous response occurs in addition to the immediate J-shaped response due to interlamellar and interfibrillar slippage resulting in time-dependent strain (creep) or stress (stress relaxation) curves.³¹⁶ Creep is defined as a time-dependent elongation that occurs in three stages: (1) primary creep with its associated decelerating strain rate, (2) secondary creep with its associated constant strain rate, and (3) tertiary creep with its accelerating strain rate until rupture.³¹⁷

Primary and secondary creep are reversible viscoelastic responses without accompanying damage, whereas tertiary creep is associated with an irreversible reduction in the strength and toughness of the structure due to damage by irreversible slippage or cracking. The cornea's unloading stress-strain curve does not overlap with the loading curve, being variably less dependent on the load or strain rate. The difference in area between the two curves represents the energy dissipated via viscous friction (i.e. hysteresis) during a single mechanical cycle. As the cornea has very small collagen fibril diameters and lengths compared to other connective tissues, like tendon and bone, and has biomechanical properties between skin and ligament, it is reported that the cornea converts approximately 35 percent of its total input energy into energy dissipation and the other 65 percent into energy storage, energy transmission, or deformation. It should be pointed out though that a single stress-strain curve has limited meaning when evaluating a material's or structure's total dynamic, temporal biomechanical properties since each curve is either load or strain rate dependent over a specific time interval and each represents only one of several different material components and orientations of the structure.

Based on the hierarchical structure of the corneal stroma (Fig. 4.28), it has been inferred that the anterior woven portion of the cornea is much stiffer and stronger than the posterior non-woven portion. In fact, this inference has been qualitatively supported by both clinical and experimental studies, which show that the posterior two-thirds of the corneal stroma is easier to bluntly dissect in a lamellar fashion than the anterior third and that the anterior corneal curvature remains relatively constant at various physiologic IOPs and stromal hydration levels compared to the posterior corneal curvature.^{318–322} After induction of corneal edema in an ex vivo setting, ultrastructural studies by Muller and associates showed that the 10 µm thick Bowman's layer and the underlying anterior 100–120 µm of the stroma proper are the most stiff regions of the cornea since they did not swell significantly, even when stromal edema resulted in total central stromal thicknesses of up to 1200 µm.²⁵⁵ Quantitative ex vivo direct measurements of human corneal stiffness are very consistent with these initial observations and inferences. Seiler and associates showed, using uniaxial strip extensiometry, that removing the Bowman's layer with the excimer laser reduced the longitudinal (x- and y-axis length-wise dimension) Young's modulus on average by 4.75 percent.³⁰² This was similar to findings discussed in a 1989 National Eye Institute-sponsored corneal biophysics workshop that described the longitudinal Young's modulus of

Bowman's layer as about 50 MPa/mm² and that of the stroma proper as ranging between 2 to 10 MPa/mm².³²³

Uniaxial strip extensiometry further demonstrated that the anterior third of the corneal stroma is 2–3-fold stiffer and stronger than the posterior two-thirds.^{303,324,325} Using inflation tests, Descemet's membrane was measured to have a longitudinal Young's modulus of 0.5–2.6 MPa/mm² depending on the physiologic stress levels used during testing, which overall is less than that of the corneal stroma.^{304,326} Recent uniaxial strip extensiometry measurements show considerable regional and directional anisotropy in the longitudinal cornea as vertical and horizontal strips were stiffer (53 percent and 40 percent, respectively) and stronger (25 percent and 13 percent, respectively) than diagonal strips.³²⁷ Cohesive or transverse (z-axis thickness-wise dimension) strength measurements, using modified strip extensiometry techniques, showed that Bowman's layer averages 50 g/mm, the anterior third of stroma proper averages 34 g/mm, the posterior two-thirds of stroma proper averages 20 g/mm, and Descemet's membrane averages 7 g/mm.^{28,93} This same study importantly documented a depth-dependent decrease in the cohesive strength in the corneal stroma, with a maximum at Bowman's layer and then an exponential decrease until reaching a plateau at approximately 40–80 percent in depth into the stroma before decreasing again in the posterior-most 20 percent. An approximately 2-fold increase in cohesive strength was also found comparing the peripheral cornea to central cornea. Interestingly, these z-directional cohesive strength measurements were quantitatively 5–50-fold less than the longitudinal x- and y-direction tensile strengths.

Inflation studies have further shown that cutting or ablating Bowman's layer down to approximately 150 µm depth into the anterior corneal stroma results in anterior corneal flattening and peripheral corneal thickening; in comparison, deeper cuts or ablations into the stroma result in progressively more anterior corneal steepening rather than flattening.^{328–330} According to Hjortdal, after taking into account load-induced volume change, shallow ablations resulted in anterior corneal flattening because of similar inward inner and outer corneal wall strains.³³¹ In contrast, deeper ablations result in anterior corneal steepening because outward outer corneal wall strains occur up to 2-fold higher than inward inner corneal wall strains.³³¹ Their conclusion was that the difference between outer and inner corneal wall strains was due to less shear resistance in the posterior two-thirds of the corneal stroma. Finally, using inflation testing, increasing age and increasing IOP have both been associated with increased stiffness of the human cornea, presumably due to age-related cross-linking of the collagen fibrils and the changes in the viscoelastic properties of the interfibrillar matrix with increasing IOP, respectively.³³⁰ Clearly, further information about the innate biomechanical material properties of the human cornea are still needed since the current information is far from complete.

Chronic biomechanical failure of the cornea – ectasia

In classical mechanics, acute damage and rupture occur when the stress reaches a critical value, which in tension is called the ultimate tensile stress (UTS). In addition to overload-induced acute rupture, if you dissect a tendon and hang a lesser load (below the UTS) from it while keeping it moist,

in a chronic, time-dependent fashion the tendon will become damaged or fatigued and eventually ruptures. This occurs because of tertiary creep and its associated micro- and nano-structural pathogenesis of interfibrillar crack initiation and propagation (known as slippage for biologic tissues). In fact, susceptibility to fatigue is a universal phenomenon in biological tissues, which typically fail through constant static load (time-dependent damage due to magnitude of the constant load and time of application of this load). In comparison, man-made structural materials typically fail through dynamic oscillatory loads (cycle-dependent damage due to magnitude of the load and frequency of the cycling time). Cycling of the load may also accelerate the time-to-rupture of biological tissues.

The human cornea's innate biomechanical properties depend on the composition and organization of collagen fibrils and the matrix structures involved in force transmission between successive lamellar and fibrillar layers of collagenous tissue. This framework is essentially composed of 25-nm diameter, heterotypic type I collagen fibrils. The exact mechanical properties of these individual corneal collagen fibrils have not been evaluated or measured specifically. However, rat tendon studies found that individual 50-nm diameter, heterotypic type I collagen fibrils are moderately stiff, strong, and tough with only slight (~10 percent) extensibility, which is usually only evident when loaded under extreme physiologic stress.³³² Therefore, it can be assumed for practical purposes that corneal type I collagen fibrils do not stretch much under normal physiologic conditions or stressors. This seems to imply, at least from a theoretical perspective, that the matrix structures involved in force transmission between lamellar and fibrillar layers (analogous to mortar in brickwork masonry) are the primary structures of the corneal stroma that are vulnerable to fatigue (tertiary creep or irreversible slippage) under normal physiologic circumstances.³³³ Ultrastructural and x-ray scattering studies of human corneas with natural ectasia, like keratoconus, or iatrogenic ectasia, like post-LASIK or post-PRK ectasia, show that a chronic two-phase biomechanical matrix failure process of the stroma proper probably is the initiating and evolving pathophysiology, resulting in irreversible interlamellar slippage and subsequent irreversible interfibrillar slippage as opposed to collagen fibril failure (Fig. 4.30).^{334–341}

In the scientific field of composite sciences, man-made laminate polymer matrix composites that are most similar to that of the human cornea (e.g. woven and non-woven, UD fiber-reinforced laminate composites made of ductile matrix material) are known to undergo two similar chronic types of biomechanical matrix (or resin) failure processes known as delamination and interfiber fracture (IFF), whereby breakdown of the matrix between lamina or fibers occurs, respectively, causing redistribution of stresses within the laminate structure.^{294,342–345} The quantitative amount of stress that causes this damage is the sum of the cycling rate of the stresses acting on the structure, the duration of time exposed to this stress, the temperature of the structure, the curvature and thickness of the structure, the laminate stacking sequence of the individual plies, and the innate biomechanical properties of the fibers and binding matrix. As a consequence of nano- and micro-mechanical damage, usually resulting from transverse compression or transverse shear stresses as opposed to transverse tension or

longitudinal shear, further damage to other plies can occur, eventually resulting in macroscopic interlaminar delamination between two plies and full-thickness intralaminar fractures of a ply. In essence, delamination and IFF cause internal stress concentration sites throughout the laminate composite and accumulation of too many of these damage sites can considerably reduce the strength and toughness of the material without detectable thinning or bulging.³³⁹

Eventually, once the biomechanical failure process progresses to at least a moderate stage, the structure usually thins to measurable or detectable levels. It typically only begins to bulge or undergo pathologic shape changes due to a significant reduction in stiffness or significant increase in extensibility in late moderate or severe stages before ultimately undergoing total structural failure during the end stage. Moreover, during the redistribution of stress phase, further damage to other adjacent plies may occur even without significant external or internal increases in wall stress. Thus, from a composite science perspective, corneal ectasia essentially is the biologic equivalent of both delamination and IFF in the stroma proper and is essentially a stereotypic, non-specific chronic biomechanical failure response to multiple different specific stimuli, such as eye rubbing, LASIK surgery, family history (genetic conditions associated with environmental or behavioral eye rubbing), or possibly external nocturnal eye pressure.^{334,342} The irreversible slippage caused by delamination and IFF can either be

Box 4.6 Clinical biomechanical testing

Because reliable *in vivo* biomechanical tests have not yet been developed, the clinical setting currently relies on placido disk topography and tomography (2- and 3-dimensional reconstruction of thickness profiles) studies to indirectly infer information about the innate biomechanical properties of the cornea based on shape and thickness changes, respectively.^{55,346} This is the unfortunate reality for clinical ophthalmology and presumably explains why we have trouble predicting the ectasia risk or susceptibility before keratorefractive surgery in some cases and also have trouble predicting the probability of ectasia progression in keratoconus patients (i.e. time-dependent thickness profile changes or shape changes are moderate to late stages in the chronic biomechanical failure process). Only with a proper understanding of the cornea's innate biomechanical properties can an accurate predictor of material behavior be developed, which would help predict ectasia risk and/or progression, optimize refractive surgery, improve accuracy of tonometry measurements, or improve the design of contact lenses. Recently, Reichert introduced an instrument, the Ocular Response Analyzer (ORA; Reichert Corporation; Depew, USA), that measures the corneal response to indentation with an air pulse (principally similar to air pulse non-contact tonometry).^{347,348} This is the first instrument that purportedly directly measures the innate biomechanical properties of the cornea *in vivo*. The two biomechanical properties that it currently measures are corneal hysteresis (CH) and corneal resistance factor (CRF). CH is reported to be IOP-dependent and predominantly reflects the viscous properties of the cornea, whereas the CRF correlates with the elasticity of the cornea. However, discrepancies compared to expected results with these measures (e.g. a decrease in these properties with aging and no change in these properties after CXL treatment) suggest that further work is needed to determine precisely what these two properties measure or represent so that they are clinically meaningful to the clinician.^{349–351}

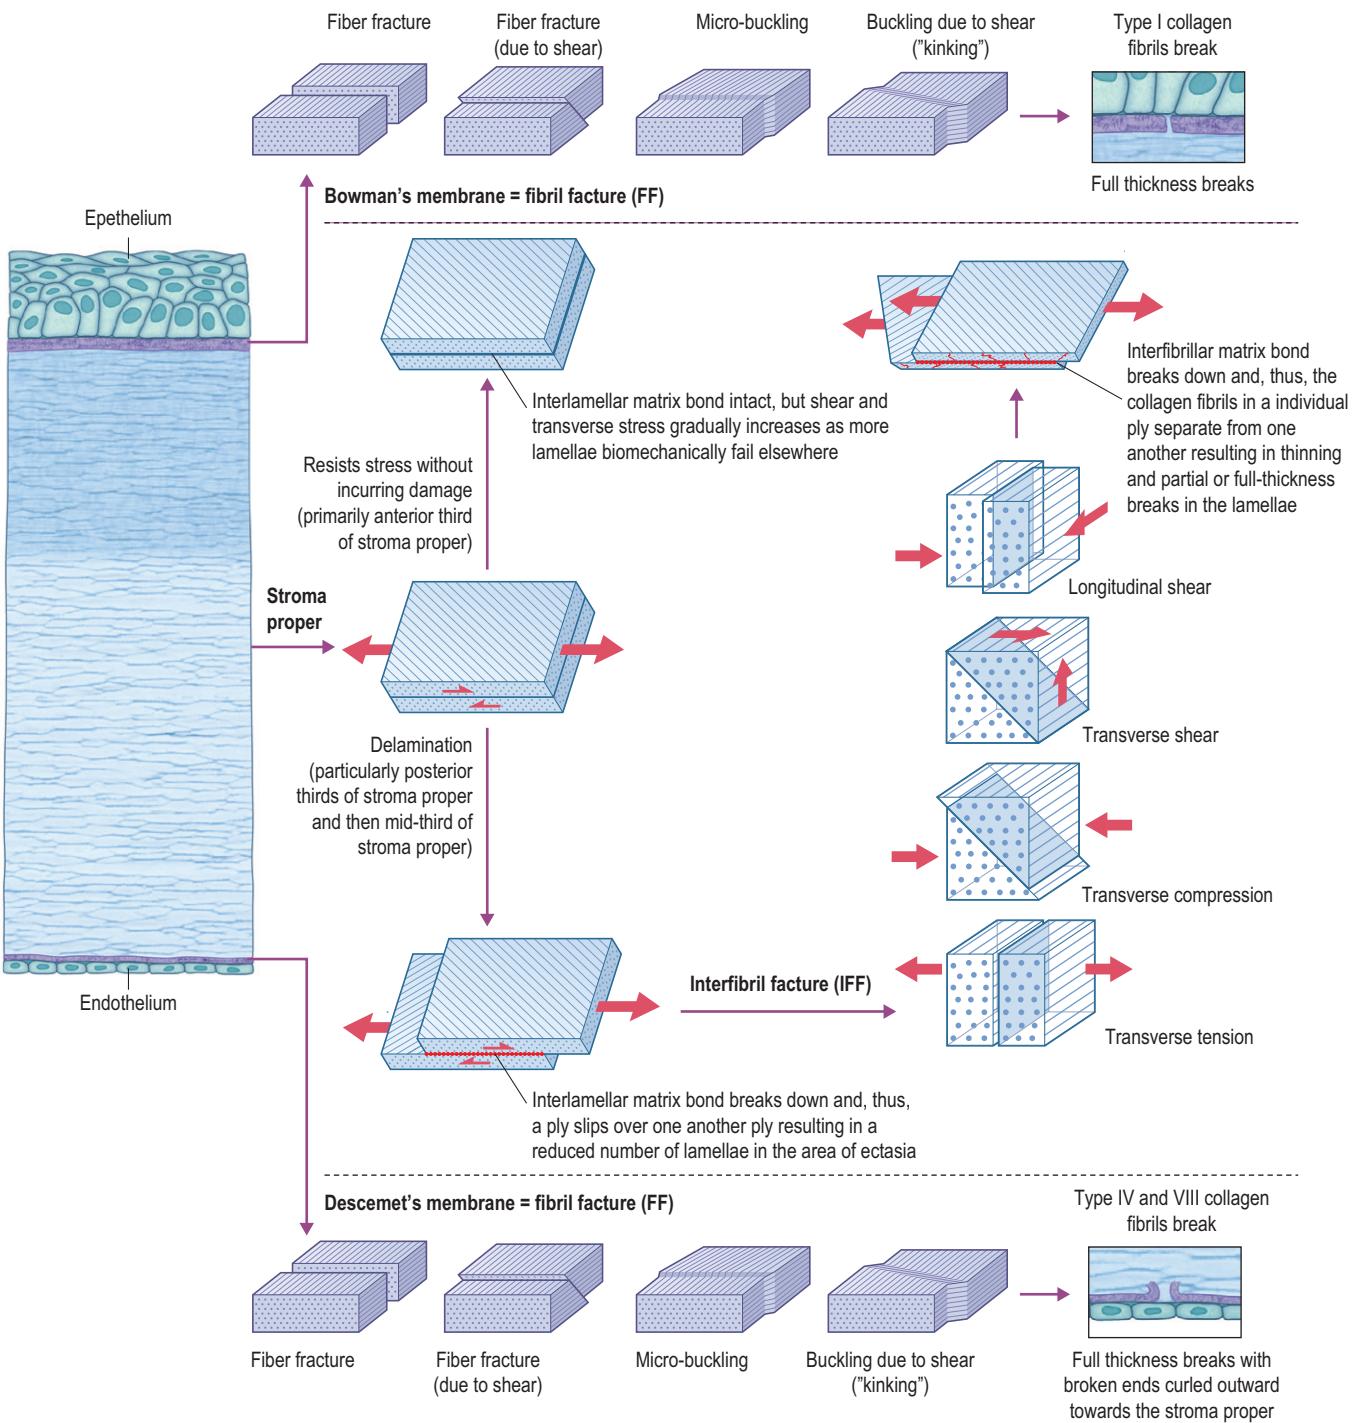

Figure 4.30 Diagram illustrating how the four composite-like regions of the cornea biomechanically fail when undergoing ectasia. In essence, ectasia appears to be a stereotypic chronic biomechanical failure response to multiple different stimuli. According to Alfred Puck's theory, laminated fiber polymer matrix composites, like the corneal stroma, biomechanically fail through three pathways: fiber fracture (FF), interfiber fracture (IFF), and/or delamination. Although FF is seen in Bowman's layer and Descemet's membrane in late stages of ectatic disease, both are not the cause for the ectasia, but rather are secondary events to the biomechanical failure process going on in the stroma proper. The initiating and evolving pathology causing the ectasia is due to delamination and subsequent IFF, which is seen in the stroma proper, particularly in the posterior-most regions of the cornea. This two-step biomechanical failure process leads to ectasia through gradual cumulative damage rather than an acute event. Interestingly, delamination and subsequent IFF can also occur in benign fashion, depending on type and degree of stress. Although delamination and IFF both take place and are clearly seen using ultrastructure studies in the posterior two-thirds of the corneal stroma, it does progress to the anterior third of the stroma proper. However, in the anterior third of the stroma proper, ultrastructurally IFF appears to dominate since the interlamellar slippage resulting from the delamination step is minimized by crack stopping mechanisms due to the interwoven nature of lamellae in this region of the stroma proper. FF usually is associated with acute ultimate failure of its individual composite-like layer, which results in acute loss of biomechanical and barrier function in that specific layer. For example, FF of Bowman's layer results in the clinical appearance of subepithelial fibrotic scarring, which is seen histopathologically as full-thickness breaks in Bowman's layer with outgrowth of hypercellular fibrotic stromal scar tissue. In another example, FF of Descemet's membrane results in the acute clinical appearance of corneal hydrops due to loss of endothelial barrier function, which is seen histopathologically as full-thickness Descemet's membrane breaks with curled outward fracture edges and endothelial cell discontinuity. Delamination may be seen clinically at the slit lamp as Vogt's striae, which are often found during early to moderate stages of ectasia in the posterior-most regions of the corneal stroma. (Adapted from Knops M. Analysis of failure in fiber polymer laminates: the theory of Alfred Puck. Heidelberg, Germany: Springer, 2008; and Reifsneider K. In: McNicol L, Strahman E, eds. Corneal biophysics workshop. Corneal biomechanics and wound healing. Bethesda, MD: NEI, 1989.)

benign or harmful to overall cornea, with the latter causing a gradual, progressive biomechanical failure process eventually leading to the ultimate failure of the structure through loss of shape and loss of refractive function. Although both delamination and IFF are universally seen in the non-woven posterior two-thirds of the stroma proper, it can progress into the woven anterior third of the stroma proper. However, the woven anterior third of the stroma has a natural crack-stopping mechanism due to the highly interwoven nature of its lamellae. This perhaps also explains why keratoconus rarely results in spontaneous rupture of the eye.

Other functions

Drug delivery

Although there are several drug delivery routes into the anterior segment of the eye (Fig. 4.31A), topical instillation of ophthalmic drugs is the most common method used to administer treatments for ocular disease – evidenced by the fact that 90 percent of ophthalmic drug formulations are geared for topical drop use. The barriers to productive topical absorption of drugs into the anterior chamber are well documented and the two major pathways to permeate these barriers are the transcorneal and transconjunctival pathways. The primary absorption pathway for small, lipophilic drugs is the transcorneal route and the primary absorption pathway for large, hydrophilic drugs is the transconjunctival (conjunctiva–sclera–ciliary body) route. In order to understand these pathways, and therefore predict the drug's biological effects on targeted anterior segment tissues, knowledge of the physicochemical properties of the drug and the pharmacokinetics of the tissues the drug must traverse is essential. Physicochemical properties describe the relationship between the chemical structure of the drug and its biological effects. Various physicochemical properties of a drug – such as its molecular size (radii, weight, and shape), lipophilicity or hydrophilicity, degree of ionization – may optimize its biological effects in the targeted tissue and/or may improve its pharmacokinetic profile. Pharmacokinetics describes the process of absorption, distribution, metabolism, and elimination of a drug in a tissue, organ, or entire body, depending on the drug delivery route and its absorption pathways. It is a function of the intrinsic physicochemical properties of the drug being applied, the applied concentration and dosing frequency of the drug, the static permeability properties of the tissue, the dynamic metabolic and elimination mechanisms of the tissues it permeates, and the bioavailability of the administered drug at its target tissue site. Bioavailability describes how much of an instilled concentration of a drug actually reaches the target tissue.

The advantages of topical drug delivery are its convenience and non-invasiveness, its avoidance of first-pass metabolism in the liver, and its ability to locally target cornea and anterior segment tissues with high drug concentrations. The main disadvantages of this route are its high dynamic drug clearance rates and its static anatomic and physiologic permeability barriers to drug absorption, both of which contribute to low bioavailability. On average, usually less than 5–10 percent of instilled topical drugs reach the aqueous humor or even the corneal stroma (Fig. 4.31B), whereas the major portion (50–99 percent) goes to the systemic circulation, primarily via absorption in the conjunctiva vasculature and lymphatics and/or via absorption in the nasal mucosal

vasculature due to drainage in the nasolacrimal duct. Moreover, on average, a drug resides in the conjunctival cul-de-sac for only about 5–6 minutes before being removed by the precorneal tear clearance mechanism (tear turnover rate of 0.5–2.2 µL/min). Even if the topical drug does get into the anterior or posterior chamber via the transcorneal or transconjunctival route, respectively, it usually only stays there briefly unless it is retained in depot form on the external surface or binds to proteins in the tissues it traverses since the aqueous humor removes it through the trabecular meshwork (aqueous humor turnover rate 2–3 µL/min) or venous blood flow removes it through the porous anterior uvea.

After topical drug instillation, the peak concentration in the aqueous humor, or even the corneal stroma, is usually reached 30 minutes to 3 hours after application, but the bioavailability or concentration of drug in the corneal stroma or aqueous humor is reduced to approximately 1/1500th for lipophilic drugs and 1/150,000th for hydrophilic drugs compared to the original concentration of the eye drop.^{352,353} From the aqueous humor, the drug does have easy access to the uvea (iris and ciliary body). Here the drug may bind to melanin, which may form a reservoir source that gradually releases the drug to the surrounding cells, thereby prolonging the drug activity (e.g. beta-blockers).^{353–355} Drug distribution to the lens is much slower than to the uvea since it is composed of tightly packed lens proteins without melanin; however, sequestration of lipophilic drugs in cell membranes of the lens may serve as another potential depot reservoir source.³⁵³ Topical drugs also reportedly can sometimes reach the vitreous cavity, most likely via the conjunctival–scleral–choroid–RPE–retina or possibly the conjunctival–orbital–optic nerve head routes, where bioavailability is approximately one-millionth of the original concentration of the eye drop (Fig. 4.31B).³⁵³ Various modifications can be made to topical drugs in order to increase their corneal absorption and bioavailability, and most fall into one of two categories: (1) drug formulations made to increase residence time in the conjunctival cul-de-sac (e.g. gels, suspensions, ointments, and inserts) or (2) compounds are added to topical drug solutions to increase corneal penetration (e.g. benzalkonium chloride [BAK], other preservatives, epithelial scraping [when treating fungal ulcers with antifungal drops]).

In addition to dynamic clearance mechanisms, topical drug delivery is also hampered by various anatomical and physiological barriers that affect the static permeability properties of the tissue.^{354,356} Topical drug delivery via the transcorneal route (Fig. 4.31A) is challenging because the drug needs to be small (< 5 kDa) and lipophilic (e.g. prednisolone acetate) to bypass the intercellular zonula occludens tight junctions of the most superficial squamous corneal epithelial cells. In fact, on average, 90 percent of the corneal barrier to hydrophilic drug penetration is due to the resistance of the paracellular (intercellular) pathway. In contrast, on average, the corneal epithelium accounts for only 10 percent of the resistance to lipophilic drug permeation since these drugs can penetrate the epithelium easily via the transcellular (intracellular) pathway. In comparison to the epithelium, the corneal stroma is highly permeable to most lipophilic and hydrophilic drugs, although the main rate-limiting criterion is having a small molecular radius (size), reflecting the 20 nm wide interfibrillar spaces used for drug diffusion.^{30,357} Although no significant changes in permeability have been

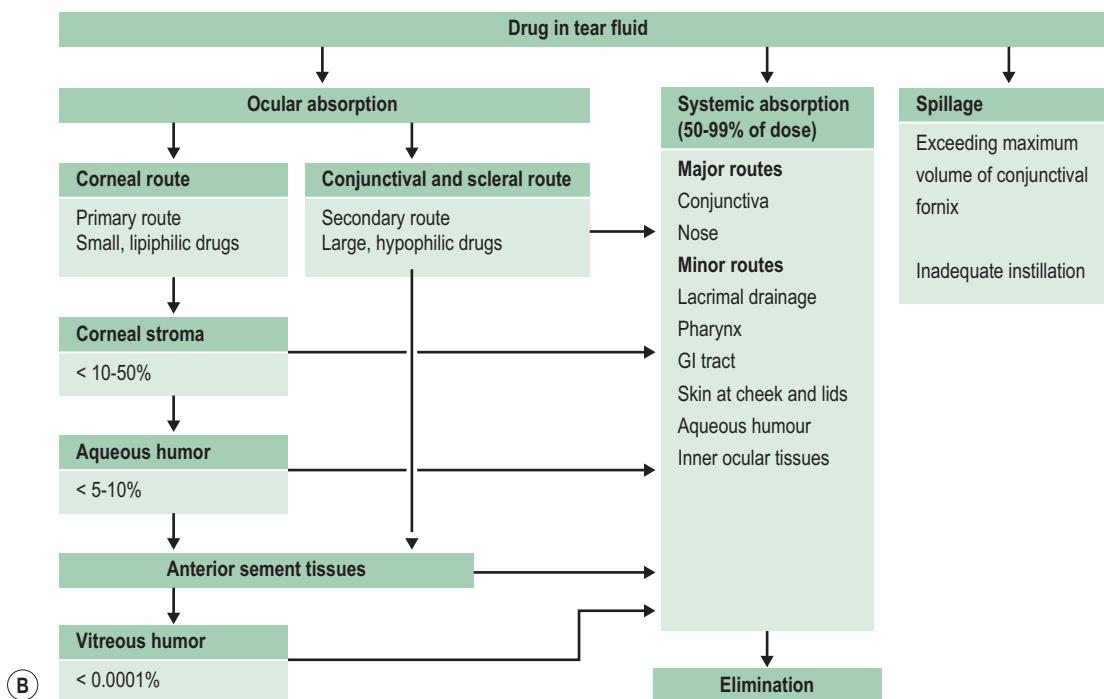

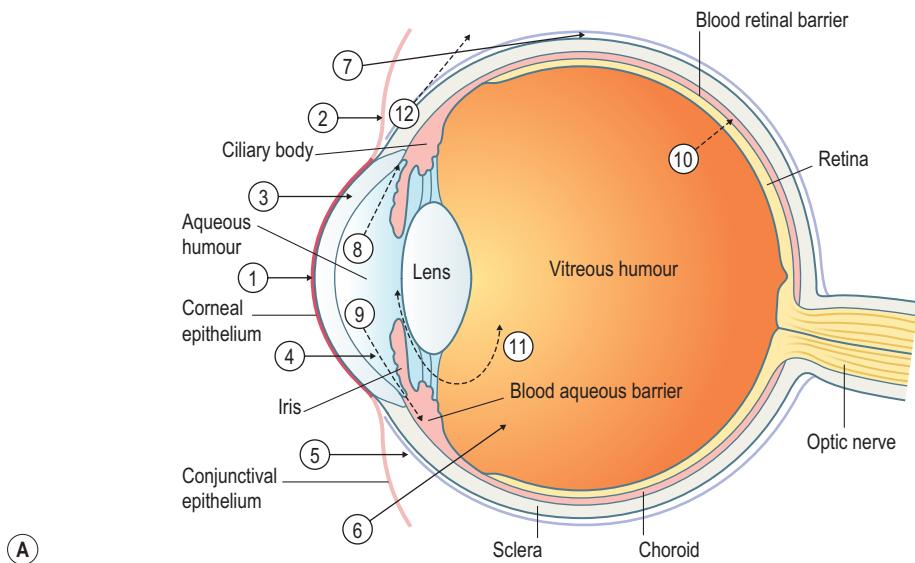

Figure 4.31 (A) Diagram of the eye with common drug delivery routes (solid arrows) and clearance pathways (dotted arrows) illustrated. The numbers refer to the following processes: (1) transcorneal route from the tear film across the cornea into the anterior chamber, (2) transconjunctival route across the conjunctiva, sclera, and anterior uvea into the posterior chamber, (3) intrastromal route directly into corneal stroma, (4) intracameral route directly into anterior chamber, (5) subconjunctival route from the anterior subconjunctival space across the sclera and anterior uvea into the posterior chamber or across the sclera, choroid, RPE, and retina into the anterior vitreous, (6) intravitreal drug injection directly into the vitreous, (7) sub-Tenon route from the posterior sub-Tenon space across the sclera, choroid, RPE, and retina into the posterior vitreous, (8) elimination of drug in the aqueous humor across the trabecular meshwork and Schlemm's canal into the systemic vascular circulation, (9) elimination of drug in the aqueous humor across the uvea into the systemic vascular circulation, (10) elimination of drug in the vitreous humor across the blood-retinal barrier to the systemic vascular circulation, (11) drug elimination from the vitreous across anterior hyaloid face to the posterior chamber or vice versa, (12) drug elimination from subconjunctival and/or episcleral space to systemic lymphatic or vascular circulation. (Modified from Urtti A, Urtti A. Advanced Drug Deliv Rev 2006; 58(11):1131–5.) **(B)** Pharmacokinetics of topical eye drop drug delivery. (Modified from Cruysberg L. Novel methods of ocular drug delivery. Ph.D thesis. University of Maastricht, 2008.)

reported with aging, the interfibrillar space of the corneal stroma does decrease 15 percent with aging.³⁰ Also, interfibrillar spacing in the corneal stroma dynamically changes depending on tissue hydration and IOP levels of the eye. Although it too shows a preference for lipophilic drugs, like the corneal epithelium, the corneal endothelium has static permeability properties for hydrophilic drugs that are only

slightly less than that of the lipophilic drugs, reflecting the 10 nm wide intercellular spaces or discontinuities in the macula occludens tight junctions. The static permeability properties of the corneal endothelium and stroma are actually quite similar. Therefore, the corneal epithelium is the main anatomic and physiologic static permeability barrier for drug absorption using the transcorneal route. However, this

can be overcome quite easily if drugs are small and lipophilic. Interestingly, ophthalmic topical drug formulations consist of drugs with low molecular radii that are relatively lipid soluble.

The transconjunctival route (Fig. 4.31A) allows passive diffusion of larger (< 20–40 kDa) or more hydrophilic molecules (e.g. beta-blockers, carbonic anhydrase inhibitors) than the transcorneal route because of its diffusely scattered goblet cell population, which contains leakier tight junctions, and a surface area is nearly 18 times greater than that of the cornea.^{357,358} Thus, the static permeability properties of the conjunctival epithelium are 50–100-times greater than the corneal epithelium.³⁵³

Other possible anterior segment drug delivery options include intrastromal, intracameral, and subconjunctival injections (Fig. 4.31A). Although all three of these routes produce the highest peak concentrations of drugs in the cornea or anterior segment, the major disadvantage is that the peak is often followed by low and persistent trough concentrations, unless given repeatedly and frequently.³⁵⁷ Thus, the overall biologic efficacy of the drug may be less than optimal using these routes compared to topical drug delivery's moderate, but sustained, drug concentrations in the targeted tissues. For example, sustained concentrations of drug are definitely needed for full biological effect against corneal or anterior segment infection. For a full review on this topic, see the following references.^{354,356,357}

Ultraviolet light filtration

The external surface of the human body is exposed to terrestrial sunlight that contains UV (~295–400 nm wavelengths), visible (400–800 nm), and infrared (IR; 800–1200 nm) light.³⁵⁹ Solar UV light undergoes significant scattering and absorption in the Earth's atmosphere such that most of the harmful, shortest wavelengths (< 290 nm), or all of the UVC rays (100–280 nm) and 70–90 percent of the UVB rays (280–315 nm) do not reach the Earth's surface. UV light contains more energy than visible or IR light and consequently has more potential to cause a photochemical injury or damage. When this radiation reaches the eye, the proportion absorbed by different structures depends on the wavelength and angle of incidence, with maximal absorption occurring when UV light rays are parallel to the pupillary axis.⁷⁵ Although the cornea is more sensitive to UV light injury than the skin since it has no melanin, individuals seldom experience acute UV sunburns unless direct high exposure occurs. Such injuries occur in "snow blindness" (this is common when skiing at mid-day without goggles as snow reflects 85 percent of incident UV light as opposed to only 1–2 percent from grass) or when welding without UV eye protection since welding arcs emit harmful UV-C and UV-B radiation.

There also is considerable variability in UV light exposure to the eye since the terrestrial UV-B exposure spectrum varies enormously with solar elevation in the sky and other exposure-related factors, such as the albedo ratio (percentage reflectance of UV light) from the ground surface, and the anatomy of the eyebrow and upper eyelid, which shields the eye from the expected terrestrial UV light dosage.³⁶⁰ Since human photoreceptors and corneal nerves cannot detect UV light, suprathreshold and, more importantly, repeated subthreshold UV light injury can take place without the

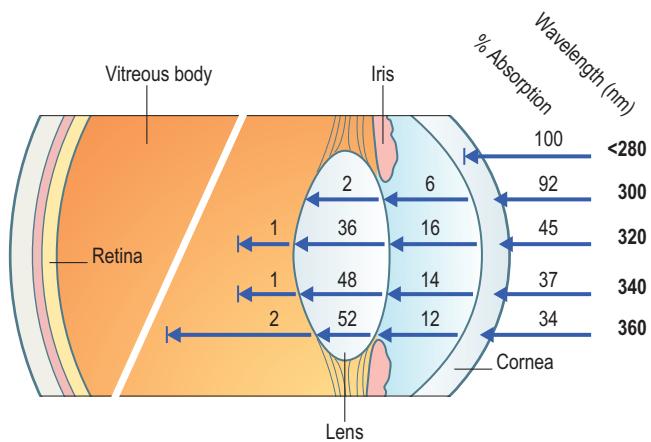

Figure 4.32 The UV light absorption spectra for different structures in the eye. (From Johnson GJ. Eye 2004; 18:1235–50.)

individual knowing it. This can cause acute photokeratitis of the epithelial surface or chronic irreversible keratopathies to the epithelium and anterior parts of the corneal stroma. The cornea absorbs 100 percent of incident UV-C, 90 percent of incident UV-B and 60 percent of incident UV-A radiation (Fig. 4.32).³⁵⁹ It, therefore, is the major filter of UV light for wavelengths of 200–300 nm, protecting the lens and retina from damage.³⁶¹ All UV-C radiation is absorbed in the corneal epithelium due to its high ascorbic acid content. UV-B is absorbed primarily in the anterior 100 µm of the human cornea, especially the epithelium and Bowman's layer, due to high amounts of tryptophan residues in the proteins of the Bowman's layer and anterior stroma and the previously mentioned high ascorbic acid content in the epithelium.^{362–366} UV-A (315–400 nm) is only partially attenuated by the cornea (Fig. 4.32), but the transmitted portion is nearly all absorbed by the lens so that only a minor percentage (<3 percent) reaches the retina. Short visible wavelengths, such as violet (~400 nm) and blue (~475 nm) light, pass through the cornea and lens predominantly unattenuated (85–90 percent transmittance) before being absorbed by the retina and RPE. These wavelengths are less harmful to biological tissues than UV light, but are still capable of photochemical injury and damage, particularly if the duration of exposure is long or cumulative. Evidence to support the detrimental health effects of UV light on the eye continues to expand.^{367,368} The acute and chronic ocular conditions for which UV light has been suggested to be a causative agent are listed in Table 4.5 and includes several conjunctival, corneal, iris, lens, and possible retinal disorders.³⁵⁹

Acute overexposure to UV-B and UV-C damages the corneal epithelium by causing apoptosis, or programmed cell death.^{369–371} UV-B and UV-C exposure directly activates signaling molecules and enzymes in corneal epithelia, including JNK, SEK, p53, caspase 9 and caspase 3, all of which lie in the pathway that leads to classic apoptotic events, such as DNA fragmentation and formation of apoptotic bodies.^{372–374} This culminates in massive shedding of corneal epithelial cells within hours of exposure. Studies of corneal epithelial cells in culture show that a very early event leading to apoptosis is activation of K⁺ channels by UV. This activation of channels occurs within minutes of exposure and apoptosis can be prevented by K⁺ channel blockers. In

Table 4.5 Ocular diseases potentially due to ultraviolet radiation exposure

	Strength of evidence
EXTERNAL:	
Photokeratitis	High
Climatic droplet keratopathy	Medium
Pterygium	Medium
Pinguecula	Low
Carcinoma in situ/conjunctival squamous cell carcinoma	Low

Photomaculopathy (more likely related to blue or visible violet light)	None
Uveal melanoma	Low
Age-related macular degeneration (ARMD)	Low

contrast, chronic overexposure to UV-B and UV-A best explains the high frequency and variable degree of acquired cytogenic DNA damage found in the keratocytes of normal adult corneas.³⁷⁵

A second injury mechanism by which UV, violet, and blue light works is through the generation of reactive oxygen species (ROS), such as hydrogen peroxide, singlet oxygen, and oxygen free radicals (superoxide anions and hydroxyl radicals), which cause cellular and extracellular damage by reacting with lipids, proteins, and DNA. Under normal physiological conditions, the cornea and anterior segment protect themselves from ROS by producing and maintaining sufficient antioxidant levels, including several low-molecular-weight (ascorbic acid, glutathione and alpha-tocopherol) and high-molecular-weight (catalase, superoxide dismutase, glutathione peroxidase, and reductase) antioxidants.³⁶¹ Ascorbic acid is thought to be the primary antioxidant in the cornea and anterior segment of the human eye since it is produced in such high concentrations in the aqueous humor.³⁷⁶ The danger to the cornea from ROS appears to stem from excessive UV-B exposure as opposed to UV-A or UV-C exposure since experiments have shown that only UV-B excess leads to profound decreases in corneal antioxidants. Thus, an imbalance in the pro-oxidant to antioxidant ratio takes place in the anterior 100 µm of the cornea, which is very likely to lead to oxidative eye injury and inflammation since the tissue components of the cornea then become the predominant absorbers and detoxifiers of UV light.^{361,366,377}

Sclera

The human sclera is a roughly spherical, relatively avascular, white, rigid, dense connective tissue that covers the globe posterior to the cornea (see Figs 4.1A,B, 4.3A, & 4.33A).^{6,32,378-380} Little interest was shown in the sclera in the past primarily because infections and tumors did not penetrate it easily and foreign material was well tolerated in it, giving it the unjustified reputation for inertness. Evidence now demonstrates that although the sclera has low baseline metabolic requirements, it constantly remodels throughout life to maintain its functions and thus is far from inert.³⁸¹ In comparison to the cornea, major differences in the sclera are that it has variably larger collagen fibril diameters and interfibrillar spaces (compare Fig. 4.34B to 4.10A,B,C); is more opaque, interwoven (Fig. 4.34D), and rigid; has a regional zone of vascularity in the episclera (Fig. 4.35D); and does not have adjacent external or internal cellular barrier layers. The color of the sclera is opaquely white because it scatters all frequencies of visible light due to spatial fluctuations in the refractive index of the tissue, which have dimensions that are greater than a half-wavelength of visible light (Fig. 4.34B,C).^{382,383} The opaqueness reduces internal light scattering, but some light actually does transmit through the sclera, evidenced when transilluminating the globe for locating intraocular tumors. The interwoven rigidity helps maintain a stable shape since deformation of the sclera could lead to poor vision or internal injury (Fig. 4.34D). It also is notable for containing a moderately rich nerve supply (Fig. 4.16A), predominantly around episcleral blood vessels, and for having no lymphatic channels, albeit the overlying conjunctiva has two well-formed lymphatic layers (Fig. 4.35C,D). The principal functions of the sclera are to provide a strong, tough external framework to protect the delicate intraocular structures and to maintain the shape of the globe so that the retinal image is undisturbed. Secondarily, it serves as a stable expansive-resistant semi-spherical structure to the forces generated by IOP, facilitates appropriate aqueous outflow, provides stable attachment sites for the extraocular muscles to rotate the globe and for the ciliary muscle to accommodate the lens, provides a conduit for vascular and neural pathways to go from inside-to-outside the eye and vice versa, and plays a critical role in determining the absolute size of the eye and thus the refractive error of the eye. For this latter function, the scleral wall must have a mechanism in place for controlling its growth.

Embryology, growth, development, and aging

The sclera is predominantly neural-crest-derived, except for a small temporal portion that comes from the mesoderm.⁶ The development of the sclera begins by 6.5 weeks of gestation and proceeds in an anterior-to-posterior and inside-to-outside fashion as the anterior periocular mesenchyme, derived from the 2nd wave of neural crest cell invasion, condenses anteriorly on the optic cup. This anterior mesenchyme subsequently differentiates into an inner vascular layer that develops into the uvea (iris, ciliary body, and choroid) and an outer fibrous layer that develops into the sclera. The retinal pigment epithelium (RPE) and/or the

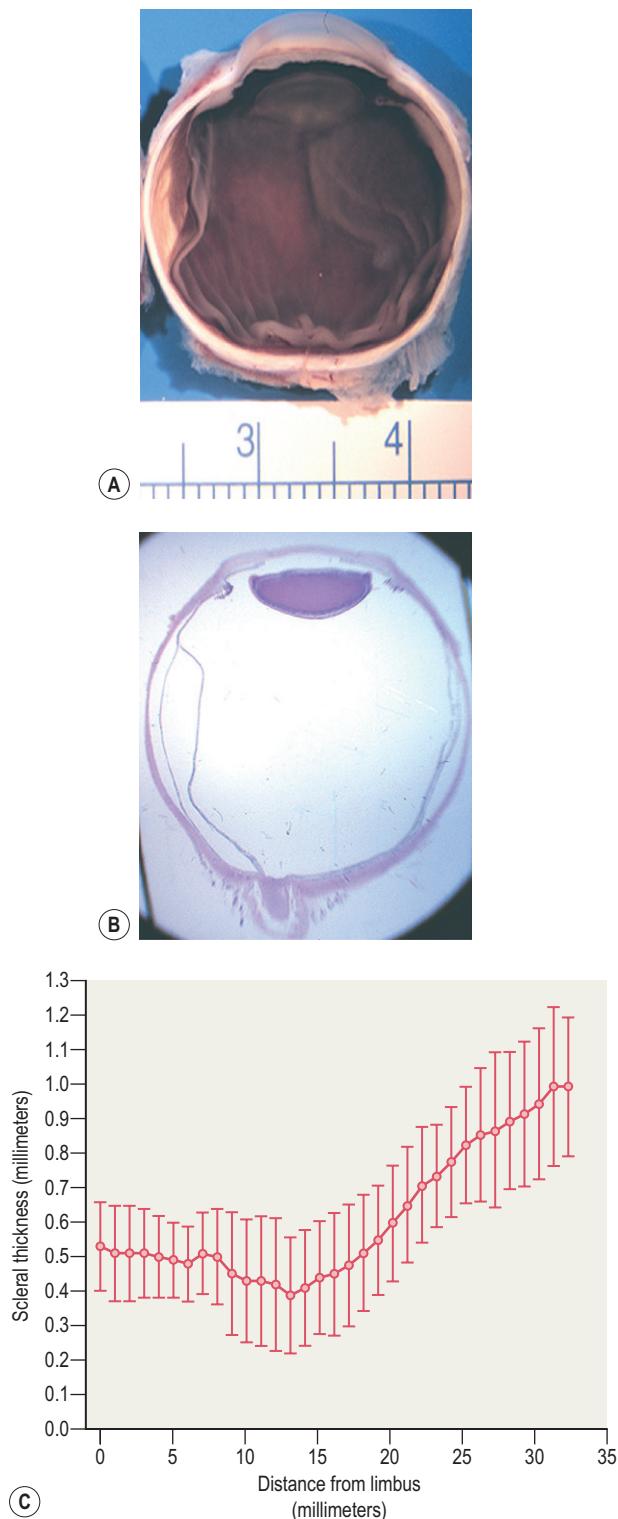

Figure 4.33 (A) Gross photo of the superior section of a horizontally bisected normal globe demonstrating the cross-sectional appearance of the sclera, limbus, and cornea. (B) Photomicrograph of a normal globe showing the cross-sectional appearance of the sclera, limbus, and cornea (PAS, $\times 2$). (C) Line graph summarizing the average scleral thickness (\pm SD) vs. distance from the limbus in normal eyes ($n = 55$). (From Olsen TW et al. Am J Ophthalmol 1998; 125:237–41.)

choroid, is directly responsible for embryonic scleral development since if the RPE or choroid is absent or not in contact with the sclera, the sclera does not develop (e.g. chorioretinal colobomas) or will not grow, respectively.³² The anterior sclera fully differentiates by 7 weeks' gestation followed by the equatorial sclera at 8 weeks' gestation and the posterior sclera by 11 weeks' gestation. It gradually increases in thickness and extracellular matrix denseness during the remaining months of gestation. It initially is primarily composed of scleral fibroblasts, collagen fibrils, and proteoglycans; elastin fibers are acquired mainly after birth, perhaps in response to IOP.³² At birth, the sclera is relatively thin, highly distensible (in infancy, the sclera is on average one-quarter as stiff as it is in adulthood), and translucent (explaining why the blue color from the underlying uvea often times shows through the infant sclera).³⁸⁴

Post-natal growth and maturation continue in a similar anterior-to-posterior fashion. During the first 3 years of life, the sclera grows rapidly in diameter and thickness, gradually losing some of its high distensibility (perhaps due to increased thickness, decreased cellularity, increased extracellular matrix denseness, or proportionally increased type I collagen fibril deposition), but it still remains relatively translucent. This early loss of distensibility explains why the sclera can expand from increased IOP (e.g. infantile glaucoma) only from birth to around an age of 3 years old, resulting in a buphthalmic "ox" eye. Thereafter, the sclera distends only slightly from increased IOP, mainly in the lamina cribrosa. After age 3, the sclera thickens further, becomes more opaque, and grows in diameter at an exponentially slower rate than the first 3 years of life, reaching adult size by 13–16 years of age.^{15,385} During this growth period, the anterior sclera develops and matures much more quickly (adult size by 2 years of age) than the equatorial (adult size by 13 years of age) and the posterior sclera (adult size by 13–16 years of age). The sclera continues to become less distensible and more rigid with advancing age, primarily due to maturation and age-related glycation-induced cross-linking of collagen fibrils (scleral stiffness reportedly increases 2–3-fold from age 3 to 20, and then another 2-fold from age 20 to 78), typically resulting in no further eye or scleral growth after age 16.^{32,386–388}

Normal eye growth is thought to be controlled in part by a visual feedback mechanism that depends on the quality of the retinal image. This feedback influences the scleral fibrocytes and thus the extracellular matrix of the sclera to undergo constant remodeling during childhood eye growth, continuing to some extent into adult life – albeit to a lesser degree.³⁸¹ This visual feedback mechanism serves to guide childhood eye growth toward emmetropia and the attainment of adult eye size, resulting in the majority of the human adult population being free of significant refractive errors. Interestingly, this visual feedback mechanism is not dependent on the CNS. In animal studies, transection of the optic nerve or blocking ganglion cell action potentials does not prevent the development or the recovery of experimentally induced myopia.³⁸¹ Rather, it is directly dependent on paracrine cytokine or growth factor pathways (e.g. dopamine, acetylcholine) originating from the retina and/or RPE.³⁸¹ Animal experiments that pharmacologically damage the retinal photoreceptors or RPE prevent visual deprivation myopia.³² Epidemiological studies suggest that environmental visual

Compare these to Figs 4.9 and 4.10A,B&C to see how much more variably larger or irregular the collagen fibril diameters, interfibrillar spaces, and collagen bundles of the scleral stroma proper are to the corneal stroma. CB = collagen bundle. E = elastin fibers. CF = collagen fibril. (C) Diagram comparing the collagen fibril diameters (O) and densities (Δ) in the cornea, limbus, and sclera. (Modified from Borcherding MS et al. Exp Eye Res 1975; 21:59–70). (D) Diagram illustrating the greater degree of interweave of collagen bundles in the sclera than collagen lamellae in the corneal stroma. Additionally, the sclera has larger and more varied in collagen fibril diameters and interfibrillar spacing. (Modified from Bron AJ, Tripathi R, Tripathi B. In: Wolff's anatomy of the eye and orbit, 8th edn. London, UK: Chapman & Hall, 1997.)

stimuli (e.g. lengthy periods of near work or accommodation; visual deprivation – particularly early in life), developmental delay in the maturation of the posterior sclera, or genetic factors may alter this visual feedback mechanism resulting in physiologic or pathologic myopia. In contrast, genetic or developmental delay in overall globe growth may result in hyperopia.³²

A minority of the population may actually have significant breakdown of this normal visually guided emmetropization process resulting in severe refractive errors or even refractive error progression outside the normal period of eye growth, such as adolescent-onset (16–20 years of age) or adult-onset (2nd to 4th decades of life) myopia, due to further axial length and posterior scleral elongation.^{389,390} The exact pathogenesis

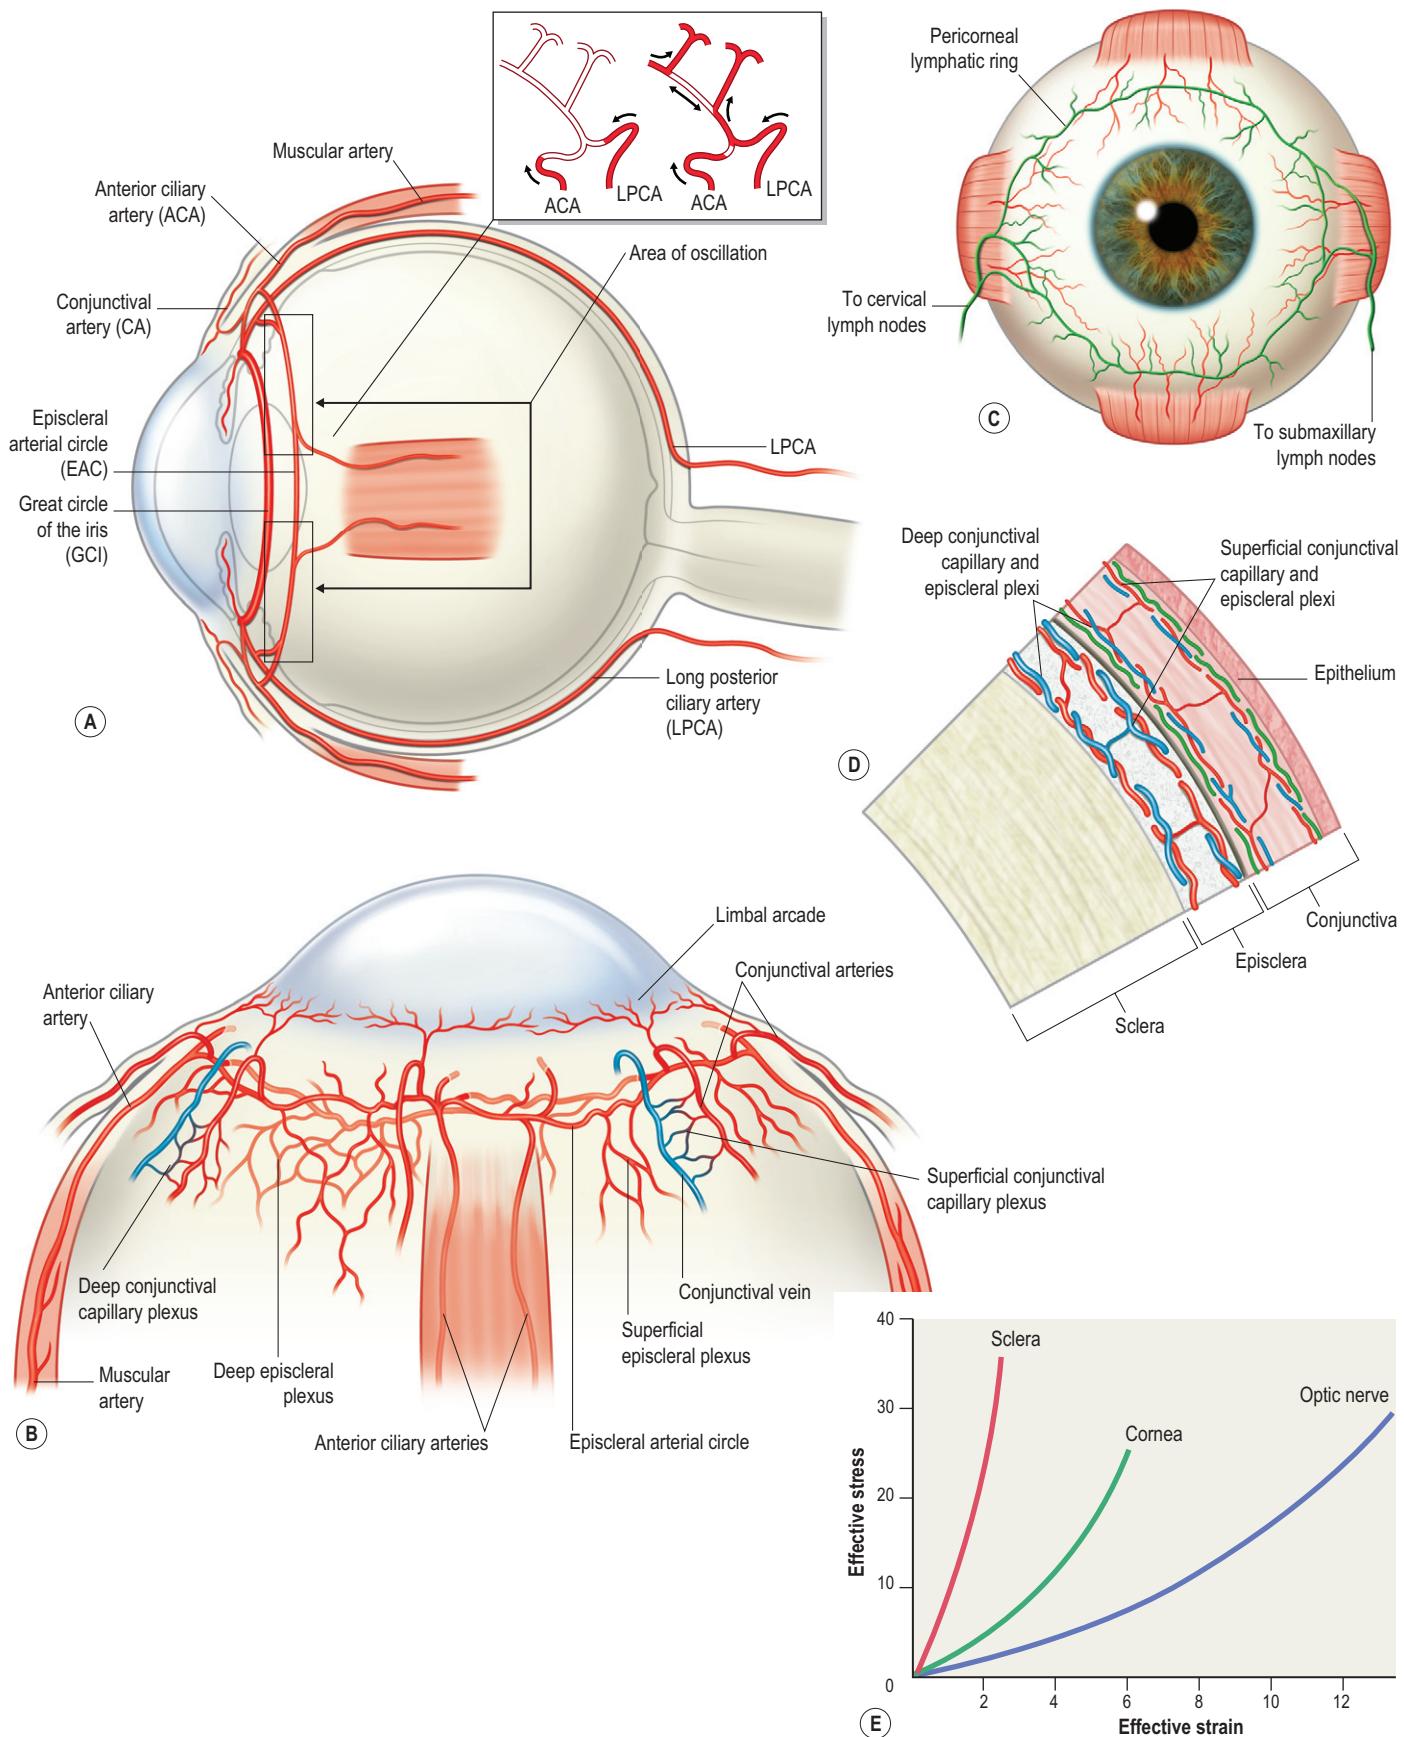

Figure 4.35 (A) The arterial supply of the anterior segment comes from the anterior ciliary arteries (ACA) and from the terminal branches of the long posterior ciliary arteries (LPCA). These vessels form two sagittal arterial circles (between superior or inferior ACA and LPCA arteries) and also anastomose together superficially and deeply to form two coronal arterial circles, called the episclera arterial circle (EAC) superficially and the greater circle of the iris (GCI) deeply. In the anterior episclera (inset), the deep perforating branches of the LPCA anastomose with the ACA, together forming the EAC. The blood flow in the EAC typically comes from LPCA (inside outwards) rather than from ACA. The EAC supplies both a superficial and a deep episcleral plexus (deep plexus not shown). The conjunctival artery derives from the EAC, passing posteriorly, while also giving off an anteriorly directed branch called the limbal artery, which subsequently forms the limbal arcade. Blood flow in the EAC (inset) is continuous near the rectus muscle insertion sites, but oscillates rather than flows between the rectus muscle insertion sites. (Modified from Watson PG, Hazelman B, Pavesio C, Green WR. The sclera and systemic disorders, 2nd edn. Edinburgh, UK: Butterworth Heinemann, 2004.). **(B)** Diagram shows a schematic of the arterial circulation of the episclera and conjunctival, which both have superficial and deep components that supply capillary plexi. (Modified from Meyer PAR et al. 1987; 71: 2–10.) **(C)** Schematic diagram showing the distribution of lymphatics (green) in relation to the blood vessels in the conjunctiva. Centripetal branches collect into a larger circular lymphatic ring, called the pericorneal lymphatic ring, which then drains medially or laterally into regional lymph nodes. **(D)** A cross-sectional representation of the conjunctiva, episclera, and sclera shows that episclera and sclera are devoid of lymphatic networks, while the conjunctiva has two lymphatic plexi – a superficial plexus (below the epithelium) and a deep plexus (within Tenon's fascia, but just above the episclera). Blood vessel plexi are found in the superficial and deep conjunctiva and episclera. (Modified from Robinson M, Lee S, Kim H, et al. Exp Eye Res 2006; 82:479–87.) **(E)** Exponential approximations of trilinear stress–strain curves for sclera, cornea (stroma), and lamina cribrosa (optic nerve). (From Woo SL, Kobayashi AS, Schlegel WA, Lawrence C. Exp Eye Res 1972;14(1):29–39.)

of myopia is still not completely understood, but myopia induction in mammalian animal models using various visual deprivation stimuli suggests that the earliest biochemical and structural remodeling changes begin with reduced scleral fibrocyte proliferation and altered metabolism resulting in reduced type I collagen fibril synthesis, increased collagen degradation (increased matrix metalloproteinase-2 expression), reduced proteoglycan synthesis, scleral tissue volume loss (loss of both scleral wet and dry weight), and posterior scleral thinning.^{381,391} Late or more chronic biochemical and structural remodeling changes include reduction of mean type I collagen fibril diameters, particularly in the outer layers of the sclera, and, in advanced end stages, localized areas of ectasia or staphyloma formation of the posterior sclera, especially at the optic nerve or the macula.^{381,391}

All of these biochemical and structural changes appear to be guided by a retino–RPE–scleral visual signaling pathway, which dynamically controls scleral extensibility under the stress of normal IOP and thus controls the innate biomechanical properties of the sclera. Biomechanical testing of myopic human eyes by Avetisov and associates supports this theory since the thinned posterior sclera was 30–40 percent biomechanically weaker in tensile strength than normal eyes.³⁸⁶ Animal studies by McBrien and associates have also shown that posterior scleral creep rates during acute periods of myopia induction are significantly higher in myopic eyes compared to normal control eyes.³⁸¹ Interestingly, using animal models, after removal of the myopia-inducing visual deprivation stimulus, recovery to normal eye size is quite rapid and is thought to be due to scleral keratocyte differentiation into contractile myofibroblasts and possibly due to resumption of normal proteoglycan synthesis.³⁸¹ In contrast to animals allowed to recover naturally, some myopic animals had their myopia corrected with optical devices (analogous to spectacles in humans). The myopic biomechanical scleral phenotype persisted and thus recovery from the induced myopic state was aborted – although the eyes did return to a more normal stable growth rate.³⁸¹ Such a finding may have important implications for the correction of myopia in humans since prevention or recovery from the aberrant remodeling process seems to be the key to any potentially successful medical or optical therapy for myopia. Another alternative promising medical treatment option is

that of cross-linking the sclera in a manner that might serve to stabilize or halt myopic progression.³⁹²

In elderly individuals, the sclera often becomes somewhat yellowish due to a fine deposition of lipid. Another common finding is a small rectangular area of grayish-blue translucency just anterior to the insertion of the medial and lateral rectus muscles. These changes are known as senile scleral plaques and are associated with deposition of calcium in scleral regions that are under strain and exposed to the environment.^{6,378–380} They never are found adjacent to unexposed superior or inferior rectus muscles.

Major scleral reference points and measurements

The sclera is an incomplete sphere (Fig. 4.33A,B) resulting in an average outer surface area of 16.3 cm², an average outer diameter of 24 mm, and an average inner diameter of 23 mm (mean radius of curvature = 11.5 mm).⁶ Knowing the topographic curvature of the sclera is important for fitting scleral contact lenses, which have certain advantages over corneal contact lenses including the ability to optically neutralize almost any corneal topographical shape since the lens is borne solely by the sclera and not the cornea; being more comfortable than some corneal contact lenses since the edge of the lens does not touch the eyelids; and being better for some forms of aqueous dry eye deficiency states since a large precorneal tear film reservoir is trapped between the lens and the entire corneal surface. On average, the sclera is thickest posteriorly near the optic nerve (1.0–1.35 mm), decreasing gradually as it approaches the equator of the globe (0.4–0.6 mm), before typically becoming thinnest under the rectus muscles just before it reaches its insertion sites (0.3 mm) (Fig. 4.33C).^{378,393} It then gradually increases in thickness at the actual muscle insertion sites (0.6 mm) and continues getting thicker up to the limbus (0.8 mm), where it blends with the cornea (Fig. 4.33C).^{378,393} These average scleral thickness measurements are subject to great variation. For example, the equatorial sclera is sometimes found to be < 0.1 mm thick.

There are two major openings in the sclera: the anterior scleral foramen (13.7 mm diameter; circumscribes the area of the cornea and limbus) and the postero-nasally located

fenestrated posterior scleral foramen or scleral canal (1.5–2.0 mm internal diameter and 3.5 mm external diameter). The inner third of the sclera forms a fenestrated scaffold in the scleral canal called the lamina cribrosa that supports the optic nerve axons, whereas the outer posterior two-thirds of the sclera merge with the dura mater of the optic nerve leaving the outer posterior two-thirds of the scleral canal essentially free of any scleral support. Since the lamina cribrosa is the least stiff and strong point of the adult human globe to expansive forces, diseases that cause chronically high IOP, like glaucoma, preferentially cause lamina cribrosa ectasia and subsequent glaucomatous optic nerve cupping and optic neuropathy. There are also other numerous minor openings in the sclera, including 30–40 emissary channels for ciliary arteries, veins, and nerves, and 4–7 vortex vein channels. The outer surface of the sclera is smooth, except for where the tendons of the extraocular muscles insert (spiral of Tillaux and oblique muscle insertion sites) and where Tenon's capsule adheres (within 1 mm of limbus, over rectus muscle insertion sites, and around the optic nerve). The superficial layer of the sclera, called the episclera, is a thin, highly vascularized, dense connective tissue. It is around 15–20 μm thick near the limbus, progressively thinning as it extends into the posterior aspect of the eye. The scleral stroma proper is a white, avascular, dense connective tissue accounting for more than 95 percent of the total scleral thickness. Finally, the inner surface of the sclera is a brown, avascular, 5 μm thick layer called the lamina fusca, which contains a large number of elastin fibers and melanocytes. In fact, these melanocytes sometimes pass through an emissary channel with nerve loops producing dark spots on the surface of the sclera. This can be mistakenly confused with a melanoma.

Mechanical properties

The mechanical behavior of the sclera is most dependent on its thickness and innate biomechanical properties (hierarchical structure of collagen and its associated cross-links). Because of its toughness, cohesiveness, and tightly interwoven architecture, the sclera is not easily dissected in a blunt fashion. The sclera is predominantly composed of water (68 percent) that is stabilized in a disorganized structural network of insoluble and soluble extracellular proteins with fewer fibrocytes than the cornea (see Table 4.1).³⁷⁸ The posterior sclera is more hydrated than the equatorial and anterior sclera (71 percent vs. 62 percent).³⁹⁴ The dry weight of the adult human sclera (see Table 4.1) is comprised of collagen, proteoglycans, fibrocyte constituents, elastin, blood vessel constituents, and other substances (lipids, salts, glycoproteins, etc.).³⁷⁹ The biomechanical properties of the sclera are dominated by the scleral stroma proper, which has a similar composite-like structure to that of the anterior third of the corneal stroma, albeit it is even more disorganized and highly irregular (Fig. 4.34D).⁶

Collagen is the major water-insoluble extracellular protein of the scleral stroma proper (80 percent type I, 5 percent type III, and minor amounts of types V, VI collagen); elastin is a minor component.³⁷⁸ In contrast to the cornea, the sclera's heterotypic type I collagen fibrils are composed of types I, III, and V collagen molecules, and are larger and more variable in diameter (mean diameter: $100 \pm 30 \text{ nm}$; range: 25–

300 nm), more irregularly spaced (mean center-to-center interfibrillar distances: $150 \pm 40 \text{ nm}$; range: 30–375), and arranged in variably sized (0.5–6 μm thick; 1–50 μm wide), highly interwoven, irregularly directed lamellar collagen bundles.^{6,87,379} The arrangement of collagen fibrils in the individual bundles is more random and they intermingle in a more wavy fashion than that of the cornea. Also, the bundles do not form a plywood-like stacking sequence, like that seen in the posterior two-thirds of the corneal stroma. Topographically, the sclera varies not only in thickness, but also in size, compactness, and angle of weave of its collagen bundles.³⁹⁵ The anterior sclera consists of medium- to small-sized, moderately compact collagen bundles with wide-angle weave, while the equatorial sclera consists of small-sized, very compact collagen bundles with narrow-angle weave.³⁹⁵ Finally, the posterior sclera consists of medium- to large-sized, loose collagen bundles with a wide-angle weave.³⁹⁵

No significant differences in the number of collagen bundles or elastin fibers have been reported when comparing these three topographic regions. There also are depth-related changes in the scleral stroma proper as the more superficial collagen fibrils are on average further apart from one another and are larger in diameter than the deeper layers where they are more compact and smaller in diameter. Additionally, the collagen bundles are thinner, narrower, and form whorl-like patterns superficially, whereas they are thicker, wider, and form a net- or rhomboid-like pattern in the deeper layers.³² The scleral proteoglycans and their covalently linked GAG side chains differ markedly from the corneal stroma as they are about one-fourth the concentration and consist of the following: core proteins – decorin, biglycan, and aggrecan; GAGs – dermatan sulfate (36 percent), chondroitin sulfate (35 percent), hyaluronic acid (23 percent), and heparin sulfate (6 percent).^{378,379} The scleral stroma proper also contains a syncytium of fibrocytes, like the corneal stroma; albeit at a much lower level of cellularity. Although the scleral stroma proper is traversed by ciliary blood vessels and nerves, it has no direct blood, lymph, or nerve supply.³⁷⁸ It derives its nutrition solely by diffusion from the overlying episcleral and underlying choroidal vascular networks.

The most superficial layer of the sclera, called the episclera, differs from the scleral stroma proper in that its collagen bundles are more loosely arranged; it contains melanocytes and a few residential histiocytes. It also has a rich nerve supply with many unmyelinated and myelinated free nerve terminals (see Fig. 4.16A), which are most densely populated near the rich direct blood supply in the episclera (Fig. 4.35A) and lymph vasculature in the overlying conjunctiva (Fig. 4.35D), presumably to help regulate blood supply and to influence aqueous outflow.⁶ The episcleral vasculature drains aqueous humor from the conventional outflow route via anastomosis with the aqueous collector channels to the episcleral venous system. Thus, outflow and IOP are dependent on the pressure gradient between IOP and episcleral venous pressure (EVP). Finally, the lamina fusca appears to merely serve as a transition zone from the sclera to the choroid.⁶

Although the sclera is constantly under stress from the IOP, which dynamically varies considerably as noted previously in this chapter, it acts in a similar manner to systemic muscular arteries in the body. It also typically displays a

limited ability to distend in adulthood (range: 0.58–6.68 percent strain), termed scleral distensibility. Considering the different possible topographical thicknesses and internal curvatures of the sclera, marked regional differences in wall stress can occur depending on each individual globe (see Law of LaPlace, previously described in this chapter). Thus, accurately calculating regional wall stress of the sclera is very complex and perhaps even more difficult to do than for the cornea. In general, the anterior sclera under the rectus muscle insertion sites and the equatorial sclera should have the highest internal wall radial stress since they are the thinnest areas with comparable internal curvatures to the rest of the sclera, whereas the limbus should have the highest circumferential wall stress since a two-fold higher amount of stress is required to sustain the curvature change from the cornea to the sclera (see Fig. 4.29A).⁸⁶ Thus, when under acute extreme stress, such as direct blunt impact to the globe, there is a tendency for the globe to rupture in these areas. However, these regions also have the highest innate biomechanical properties, which were measured using ex vivo strip extensiometry or inflation tests, perhaps explaining the chronic lengthening of the posterior sclera in myopia or the chronic ectasia of the lamina cribrosa seen in glaucoma that have no effect on these regions. In fact, structural alterations in the sclera caused by myopia or glaucoma may considerably change the expected normal stress distribution in the scleral eye wall (e.g. posterior scleral stress may increase up to four-fold with severe myopic globe elongation).

Using inflation testing and finite element modeling, the longitudinal Young's modulus of the adult human sclera averages 1.7×10^7 dyne/cm² (Fig. 4.35E).³⁹⁶ This is approximately 3.7-fold stiffer than the cornea and 5.3-fold stiffer than the lamina cribrosa (Fig. 4.35E).³⁹⁶ Using uniaxial strip extensiometry, cohesive strength measurements of the anterior sclera averaged 55 g/mm, which was approximately two-fold stronger than the cornea.⁹³ Human uniaxial strip extensiometry testing has also shown topographical differences in the sclera's longitudinal Young's modulus as the equatorial sclera was the stiffest at 23 ± 8 g/mm², the posterior sclera was the least stiff at 3 ± 1 g/mm²; the anterior sclera was between these at 4 ± 1 g/mm².³⁹⁵ The greater extensibility of the posterior sclera had previously led to a "dual function" theory of the sclera where the anterior and equatorial sclera were thought to be essential for the rigid support and stability of the globe, whereas that of the posterior sclera served to act as a mechanical buffer or cushion against acute increases in IOP, which could be injurious to the delicate globe.³⁹⁵

Like most biological systems, the sclera's elastic stress-strain curve exponentially or non-linearly increases with higher elevations in IOP or stress and then, because of viscosity, shows a time-dependent decrease with time. The J-shaped stress-strain curve of the sclera involves an immediate elastic response dominated initially by elastin, non-collagenous matrix, and collagen fibrils at the lower part of the J and then later by collagen fibrils in the upper part of the J. Overall, the non-linearity arises from the gradual loading of highly extensible elastin fibers and the wavy collagen fibrils that take up slack initially, followed by gradually increasing in resistance to stress as maximal recruitment is attained. Finally, a slower, time-dependent viscous response results over time, where the resistance to stress gradually

decreases with time due to creep. The viscoelastic properties of the sclera also mean the loading or unloading stress-strain curves do not overlap, with the unloading curve being less than the loading curve – depending on the loading rate. This allows energy dissipation via viscous friction during the mechanical cycle and, ultimately, the return of the original shape of the material in a slow, time-dependent fashion. Therefore, the amount of distension of the sclera is not fixed, but determined by the level of the pressure changes and how long they have acted on the sclera and on the innate biomechanical properties and thickness of the sclera.³⁹⁷

A good example of this is when measuring IOP by indentation methods. The pressure measurement recorded by indentation initially increases the IOP of the eye by indenting the cornea inward (immediate elastic response), but by the time the measurement is made several seconds later it is typically back to normal levels (slow viscous response). However, in some individuals (e.g. high myopes or severely thinned sclera from scleral malacia perforans), the sclera will distend much more than normal because of the lower innate biomechanical properties or thinner sclera – resulting in false low readings. In contrast, false high readings may occur in the cases of more rigid scleras (e.g. scleral buckles). Therefore, most people choose to use applanation (e.g. Goldman applanation tonometry) over indentation (e.g. Schiotz tonometry) to measure IOP since it is more accurate as it eliminates artifacts caused by the sclera.

Scleral dehydration and edema

Hydration of the sclera is most closely associated with the extracellular proteoglycan concentrations in the sclera. Since the normal, healthy sclera has one-fourth the concentration of proteoglycans (scleral swelling pressure of 20–30 g/cm) between collagen fibrils than the cornea, it is not surprising that it contains less water (68 percent) than the cornea (78 percent).³⁷⁹ However, if the normal water content of sclera is reduced to < 40 percent, it becomes somewhat translucent. This is a common observation made during long surgical procedures on the sclera when scleral flaps are dissected and sometimes inadvertently exposed to air for prolonged time periods, which reduces the hydration level through evaporation. Similarly, if the water content is increased to > 80 percent, the sclera again becomes somewhat translucent due to the hydration of scleral proteoglycans.

Episcleral vasculature

The blood supply of the episclera is particularly prominent along a 4 mm zone anterior to the rectus muscle insertion sites, while being markedly less vascular in more posterior aspects. The former area is called the episcleral arterial circle (EAC) (see Fig. 4.35A), which is fed by seven anterior ciliary arteries (ACA) and several (≤ 12 per principal meridian) anastomotic terminal branches from the long posterior ciliary arteries (LPCA), which are more commonly found superiorly and inferiorly than medially or laterally.³⁷⁸ This unusual dual artery-to-artery anastomosis typically flows inward to outward, but it can change direction if needed and thus ensures that the anterior segment of the eye is always supplied with adequate blood flow. The EAC has both superficial and deep branches (Fig. 4.35B,D) that directly nourish the episclera through corresponding superficial or deep episcleral capillary plexi. The EAC also has separate

Box 4.7 Immune disease and the sclera

The pre-capillary arterioles and post-capillary venuoles of the superficial and deep episcleral, limbus, and conjunctiva capillary plexi are notable for having continuous non-fenestrated endothelium without intercellular tight junctions (20 nm intercellular spaces).³⁹⁸ Therefore, these vessels are leaky and are highly permeable to small molecules, but do at least resist bulk fluid flow. Since the pre-capillary arterioles of the anterior segment do not have a smooth muscle wall, they tend to be thrown into tortuous folds resulting in areas of turbulent blood flow. When you combine this with the fact that a notable disadvantage to having artery-to-artery anastomosis is that regions between the rectus muscles may not have continuous high arterial perfusion pressures, but rather oscillatory blood flow due to being further away from the feeding ACA and LPCA vessels, then it should not be surprising that extravasation of fluid or stagnation of cells commonly occurs in these regions. If the individuals have systemic infections or autoimmune diseases (such as hepatitis viral infections, systemic lupus erythematosus, rheumatoid arthritis, or Wegener's granulomatosis), deposition of antigens or immune complexes occurs in this region of stagnation, resulting in inflammatory microangiopathy (e.g. peripheral ulcerative keratitis, episcleritis, scleritis, Mooren's ulcers).³⁷⁸ Moreover, since some of these regions (sclera and peripheral cornea) are far from lymphatic drainage sites, which are efficient mechanisms for removal of unwanted antigens or immune complexes, chronic problems often follow.³⁷⁸

conjunctival or limbal artery branches that have their own capillary plexi (Fig. 4.35B,D). For example, during internal eye infection or inflammation or with severe corneal infection or inflammation, the limbal plexus is notable for dilating and causing a limbal ciliary flush pattern to appear around the periphery of the cornea on slit lamp examination, usually indicating more serious disease is present than just a simple conjunctivitis.

Wound healing

Although injury converts scleral fibrocytes to metabolically active fibroblasts, similar to the cornea, superficial lacerations of the sclera heal more aggressively and completely than the cornea because episcleral fibrovascular granulation tissue migrates into and fills the wound.⁶ Similarly, lacerations involving the inner portion of the sclera also heal predominantly through fibrovascular granulation tissue, which grows outward from the choroid.⁶ Penetrating scleral lacerations typically heal because fibrovascular granulation tissue grows from both of these sites. Such healing is usually very strong since it causes fibrovascular scarring. As time passes, a gradual remodeling or reorganization occurs to this scar; however, it can always be identified histologically by the abrupt change in scleral collagen fibril orientation, the persistent vascularity, or the disorganization of the surrounding tissue architecture.

Drug delivery

Although most of the bulk transport of fluid out of the eye takes place through the anterior segment's trabecular meshwork/Schlemm's canal system or via uveoscleral outflow, an appreciable amount is also drained transretinally to the choroid where it can get into the systemic circulation by

diffusion into the choroidal vasculature or can travel extraocularly via the trans-scleral pathway (see Fig. 4.31A). The trans-scleral pathway is very intriguing to researchers and clinicians since it may serve as a potential route for non-invasive delivery of medications into the eye.³⁹⁹ Currently, the medical treatment for posterior segment disease is to a large extent limited by the difficulty in delivering therapeutically effective doses of drugs to the posterior segment tissues (vitreous and retina). Unfortunately, the topical drug delivery route does not consistently or even efficiently yield therapeutic drug levels in posterior segment tissues. Although systemic administration (oral or intravenous routes) can deliver drugs to the choroidal vasculature at therapeutic levels, the duration of choroidal drug delivery is too brief (usually less than 30 minutes) to result in meaningful intraocular drug levels and the large systemic doses necessary are often associated with significant systemic side effects or toxicities.

Intravitreal injection delivers agents directly into the vitreous and next to the retina (Fig. 4.31A). Thus, it has the advantages of achieving the highest intraocular peak drug levels, while minimizing systemic exposure. However, it also has the disadvantages of being the most invasive or traumatic technique available and can lead to persistent trough levels unless given repeatedly and frequently since drugs usually are rapidly eliminated via anterior segment and/or posterior segment bulk flow. In fact, the intravitreal route is often poorly tolerated and places patients at risk for high IOP, floaters, transient blurry vision, retinal hemorrhage, retinal tears, retinal detachment, endophthalmitis, and cataract. The acceptability of such an invasive direct approach is likely more a function of the poor visual state of the eye due to the disease and the change in prognosis due to intervention (e.g. endophthalmitis and intravitreal antibiotic injections, wet age-related macular degeneration [AMD] and intravitreal anti-angiogenic drugs).

Periocular drug delivery is an alternative, minimally invasive approach to drug delivery to the posterior segment as it commonly delivers moderately sustained concentrations of drugs.³⁵⁷ The various periocular techniques include subconjunctival, retrobulbar, peribulbar, and sub-Tenon's injections (see Fig. 4.31A). They are far less invasive than the direct intravitreal route, but they do have notable shortcomings, mainly from having to permeate more static anatomical barriers and from encountering enhanced dynamic clearance mechanisms. In general, periocular drug delivery involves placing the drug, usually by needle injection, into the tissue surrounding or adjacent to the posterior segment of the eye. Corticosteroids are the most common drugs given by these techniques (e.g. sub-Tenon's triamcinolone injection). The feasibility of using these techniques depends, to a large extent, on the permeability of the sclera to the drugs and the accuracy of the clinician in injecting the drug to the desired location. In fact, although three possible absorption pathways exist (trans-scleral, systemic hematogenous circulation, and anterior routes) for the various periocular drug delivery techniques, the trans-scleral pathway has been proven to be the main route for delivering sufficient drug concentrations into the choroid, RPE, retina, and vitreous.⁴⁰⁰ A recent in vivo dynamic periocular drug delivery study by Ghate and associates (clearance mechanisms were all fully functional and active as well as the static permeability properties of the

tissue) using rabbits found that sub-Tenon's injection resulted in the highest and most persistent vitreous concentrations with the least systemic exposure of the various periocular techniques. Subconjunctival injection resulted in the highest and most persistent anterior segment concentrations with slightly less vitreous concentrations than that of sub-Tenon's injection – with the caveat of some higher risk for systemic exposure.⁴⁰⁰

Although preliminary studies several decades ago suggested that it might be possible to exploit the trans-scleral route for drug delivery to intraocular tissues in the posterior segment, it has only recently seen renewed interest and focused detailed attention – probably based more on the success of anti-vascular endothelial growth factor (VEGF) drug therapy for wet AMD and the risk involved with frequent repeated intravitreal injections required to keep the disease in check.⁴⁰¹ Of these initial studies, Barza was the first to clearly establish that drugs could permeate through various ocular tissues including the sclera when they were

administered by either subconjunctival or retrobulbar injection.^{402,403} Anders Bill further demonstrated that albumin or dextran injected into the suprachoroidal space of the rabbit eye could diffuse across the sclera and accumulate in extraocular tissues.⁴⁰⁴ In vitro permeability studies on human sclera by Olsen and associates further demonstrated that the tissue was permeable to drugs up to a molecular weight of 70 kDa.⁴⁰⁵ Scleral permeability is expressed as a pharmacokinetic volume transfer coefficient known as its K_{trans} (cm/sec), which reflects the tissue's surface area permeability to a specific perfusion flow of the drug.⁴⁰⁵ A number of permeability studies have been published, using essentially comparable methods, and have shown that the sclera is quite permeable to a wide range of drugs (Table 4.6).^{352,399,406} Collectively, the results indicate that scleral permeability is 5–15 times better than that of the corneal stroma, depending on the molecular radius of the drug studied. The sclera shares a similar ultrastructure and composition to corneal stroma, albeit the sclera has variably larger interfibrillar spaces (50 nm [range:

Table 4.6 Known scleral permeability values for certain drugs or agents

Drug	Molecular weight (g/mol)	K_{trans} (cm/sec)	Source
Polymyxin B	1800	$3.90 \pm 0.59 \times 10^{-7}$	2
Doxil	580	$4.74 \pm 0.73 \times 10^{-7}$	8

5–120 nm] vs. 20 nm [range: 5–35 nm]) one-fourth the ground substance, one-fifth the cellularity, a 10 percent less hydration level, and a much more variable thickness profile.³⁵²

Like the corneal stroma, the primary transportation route through the sclera is by passive diffusion through the interfibrillar spaces. Also, as in corneal stroma, sclera permeability was found to be primarily dependent on the molecular radius of the drug (scleral permeability declines roughly exponentially with increasing molecular radius; 8 nm molecular radii drugs or less have been successfully shown to permeate the sclera) and secondarily dependent on the shape and molecular weight of the drug.^{405,407} As the sclera stroma proper is hypocellular and is essentially devoid of melanin, it has no intercellular barriers, few proteolytic enzymes, and few protein-binding sites to interfere with drug permeation and, thus, shows no preference for hydrophilic or lipophilic drugs. Although several studies have not found significant changes in scleral permeability to small molecules when associated with aging, tissue hydration, or various IOP levels, the hydration level and interfibrillar space of the scleral stroma have been found to decrease 35 percent and 20 percent with age, respectively, due to the effects of age-related collagen fibril cross-linking rather than an age-related change in the concentration of proteoglycans. The interfibrillar spaces also dynamically change based on the IOP of the eye (i.e. high IOP compresses the sclera and narrows the interfibrillar spaces, and vice versa).^{30,394,405,406,408,409} Thus, the effect of aging, tissue hydration, or IOP may be more important for drugs in the size range of large macromolecules (e.g. monoclonal antibodies, vectors for gene-based therapy).³⁹⁴

Periocular drug delivery using the trans-scleral diffusion route is proven to consistently deliver drugs to choroid efficiently since this pathway is highly permeable to most ophthalmic drugs. However, this comes with one important caveat in that the clearance mechanisms in the subconjunctival space near the limbus appear to be superb (Fig. 4.31A), which can affect the amount and retention time of depot drug that is available for absorption trans-sclerally – especially when given via subconjunctival injection. Only recently has how the drug permeates through the inner tissue layers of the eye directly adjacent to the sclera to eventually reach the targeted tissues of the retina or vitreous been examined.^{407,410} In fact, knowing a specific drug's scleral permeability properties is now known to be insufficient information to accurately predict the drug delivery rate to the retina or vitreous humor, particularly for large, hydrophilic drugs. The permeability properties of the choroid and Bruch's membrane have recently been studied and they are rather porous as their permeation properties are better than that of the sclera.⁴¹¹ Nonetheless, the permeability properties of Bruch's membrane did gradually decline with age due to lipid accumulation. The major rate-limiting step for retinal or vitreous targeted drug delivery via the periocular route has recently been determined to be the RPE (10–100-fold less permeable than the human sclera and 14–16-fold less permeable than the choroid or Bruch's membrane for large, hydrophilic drugs; comparably similar to sclera, choroid, or Bruch's membrane for lipophilic drugs), which forms the outer part of the blood-retinal barrier due to the apical zonula occludens tight junctions found in its intercellular space (most similar to that of the corneal epithelium).^{358,410}

While drug metabolism does not appear to be a major source of drug removal in the posterior segment, dynamic drug clearance mechanisms via orbital blood vessels and lymphatics, conjunctival blood vessels and lymphatics, episcleral blood vessels, and the choroidal vasculature are another confirmed inhibitory factor for successful periocular drug delivery.⁴¹² Currently, animal studies show that the orbital (~25 percent drug removal rate using retrobulbar injection since drugs disperse throughout the orbit) and conjunctival (~5–80 percent drug removal rate using sub-Tenon's injection since drugs disperse circumferentially around the eye, but not into the orbit; the clearance rate for triamcinolone is estimated to be between 8 and 13 µg/hr) clearance mechanisms are of more importance than that of the choroid (~2–20 percent drug removal rate using sub-Tenon's injection).^{400,412,413} Therefore, for large, hydrophilic drugs, the major barrier to drug entry into the retina or vitreous is the RPE, whereas small, lipophilic drugs are relatively unaffected since it transverses RPE quite easily using the intracellular (transcellular) route. Overall then, the rate-limiting factors for posterior segment drug delivery using this drug delivery route come down to avoiding or abrogating the dynamic physiologic clearance mechanisms and the individual physiochemical properties of the drug itself – predominantly the molecular radius (≤ 8 nm molecular radii drugs) and the lipophilicity of the drug, and, secondarily, the shape, MW, protein-binding properties, and ionic charge of the drug. Other issues on these various periocular drug delivery routes still need to be worked out and, as such, the information on this topic is far from complete.

In summary, there is now definitive in vitro and in vivo evidence to suggest that periocular drug delivery is the most efficient means to treat choroidal and RPE disease without significant systemic or intraocular risk since it diffuses through the static permeability barriers in the sclera and choroid quite easily. However, one caveat is that the drug depot site must have a drug release rate that exceeds the dynamic tissue clearance rates stated above. The feasibility of treating retinal or vitreous diseases is less certain, but is promising, likely depending more on the molecular size and lipophilicity of the drug being administered. Due to recently published data on static permeability properties of the sclera, choroid, Bruch's membrane, and RPE, we can at least now understand how the posterior segment is amenable to pharmacologic intervention other than direct, invasive intravitreal injection and should follow these periocular treatment modalities more closely as it may change the way retinal or posterior segment disease is treated since it basically is a crossroads between nanomedicine and ophthalmology. One promising offshoot drug delivery technology from the periocular drug delivery research efforts is that of minimally invasive drug-eluting microneedles (<1 mm diameter) that deliver drugs into the cornea, sclera, or suprachoroidal space.^{414–416} Preliminary animal studies suggest that by circumventing the subconjunctival/episcleral clearance mechanism microneedle-based drug delivery markedly improves (80-fold) the intraocular bioavailability and moderately improves (3-fold) the duration of action over periocular drug delivery techniques. Because of our improved understanding of the pharmacokinetics involved in periocular drug delivery, attention should probably now shift more toward optimizing the physiochemical properties of existing

drugs so that it prolongs residence time or enhances penetration into the retina and vitreous using these periocular drug delivery routes.⁴¹⁷

The Lens

David C. Beebe

The lens is a remarkably specialized epithelial tissue that is responsible for fine-tuning the image that is projected on the retina. To perform this function it must be transparent, have a higher refractive index than the medium in which it is suspended, and have refractive surfaces with the proper curvature. Because the refractive power of the lens is variable, it permits the diopteric apparatus to focus on objects that are near or far.

To maintain transparency and a high refractive index, lens fiber cells are precisely aligned with their neighbors, have minimal intercellular space, and accumulate high concentrations of cytoplasmic proteins, the crystallins. Disruption of the precise organization of the lens fiber cells or aggregation of the proteins within them can destroy the transparency of the lens – a process known as cataract formation. Cataracts are the leading cause of blindness worldwide and the removal of cataracts is the most common surgical procedure in the aged population.

This chapter provides an overview of the structure, development, biochemistry, physiology, and pathology of the lens. Information about the human lens is emphasized, although studies using animals are included when data are not available for humans. Information is provided on the causes of cataracts and the mechanisms that are thought to protect the lens from cataract. The unsolved issues in the biology and pathology of the lens are highlighted throughout. References to comprehensive reviews and original source material are included to assist the reader. The citations provided are not meant to be inclusive, but to highlight articles of special relevance.

The anatomy of the adult lens

The lens is formed from two populations of specialized epithelial cells (Fig. 5.1). A sheet of cuboidal cells, the lens epithelium, covers the surface of the lens closest to the cornea. The bulk of the lens consists of concentric layers of elongated fiber cells. The outer shells of fiber cells extend from just beneath the epithelium to the posterior lens surface, a distance of over 1cm in adults. An elastic extracellular matrix, the lens capsule, which is secreted by the epithelial and superficial fiber cells, surrounds the entire lens. In the adult lens, most epithelial cells and all fiber cells are

not dividing. Cells near the equatorial margin of the lens epithelium, in a region called the germinative zone, proliferate slowly. Most of the cells produced by mitosis in this region migrate towards the posterior of the lens and differentiate into fiber cells at the lens equator.¹ These new fiber cells elongate and accumulate large amounts of crystallins. During elongation the posterior (basal) ends of the fiber cells move along the inner surface of the capsule and their anterior (apical) ends slide beneath the epithelium until they meet elongating cells from the other side of the lens near the posterior and anterior midlines (Fig. 5.1). The junctions between the ends of cells from the opposite sides of the lens are called the sutures. Once fiber cells reach the sutures they stop elongating and their basal ends detach from the capsule (Fig. 5.1, inset). Soon after reaching the sutures, fiber cells degrade all intracellular membrane-bound organelles, including their nuclei, mitochondria, and endoplasmic reticulum.²⁻⁵ Mature fiber cells are gradually buried deeper in the lens as successive generations of fibers elongate and differentiate. In this way the lens continues to increase in size and cell number throughout life.⁶ Because protein synthesis ceases just before organelle degradation,⁷ the components of mature fiber cells must be much more stable than those in cells found in other parts of the body. In fact, since the fiber cells in the center of the lens are present at birth and persist until death (or cataract surgery), their constituent proteins and membranes may last for more than 100 years.

The lens is suspended in the anterior of the eye by a band of inelastic microfibrils, the zonules, which insert into the lens capsule near the equator (Figs 5.1 & 5.2). These fibrils originate in the non-pigmented layer of the ciliary epithelium, a tissue that is located just posterior to the iris. They are composed of the protein fibrillin, one of the components of elastic fibrils in many connective tissues throughout the body.^{8,9} However, the zonules do not stretch appreciably. Changes in the tension applied to the zonules are responsible for the alterations in lens curvature that occurs during accommodation, the process by which the lens focuses on objects nearby or at a distance.

The basics of lens refraction and transparency

The refractive properties of the lens are the result of the high concentration and graded distribution of crystallin proteins

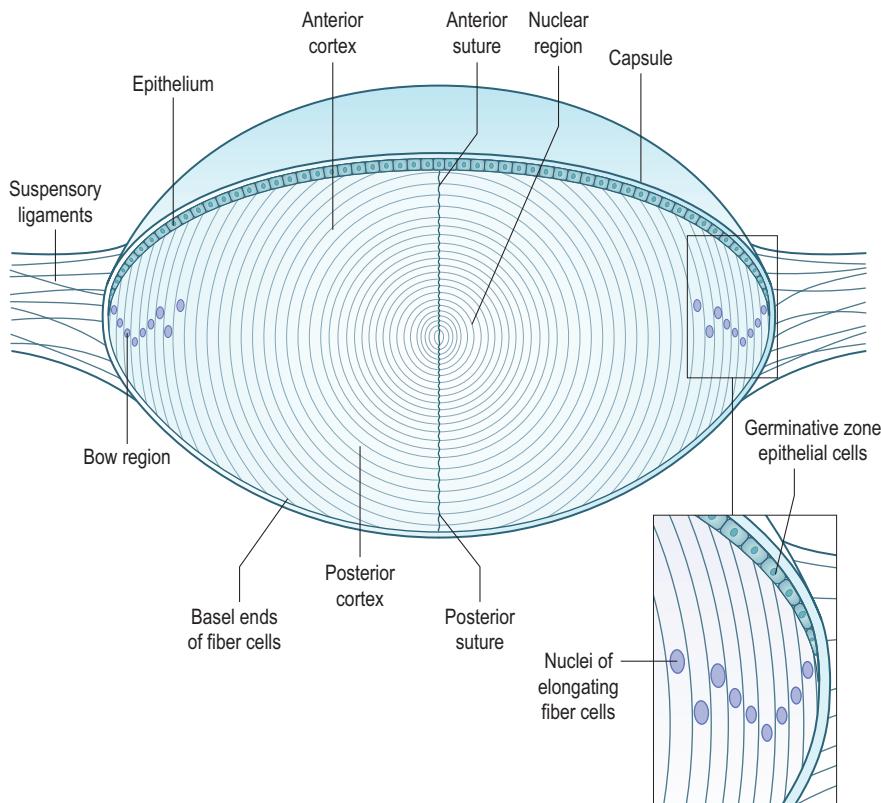

Figure 5.1 Diagram of the adult human lens. The expanded regions show the relationships between the elongating lens fiber cells and the posterior capsule as the basal ends of the fibers reach the posterior sutures and the changes in cell shape and orientation that occur as lens epithelial cells differentiate into lens fibers at the lens equator.

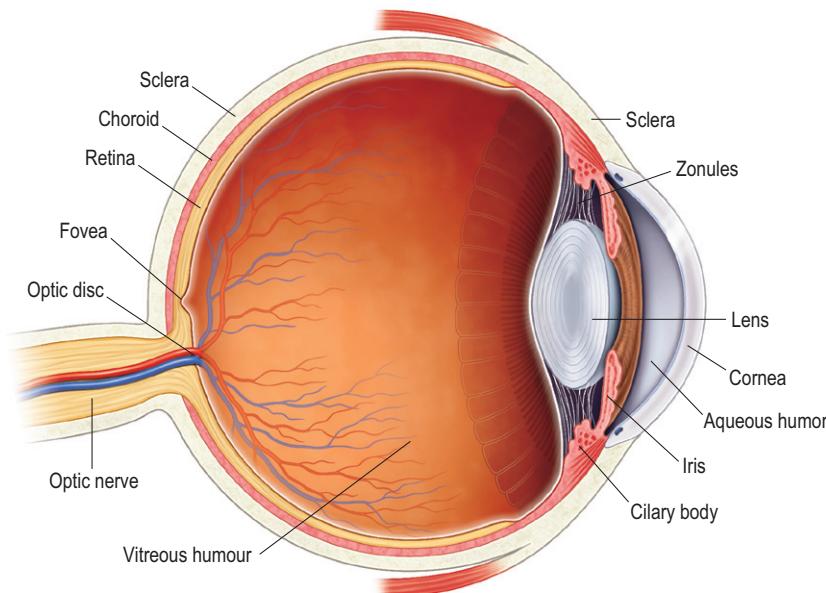

Figure 5.2 Diagram showing the relationship of the lens and zonules to the other structures in the adult eye.

in the cytoplasm of the lens fiber cells and the curvature of the lens refractive surfaces. Lens crystallins accumulate to concentrations that are up to three times higher than in typical cells.¹⁰ This gives the fiber cells a significantly higher refractive index than the fluids around the lens. In the emmetropic eye the curvature of the refractive surfaces of the lens focuses light at the photoreceptors of the retina. The curvatures of the lens surfaces are the result of the tension on the zonules, the elasticity of the capsule, and the growth properties of the lens fibers and epithelial cells. In younger individuals refractive

error, myopia or hyperopia is often caused by abnormalities in corneal curvature or the length of the globe, but rarely by defects in the curvature or refractive index of the lens.

Transparency depends on minimizing light scattering and absorption. Light passes smoothly through the lens as a result of the regular structure of lens fibers (Fig. 5.3), the absence of membrane-bound organelles in the deeper fiber cells, and the small and uniform extracellular space between the fiber cells. Paradoxically, the high crystallin concentration of the lens fiber cell cytoplasm is an essential

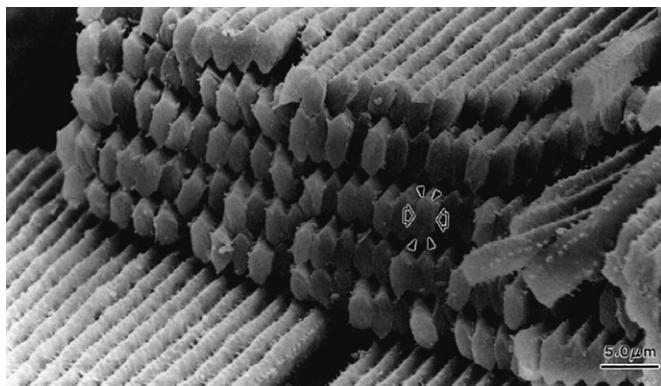

Figure 5.3 Scanning electron micrograph showing the orderly arrangement of hexagonal lens fibers in the vertebrate lens. (Courtesy Dr. J. Kuszak.)

component of lens transparency. Reduced light scattering is due to short-range interactions between the highly concentrated crystallins.^{11,12} Although it absorbs increasing amounts of the shorter wavelengths of visible light as it ages, giving the lens a pale yellow to brown color, the young human lens is nearly colorless.^{13,14}

The early development of the lens

The cells that form the lens are originally part of the surface ectoderm covering the head of the embryo. Interactions between the future lens cells and nearby tissues during early development give these cells a "lens forming bias."¹⁵ As a result of these interactions, patches of cells that lie on either side of the head are marked by expression of the transcription factor, Pax6.¹⁶ At the same time, neural epithelial cells on either side of the diencephalon in the embryonic forebrain bulge laterally to form the optic vesicles, which eventually contact the surface ectoderm cells (Fig. 5.4A). The cells of the optic vesicle also express Pax6 and Pax6 function in these cells is essential for eye formation.^{17,18} Some of the genes that regulate and are regulated by Pax6 at early stages of eye formation are now known, although the number of genes involved and knowledge about their interactions is likely to increase.^{19–25}

Members of the bone morphogenetic protein (BMP) family of secreted factors play an essential role in lens formation. Deletion of the genes encoding BMP4 or BMP7 in the mouse embryo prevents lens formation in most cases (a minority of BMP7 null animals make a small, abnormal lens).^{20,26–27} Deletion of BMP4 leads to decreased expression of the transcription factor Sox2 in the lens placode, while loss of BMP7 is associated with absence of Pax6 expression. BMP4 appears to be derived primarily by the optic vesicle; implantation of a bead containing BMP4 into the lumen of the vesicle can rescue lens formation in BMP4 knockout embryos.²⁷ BMP7 mRNA mainly localizes in the pre-lens surface ectoderm, suggesting that BMP7 acts as an autocrine or paracrine factor to promote lens formation.

After they make contact, the optic vesicles and the prospective lens ectoderm cells secrete an extracellular matrix that causes these cell layers to adhere tightly to each other (Fig. 5.4B).²⁸ The surface epithelial cells then elongate,

forming the thickened lens placode (Fig. 5.4B).²⁹ Soon afterward, the lens placode and the adjacent cells of the optic vesicle buckle inward to form the lens pit (Fig. 5.4C).³⁰ This morphological transformation is accompanied by the formation of the bi-layered optic cup. The invaginated lens placode soon separates from the surface ectoderm by a process involving the death of the cells in the connecting stalk between the cells of the surface ectoderm and the lens (Fig. 5.4D).³¹ The Pax6-expressing ectodermal cells adjacent to the lens placode that remain on the surface of the eye become corneal and conjunctival epithelial cells.³²

During lens invagination, the extracellular matrix between the optic vesicle and the lens begins to diminish and the two tissues separate (Fig. 5.4E).^{28,33} The space that is formed between them is rapidly filled with a loose extracellular matrix, the primary vitreous body, that is secreted by the cells of inner layer of the optic cup (Fig. 5.4E).³⁴

The epithelial cells that give rise to the lens vesicle originally lie on a thin basal lamina. In the process of invagination, this basal lamina comes to surround the lens vesicle. It gradually thickens by the deposition of successive layers of basal lamina material to form the lens capsule.^{35–37}

Soon after the lens vesicle separates from the surface ectoderm, the cells in the portion of the vesicle that are closest to the retina begin to elongate. The elongation of these primary fiber cells soon obliterates the lumen of the vesicle as their apical ends contact the apical ends of the anterior epithelial cells (Fig. 5.4E,F). Primary fiber cell formation establishes the fundamental structure of the lens, with epithelial cells covering the anterior surface and elongated fiber cells filling the bulk of the lens.

At early stages of lens formation, most of the lens epithelial cells are actively proliferating. Cells at the margin of the epithelium are pushed or migrate towards the equator and are stimulated to differentiate into secondary fiber cells by factors present in the vitreous body.^{38–41} As the secondary fibers elongate and their basal and apical ends curve towards the center of the lens, they displace the central primary fibers from their attachments with the capsule and the lens epithelium. This process buries the primary fiber cells in the center of the lens (Fig. 5.1). In the adult lens these cells comprise the "embryonic nucleus." Deposition of successive layers of secondary fiber cells continues throughout life. The rate of fiber cell formation, and therefore lens growth, is rapid in the embryo and slows greatly after birth (Fig. 5.5).⁶

In addition to Pax6, at least one additional transcription factor may be essential for lens formation.²¹ In chicken embryos, prospective lens cells express L-maf, a member of the maf family of b-ZIP transcription factors, soon after they contact the optic vesicle.⁴² When modified forms of this protein that bind to DNA but do not activate transcription are expressed in the prospective lens-forming region of chicken embryos, the formation of the lens placode and lens vesicle is suppressed. Expression of L-maf in regions of the head ectoderm outside of the lens placode (but within the area expressing Pax6) leads to the formation of extra lenses.⁴² Although members of the maf family of transcription factors are expressed during lens formation in mammals, there is no factor comparable in function to chicken L-maf. Since deletion of individual members of the maf family does not prevent lens formation in mice, multiple maf family members may assume the function of L-maf in mammals.

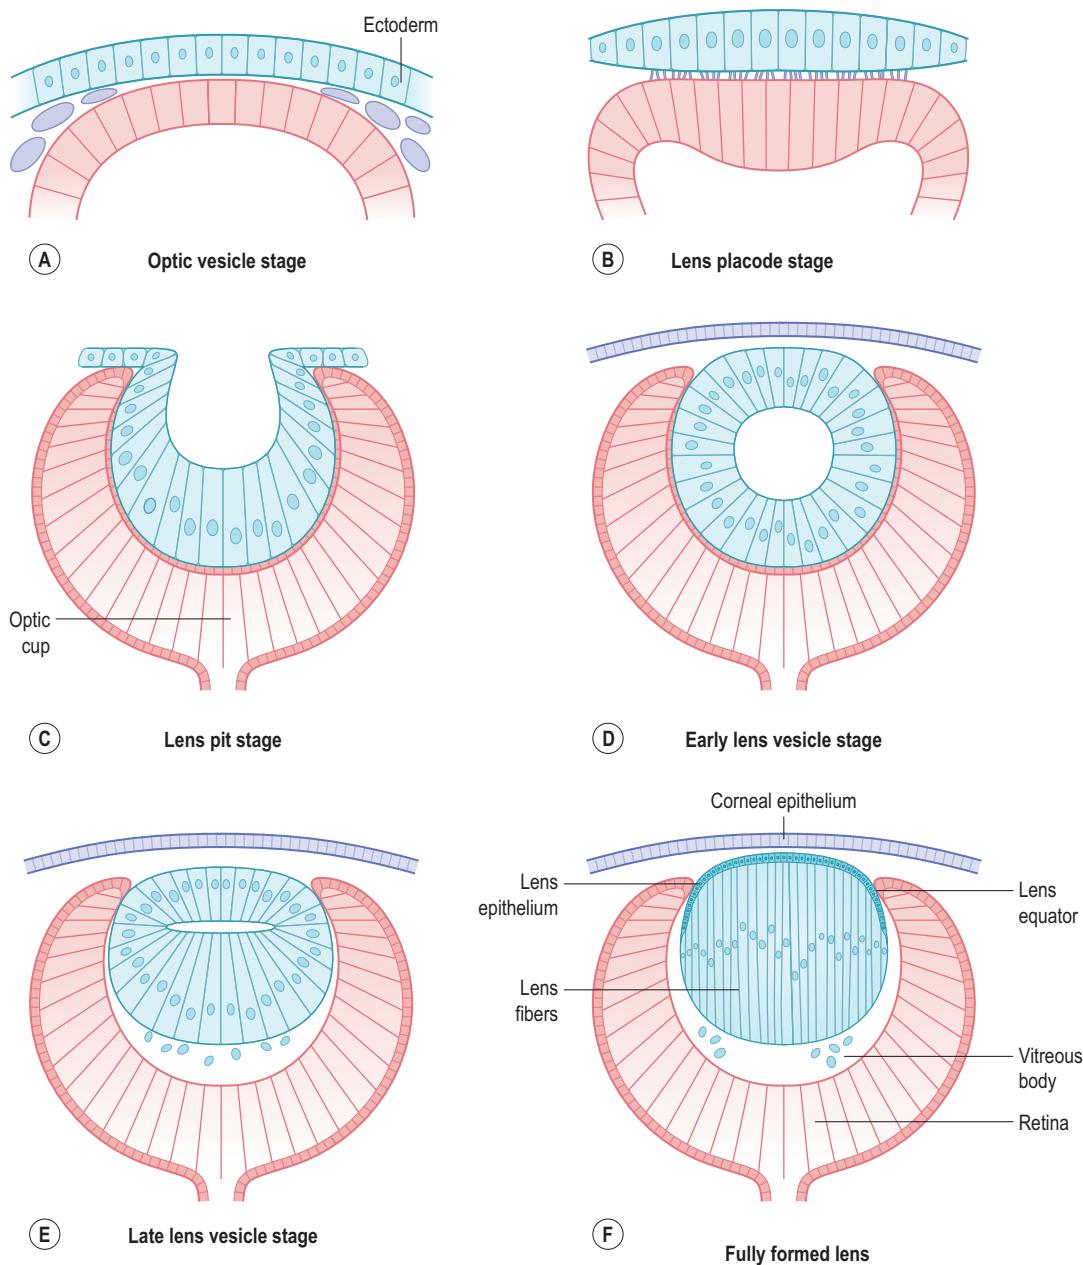

Figure 5.4 The early stages of lens formation. (A) The lens vesicle contacts the surface ectoderm. (B) The optic vesicle adheres to the surface ectoderm and the prospective lens cells elongate to form the lens placode. (C) The lens placode and the outer surface of the optic vesicle invaginate to form the lens pit and the optic cup, respectively. (D) The lens vesicle separates from the surface ectoderm. (E) The primary lens fibers elongate and begin to occlude the lumen of the vesicle. The posterior of the lens vesicle separates from the inner surface of the optic cup. Capillaries from the hyaloid artery invade the primary vitreous body. (F) The configuration of the lens as it begins to grow. Secondary fiber cells have not yet developed and organelles are still present in all fiber cells. (Modified from McAvoy J, Developmental biology of the lens. In Duncan G (Ed), Mechanism of cataract formation. Academic Press, pp 7-46. Copyright Elsevier 1981⁴⁸⁰)

The proper separation of lens vesicle from the overlying presumptive corneal epithelium is defective in the mouse mutant, *dysgenetic lens* (*dyl*). A mutation was identified in the gene encoding the “forkhead” transcription factor, Foxe3, in the *dyl* strain. Foxe3 is selectively expressed in the lens placode and developing lens epithelium.^{24,43} Lenses lacking Foxe3 show severe defects in lens epithelial cell proliferation and subsequently degenerate.⁴⁴ A similar phenotype is seen in lenses lacking the transcription factor, AP-2α. These also fail to separate from the surface ectoderm and show defects in epithelial cell differentiation.⁴⁵

Targeted disruption of the genes encoding three additional transcription factors that are normally expressed during primary fiber cell differentiation, c-Maf, Sox1, and Prox1, causes failure of elongation of primary lens fiber cells.⁴⁶⁻⁴⁹ In mice lacking any one of these genes, lens fiber cells do not elongate or express the high level of lens crystallins that are characteristic of primary fiber cells. The diffusible factors that trigger fiber cell formation and the mechanisms responsible for fiber cell elongation and the regulation of crystallin synthesis are discussed below (see Box 5.1).

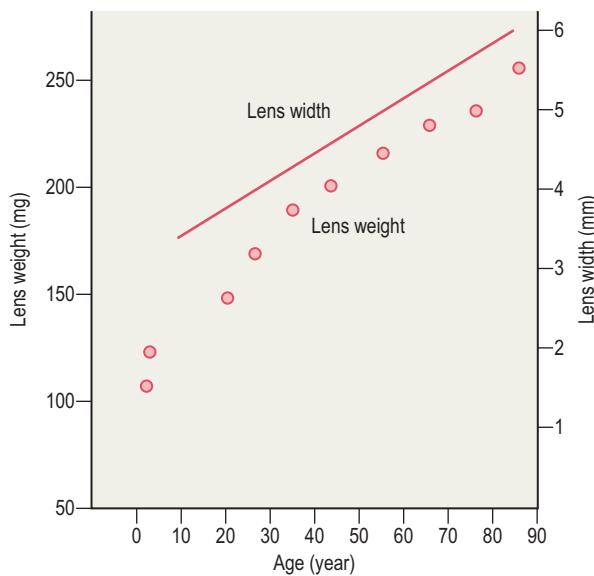

Figure 5.5 Changes in lens width and height from birth to 90 years of age. (Data from Scammon, R.E. and M.B. Hesdorfer, Growth in mass and volume of the human lens in postnatal life. Arch. Ophthalmol., 1937. 17: p. 104-112 and Brown, N., Slit-image photography and measurement of the eye. Med Biol Illus, 1973. 23(4): p. 192-203⁴⁸¹)

Box 5.1 Mutations in genes involved in lens formation contribute to the formation of congenital cataracts and anterior segment dysgenesis

Several genes have been identified that are required for the formation of the normal lens. The proteins encoded by these genes, including Pax6, Pitx3, c-Maf and Foxe3, are transcription factors; they control the expression of batteries of genes required to make a lens. Most of these mutations are dominant and result from "haploinsufficiency;" loss of the function of one copy has a severe effect on lens development. Defects may range from mild cataracts to absence of the lens. Many of these mutations are associated with defects in the development of the anterior segment, including the corneal endothelium and stroma and the aqueous humor outflow pathway. Anterior segment defects can be secondary to Peters anomaly, the failure of the lens to separate from the surface ectoderm, or to less obvious interactions between the developing lens and the mesenchymal cells that form the structures of the outflow pathway.

Mice homozygous for the *aphakia* mutation form lens vesicles, but the lens cells degenerate soon after.⁵⁰ The *aphakia* mutation was mapped close to the gene encoding a homeodomain transcription factor, Pitx3, that is expressed early in lens development.^{51,52} Two families were described in which affected individuals have hereditary congenital cataracts and point mutations in Pitx3.⁵³ Deletions were found in the region upstream and in the coding sequence of Pitx3 in the *aphakia* strain.^{51,54} A microarray study indicated that Pitx3 mRNA expression is decreased in lenses lacking a single copy of Pax6.²⁵

Lens fiber cell differentiation

Lens fiber cell differentiation is characterized by an exceptional degree of specialization. During their differentiation,

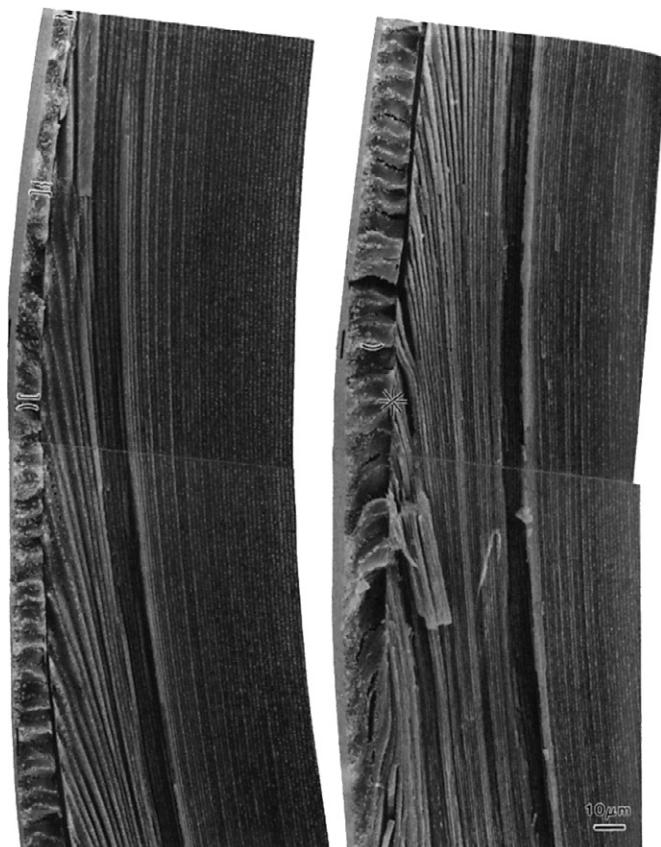

Figure 5.6 A montage of photomicrographs showing the organization of cells in the pre-germinative zone (curly brackets), germinative zone (square brackets) and transitional zone (curved brackets) of the equatorial lens epithelium. The image on the right is a continuation of the one on the left showing the change in cell morphology as the cells of the transitional zone elongate (asterisk) to form lens fiber cells. The images were obtained using a scanning electron microscope (magnification $\times 780$). (Courtesy of Dr. J. Kuszak.)

fiber cells withdraw from the cell cycle, elongate greatly, express large amounts of proteins (the crystallins), acquire several specializations of their plasma membranes, and eventually degrade all membrane-bound organelles.

In mature lenses, the first evidence of fiber cell differentiation is the withdrawal from the cell cycle of epithelial cells near the lens equator. After their last mitosis, these cells move in a posterior direction into the transition zone (Fig. 5.6). This movement has been termed "migration," but it may simply result from displacement caused by the proliferation of cells in the germinative zone, a kind of "mitotic pressure." Cells in the transition zone are postmitotic, but have not yet begun to elongate. As they move posteriorly they are exposed to factors that stimulate their elongation. Studies in chicken embryos and newborn mice, in which the lens was rotated so that the epithelial cell faced the vitreous body, first demonstrated the existence of these factors.^{38,55} Epithelial cells exposed to vitreous humor in this manner elongated like primary fiber cells. Furthermore, chicken embryo lens epithelial cells stopped progressing through the cell cycle within 9 hours after lens rotation, indicating that suppression of lens cell proliferation at the initiation of fiber cell differentiation is dependent on factors from outside the lens.⁵⁶

Proteins that are known to be involved in regulating the cell cycle in many cell types appear to play an essential role in the cessation of lens fiber cell proliferation. Included in this group are the cyclin-dependent kinase inhibitor protein, p57 (KIP2) and the retinoblastoma protein (pRb). Progression through the cell cycle requires the phosphorylation of regulatory proteins, called cyclins, by cyclin-dependent kinases. The cyclin-dependent kinase inhibitor protein, p57, an inhibitor cell cycle progression, is expressed in the early stage of lens fiber cell differentiation, where it is found bound to cyclins.^{57,58} In lenses that lack the gene for pRb, a well-known regulator of the cell cycle, p57 levels are low and lens fiber cells do not withdraw from the cell cycle.^{59,60} This finding suggests that pRb is required for the expression of p57 and that at least one function of p57 is to maintain lens fiber cells in the non-proliferating state by complexing with cyclins. Absence of the two main cyclin-dependent kinase inhibitors expressed in the lens, p27 and p57, leads to extensive lens fiber cell proliferation, even in the presence of pRb, confirming that these molecules play an essential role in the withdrawal of fiber cells from the cell cycle.⁶¹ Lenses lacking both p27 and p57 also do not make detectable levels of crystallins, suggesting that the function of these molecules is essential for normal gene expression during fiber cell differentiation.⁶¹ In addition to the requirement for pRb, the transcription factor Prox1 is also required for high levels of p57 accumulation in the nuclei of lens fiber cells.⁶² Prox1 is present in lens epithelial cells, but localizes to the cell nucleus at the onset of fiber cell differentiation.⁶³

Some of the basic mechanisms responsible for the extensive cell elongation that characterizes lens fiber cell differentiation have been described, but this process is still not well understood. Early studies suggested that the microtubules of the lens fiber cytoskeleton are required for fiber cell elongation.^{64,65} However, later experiments showed that fiber-like cells could elongate in the absence of microtubules.⁶⁶ Whether other components of the cytoskeleton play an essential role in fiber cell elongation *in vivo* has not been demonstrated.

In chicken embryo lenses, the early stages of lens fiber cell elongation may be driven by an increase in cell volume.⁶⁷ In these cells, initiation of fiber cell elongation is accompanied by changes in the ionic permeability of the plasma membrane. The resulting accumulation of potassium and chloride ions in the cytoplasm leads to an osmotically driven increase in cell volume.⁶⁸ Continued cell elongation depends on sustained protein synthesis.^{69,70} In mouse lenses, secondary fiber cells appear to initiate elongation without increasing in volume.⁷¹ The mechanism by which fiber cell elongation is regulated at later stages of their differentiation, especially when fiber cells reach the sutures and stop elongating, has not been studied.

Several growth factors are capable of initiating lens fiber cell differentiation when added to cultured lens epithelia or, in some cases, when over expressed in the lens *in vivo*. Among these are members of the fibroblast growth factor (FGF) and insulin-like growth factor (IGF) families. Studies in chicken embryos identified IGF-1 as a potent activator of fiber cell differentiation.⁷² However, experiments in rats and mice showed that, although IGFs may play some role in fiber cell differentiation, members of the FGF family appear to be more important in mammals and also contribute to fiber

cell differentiation in chicken embryos.^{41,73–83} Studies using mouse lenses deficient in three of the four FGF receptors have conclusively demonstrated that FGF signaling is required for the formation of lens fiber cells.⁸⁴ Other soluble factors, especially members of the BMP family, appear to modulate or potentiate the effects of FGFs on lens fiber cell differentiation.^{85–87}

Lens crystallins

The synthesis and accumulation of very large amounts of crystallin proteins is a major characteristic of lens fiber cell differentiation. As much as 40 percent of the wet weight of the lens fiber cell can be accounted for by crystallins,¹⁰ a protein concentration that is about three times higher than in the cytoplasm of typical cells. Crystallin proteins can be classified as either "classical" or "taxon-specific". The classical crystallins are comprised of two α -crystallins and several members of the beta/gamma (β/γ)-crystallin superfamily. All vertebrate lenses accumulate large amounts of classical crystallins in their fiber cells. In many species, fiber cells also produce large amounts of taxon-specific crystallins (see reviews^{88,89}). As the name implies, different taxon-specific crystallins are found in the lenses of different taxonomic groups. Taxon-specific crystallins are functional enzymes or proteins that are structurally very similar to enzymes, but with little or no enzymatic activity. The levels of taxon-specific crystallins sometimes exceed those of the classical crystallins. Adult human lenses do not produce taxon-specific crystallins, although the enzyme betaine-homocysteine methyltransferase is present at high levels in the embryonic nucleus of the rhesus macaque lens, suggesting that this enzyme may serve as a taxon-specific crystallin during the early development of the primate lens (see Box 5.2).⁹⁰

Many of the transcription factors that promote the abundant expression of the crystallin genes in lens fiber cells have been identified. The details of these studies are described in comprehensive reviews and will not be considered further here.^{21,23,91–96}

Human lenses express two α -crystallin genes, α A and α B. Examination of the protein structure of the α -crystallins revealed that they are members of the widely distributed family of small heat shock proteins.^{97–99} An important function of small heat shock proteins is to stabilize proteins that are partially unfolded and prevent them from aggregating (this is termed their "chaperone" activity). The role of the α -crystallins in preventing protein aggregation and precipitation has been demonstrated in experiments performed *in vitro*.¹⁰⁰ A similar, *in vivo* role for α A crystallin has been inferred in mice in which α A crystallin gene was disrupted.¹⁰¹ The function of the α -crystallins in preventing protein aggregation has obvious importance for the lens, because the proteins in lens fiber cells must persist for the life of the individual and excessive protein aggregation could lead to light scattering and cataract formation (see below).

α -Crystallins are also enzymes, since they possess serine-threonine auto-kinase activity.¹⁰² It is not yet clear whether the α -crystallins phosphorylate other proteins in lens fiber cells. The α -crystallins are, themselves, normally phosphorylated *in vivo* and can be phosphorylated *in vitro* in a cyclic AMP-dependent manner.^{103,104} The factors that regulate the phosphorylation of α -crystallins and the

Box 5.2 Mutations in genes that are expressed at high levels in the lens often underlie congenital cataracts

Lens fiber cells accumulate high concentrations of lens-preferred crystallin proteins. Their plasma membranes also have large amounts of protein that form lens-specific gap junctions, water channels or cell-cell adhesions. Mutations in the genes encoding these abundant proteins are responsible for many of the hereditary congenital cataracts that have been identified over the past decade. Most mutations that cause hereditary congenital or juvenile cataracts show a dominant mode of inheritance. Experimental studies in animal models and study of the mutant proteins in cultured cells suggest that the defective proteins encoded by these genes cause cataracts by interfering with the normal function of lens fiber cells or by promoting their own aggregation and, perhaps, the aggregation of normal lens proteins. Therefore, these cataracts are not caused by loss of the normal function of the mutant proteins, but by the acquisition of an abnormal function. This conclusion is supported by studies in experimental animals in which complete removal of one copy of these genes has no effect on lens transparency. Interestingly, mutations in crystallin genes are sometimes associated with microcornea. Since most of these genes have not been detected in the cornea, it appears that defects that originate in the lens lead to alterations in the size of the cornea.

importance of this phosphorylation for the function of the α -crystallins in the living lens have not been determined.^{105–107}

Alpha-crystallin proteins normally associate in the lens cell cytoplasm to make high-molecular-weight complexes containing approximately 30 subunits. The structure of these complexes has been revealed by cryoelectron microscopy.¹⁰⁸ These observations show that native α -crystallin complexes can be assembled in a number of configurations, indicating that there is substantial flexibility in the way the subunits associate. Alpha-crystallin monomers also readily exchange between high-molecular-weight complexes, further supporting the view that α -crystallin complexes are quite plastic.¹⁰⁹

The phenotype of α A-crystallin knockout mice provides insight into the function of α -crystallins *in vivo*.¹⁰¹ The lenses of these animals are slightly smaller than normal, but structurally quite similar to the normal lens. Mature fiber cells contain aggregates of proteins that lead to the formation of cataracts, beginning a few weeks after birth. Analysis of these aggregates shows that they contain large amounts of α B crystallin and smaller amounts of other proteins. These results suggest that, in the fiber cell cytoplasm, α A crystallin is partly responsible for preventing α B from aggregating. In addition, when lens epithelial cells from these animals were cultured *in vitro*, they grew more slowly than normal cells, were more sensitive to stress, and had a higher rate of apoptosis, accounting for the smaller size of the knockout lenses.¹¹⁰ Therefore, α A crystallin appears to be important for the normal function of lens epithelial and fiber cells.

In addition to being expressed at very high levels in the lens, α B crystallin is present in a variety of cells throughout the body, especially in heart and skeletal muscle.¹¹¹ The protein is also found in damaged areas of the central nervous system in a variety of neurodegenerative diseases, including

in the “drusen” that accumulate at the basal surface of the retinal pigmented epithelial cells in age-related macular degeneration.^{112–114} A naturally occurring mutation in the α B crystallin gene (CRYAB) leads to the formation of cataracts and “desmin-related” myopathy.¹¹⁵ *In vitro* tests showed that the mutant form of the protein had no chaperone activity and even enhanced the aggregation of test proteins.¹¹⁶ These studies suggest that α B crystallin has important chaperone functions in the lens and in other cells of the body. However, the fact that the mutant protein accelerated the denaturation of test proteins leaves open the possibility that the mutant is a gain-of-function. In this case, the cataracts and myopathy seen in individuals harboring this mutation could be due to the destabilizing function of the protein, rather than loss of its function as a chaperone. However, additional mutations in CRYAB, which do not have myopathy as part of their phenotype, support the view that loss of its chaperone function contributes to cataract.¹¹⁷

The β/γ crystallin superfamily is more diverse than the α -crystallins and the function of its members in the lens is less evident. The β - and γ -crystallins were originally thought to be two distinct protein families. However, once the protein sequences of representative members of these families were available, it was clear that they were closely related.¹¹⁸ The major difference in these proteins is the tendency for most of the β -crystallins to form multimers, while the γ -crystallins exist as monomers. Solving the three-dimensional structure of these molecules confirmed their close structural relationship. It also confirmed that the N- and C-terminal extensions of the β -crystallins provided a structural rationale for why these family members form higher-order aggregates.^{119,120} There are six beta crystallin polypeptides (β A1, β A3, β A4, β B1, β B2, β B3), and three gamma crystallins (γ S, γ C, γ D) expressed in the human lens,¹²¹ although the β A1 and β A3 polypeptides are derived from the same gene (β A3/A1).¹²² Beta- and gamma-crystallins bind calcium *in vitro* and may buffer this important cation in the lens fiber cell cytoplasm.^{123–125}

The lens fiber cell cytoskeleton

Microtubules are abundant beneath the plasma membranes of lens fiber cells where they probably play an important role in stabilizing the fiber cell membrane.¹²⁶ Microtubules may also be important for transporting vesicles to the apical and basal ends of elongating fiber cells, although neither function has been demonstrated *in vivo*. In addition to microtubules, there is an abundant network of actin-containing microfilaments beneath the plasma membrane of lens fiber cells. These microfilaments associate with the cytoplasmic surfaces of the adhesive junctions between lens fibers and are also likely to interact with the spectrin-containing submembrane meshwork.^{127,128} This sub-membrane scaffold also contains tropomyosin and tropomodulin, proteins that may modulate the structure of the microfilaments.¹²⁹

Lens fiber cells also contain an unusual complement of intermediate filaments, including those composed of vimentin.¹³⁰ This is unusual, because vimentin intermediate filaments are usually restricted to cells of mesodermal, not epithelial origin. The function of vimentin-containing intermediate filaments in the lens is not evident, because mice lacking vimentin appear to have normal lenses.¹³¹

Over-expression of vimentin in the lens leads to cataract formation and defects in fiber cell differentiation.¹³² Whether this is a specific effect of excessive vimentin levels in the lens, or the response of the lens to protein over-expression in general, has not been demonstrated.

In addition to vimentin, the lens contains intermediate filaments composed of the proteins filensin and phakinin (see reviews^{133,134}). These filaments have an unusual "knobby" structure, leading to the name "beaded filaments."¹³⁵ Beaded filament proteins have only been found in lens fiber cells, suggesting that they have a specialized role in these cells.¹³⁵ Mutations of both genes are associated with the formation of human cataracts, often involving the sutures.^{136,137} Deletion of the phakinin gene (*Bfsp2*) in mice caused a mild, progressive cataract that was associated with decreased levels of its binding partner, filensin, but no obvious defects in fiber cell differentiation.¹³⁸

Other cellular and biochemical specializations found in lens fiber cells

In fiber cells at early stages of elongation the lateral plasma membranes are smooth. However, as fiber cells reach the sutures, the membranes become progressively more interdigitated, forming interlocking "ball-and-socket" junctions (Fig. 5.7).^{139–141} Ball-and-socket junctions may stabilize the lateral membranes of the fiber cells and assure that the cells remain tightly connected during accommodation. The mechanisms responsible for the formation of these unusual membrane specializations have not been identified.

The membranes of mature fiber cells have an unusual lipid composition. Human lens fiber cells have the highest proportion of cholesterol of any plasma membrane in the body and the amount of cholesterol increases as the fiber cells mature.^{142,143} The cholesterol/phospholipid ratio of nuclear fiber cells is nearly three-fold greater than in cortical fiber cells. Partially purified fiber cell membranes have substantially lower cholesterol/phospholipid ratio than was found in the whole tissue, although membranes from nuclear fibers still have proportionally higher cholesterol content than membranes from the cortex.¹⁴² This finding suggests that some of the cholesterol in mature lens fiber

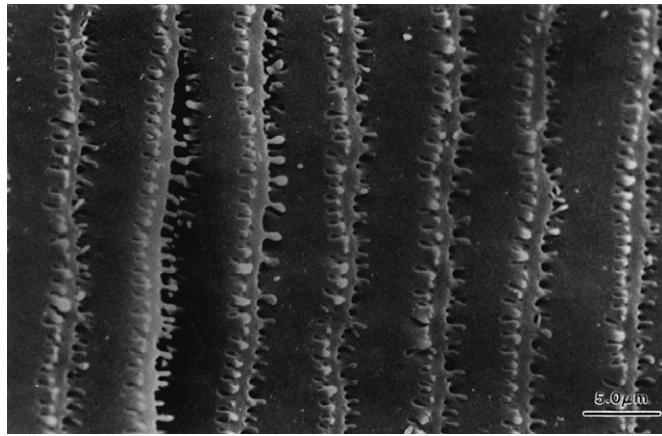

Figure 5.7 Visualization of the ball-and-socket interdigitations at the lateral surfaces of lens fiber cells. The tissue was fractured to show the surface morphology of the cells and viewed with a scanning electron microscope. (Courtesy of Dr. J. Kuszak.)

cells may be associated with a complex that is not an integral component of the plasma membrane. There is also a high percentage of sphingomyelin in lens membrane phospholipids.¹⁴³ The presence of high concentrations of cholesterol and sphingomyelin is likely to cause lens fiber cell membranes to be quite rigid.¹⁴² The functional significance of these biochemical specializations is not known.

In addition to its unusual lipid content, lens fiber cell plasma membranes contain several unique proteins. The most abundant of these is the "major intrinsic polypeptide" (MIP). MIP accounts for as much as 50 percent of the total protein of the lens fiber cell membrane and has not been detected in any other cells in the body. When the MIP cDNA was first cloned and sequenced it encoded a protein sequence that was unrelated to any known protein.¹⁴⁴ Later, when the aquaporin family of water channel proteins was identified, MIP was recognized to be its "founding" member.¹⁴⁵ In spite of its strong structural resemblance to the other aquaporins, MIP is a relatively inefficient water channel and may play a more important role in cell-cell adhesion.^{146,147} Mutations in the MIP gene lead to cataracts in mice and humans.^{148,149} These mutations could cause cataracts because they reduce MIP function, or because they interfere with the formation or function of lens fiber cell membranes.¹⁴⁸

The gap junctions of the lens are assembled from a unique set of subunits, or connexins. The cell-to-cell transport of small molecules (< 1 kDa) mediated by these gap junctions is likely to be important for the function of the lens, since most of the fiber cells are far from the nutrients supplied by the aqueous and vitreous humors.¹⁵⁰ Not surprisingly, lens fiber cells have the highest concentration of gap junction plaques of any cells in the body (Fig. 5.8).

There are three connexins found in lens cells, $\alpha 1$, $\alpha 3$, and $\alpha 8$. Connexin $\alpha 1$ (also known as Cx43) is found in many tissues in the body. In the lens, it is present only in the epithelial cells.¹⁵¹ Connexins $\alpha 3$ (Cx46) and $\alpha 8$ (Cx50) are abundant in fiber cells, but $\alpha 8$ is also expressed in lens

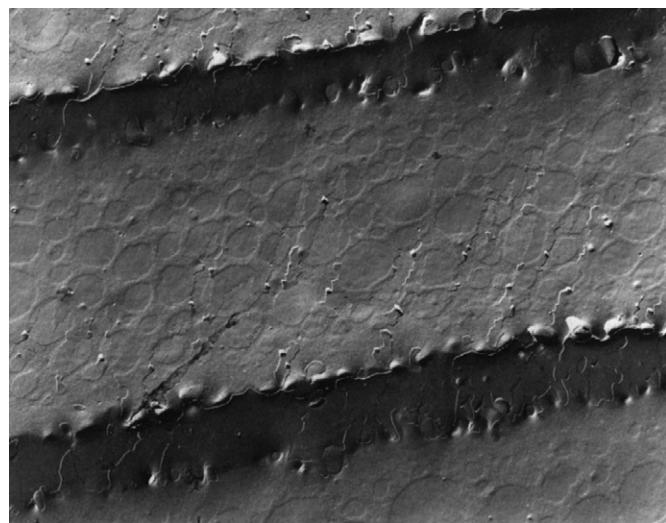

Figure 5.8 Scanning electron micrograph showing the abundant gap junction plaques on the surface of young lens fiber cells (magnification $\times 270,000$). Horwitz, The distribution of the main intrinsic membrane polypeptide in ocular lens. *Curr Eye Res*, 1985. 4(11): p. 1203-18. p 1204⁴⁸²)

epithelial cells.^{152,153} In mice, epithelial α 8-containing gap junctions are required for maximal proliferation of the epithelial cells in the first weeks of postnatal life.^{154,155} Gap junction plaques containing both connexins α 3 and α 8 are present along the lateral membranes of lens fiber cells.¹⁵⁶ Mutations in α 3 or α 8 are responsible for dominant congenital cataracts in several families.¹⁵⁷

While the presence of a large number of gap junctions would seem to be essential for the normal function of the lens, recent studies have shown that the lenses of mice lacking either the connexin α 3 or α 8 gene are relatively mildly affected. In the case of the α 3 knockouts, fiber cell differentiation proceeds normally, although nuclear cataracts appear shortly after birth.¹⁵² However, no cataracts form when the disrupted α 3 connexin gene is bred onto a different genetic background, indicating that genetic modifiers can compensate for the absence of this connexin in maintaining lens transparency.¹⁵⁸ The lenses of the α 8 knockouts develop diffuse nuclear cataracts.¹⁵⁴ Considering the abundance of specialized connexins in the lens, these phenotypes seem surprisingly mild. Mouse lenses lacking α 3 and α 8 have more severe cataracts, suggesting that the functions of these proteins partially overlap.¹⁵⁹

A second pathway, which mediates the diffusion of larger molecules between lens cells has also been described. In chicken embryos, fiber cells fuse with their neighbors late in their differentiation, just before they degrade their organelles.¹⁶⁰ Fiber cell fusions have been described in previous morphological studies in the lenses of several species.^{161,162} Examination of fiber cell fusions in postnatal mouse lenses suggests that they mainly mediate the diffusion of proteins between fiber cells at a similar depth in the lens, rather than providing a diffusion pathway between more superficial and deeper fiber cells.¹⁶³

The second most abundant protein in the lens fiber cell membrane is MP20 (Lim2). The sequence of MP20 places it in the tetraspanin family of proteins, with diverse functions in many cell types. Mutations in this gene lead to the formation of congenital cataracts in mice and humans. Knockout of *Lim2* causes cataracts and defects in the lens refractive gradient.^{164,165} The fiber cells in these lenses fail to fuse with their neighbors to establish the normal intercellular macromolecular diffusion pathway.¹⁶⁶

Lens fiber cells are linked to their neighbors all along their lateral membranes by N-cadherin, a calcium-dependent, homophilic cell adhesion molecule.^{167,168} N-cadherin is typically linked to the actin cytoskeleton by a complex of proteins that includes α - and β -catenin. As the lens changes shape during accommodation, the lateral membranes of the fiber cells are held together tightly by interlocking ball-and-socket junctions and N-cadherin-containing cell-cell adhesion complexes. These adhesion complexes, along with Lim2, which has a role in cell-cell adhesion in the lens, are likely to contribute to the close association between the lateral membranes of lens fiber cells. Minimizing the extracellular space is important for reducing light scattering to maximize transparency.

In addition to the lateral cell adhesion complexes, lens fiber cells are joined tightly to each other at their apical and basal ends.¹⁶⁸⁻¹⁷⁰ These complexes contain abundant N-cadherin and vinculin, a protein that plays an important role in regulating the interaction between adhesion molecules

and the actin cytoskeleton. Membrane complexes at the basal ends of the lens fiber cells, along the posterior capsule, probably attach the fiber cells to the capsule, since they contain a rich actin cytoskeleton, the contractile protein myosin, and integrin extracellular matrix receptors.^{169,171} It is possible that the basal membrane complex also plays a role in the migration of the basal ends of the lens fiber cells towards the sutures.¹⁶⁹

The lens grows by progressively adding new layers of fiber cells to its outer surface. These new fiber cells elongate, gradually extending their apical and basal ends towards the sutures. Once the tips of an elongating fiber cell reach the sutures they meet a fiber cell coming from the opposite side of the lens. The cells then form new junctions at the apical and basal ends and detach from the posterior capsule (see Fig. 5.1). After they detach from the capsule, the fiber cells are gradually buried deeper within the lens by successive layers of "younger" fiber cells.

Soon after they detach from the posterior capsule, fiber cells suddenly degrade all of their membrane-bound organelles, including their mitochondria, endoplasmic reticulum, and nuclei.^{2,3,5,172} Organelle degradation is complete within a few hours.³ The mechanism responsible for organelle degradation in lens fiber cells is not known, although it has been suggested that the enzyme 15-lipoxygenase mediates organelle loss in the lens, as it does during the maturation of erythrocytes.¹⁷³

Numerous studies have pointed to the similarity between organelle degradation in the lens and the initiation of apoptosis (programmed cell death) in many other cell types. Although several biochemical similarities are striking, mice lacking the "executioner" caspases 3, 6 and 7 (which are critical mediators of apoptosis) showed normal organelle degradation.¹⁷⁴ Knockout of the lysosomal enzyme, DNase II β , revealed that it plays a role in the removal of DNA fragments remaining after nuclear membrane fragmentation, but is not required for the initiation of organelle breakdown.¹⁷⁵ Mice lacking the heat shock transcription factor, HSF4, have cataracts and failure of proper organelle loss, raising the possibility that HSF4 controls this process.^{176,177}

In primates, the outer shell of fiber cells that contain organelles is only about 100 microns wide. These organelle-containing cells are located, for the most part, outside of the optical axis of the lens (see Fig. 5.1).⁴ The absence of organelles in most lens fibers increases transparency by reducing light scattering.¹⁷⁵ However, organelle loss also makes the fiber cells in the center of the lens dependent on the superficial fiber cells, an arrangement that may contribute to age-related cataract formation (see below).

The control of lens growth

The human lens grows rapidly in the embryo and during the first postnatal year. The rate of lens growth slows between ages 1 and 10, then continues at a much slower, nearly linear rate throughout life (see Fig. 5.5).^{6,178} The factors that regulate lens growth in humans are not known. Many growth factors have been shown to stimulate lens epithelial cell proliferation in vitro and the receptors for several families of growth factors have been identified in the human lens and in the lenses of other species. These include the fibroblast growth factor family,¹⁷⁹ the insulin-like growth factor

family,¹⁷⁹ the epidermal growth factor family,^{179,180} platelet-derived growth factor,^{180,181} hepatocyte growth factor,^{180,182} and vascular endothelial cell growth factor.¹⁸³ In addition to these growth factor receptors, there are a variety of other kinds of receptors, including muscarinic acetylcholine receptors and purinergic receptors.^{184,185} It is not known whether any of these signaling systems is essential for lens growth *in vivo*. In this regard, deletion of EGF, PDGF, FGF or IGF receptors has not been associated with defects in lens growth or development.^{184,186}

Recent studies revealed an endogenous system regulating the growth of rodent lenses *in vivo*. The environment around the lens is severely hypoxic. When mice or rats breathed increased amounts of oxygen, oxygen levels increased in the eye. In older animals, oxygen treatment was associated with a more than three-fold increase in lens epithelial cell proliferation and long-term treatment led to greater lens wet weight.¹⁸⁷ Younger lenses were not affected by oxygen levels and breathing lower oxygen did not alter lens growth at either age. These results suggest that the low oxygen levels that normally exist in the eye are required for the decline in lens growth that normally occurs with age. Subsequent studies showed that this decline probably required the oxygen-regulated transcription factor, HIF-1, since expressing oxygen-insensitive forms of HIF in lens epithelial cells suppressed the effect of oxygen on their rate of proliferation.¹⁸⁸ Since lens size is an important risk factor for age-related cataracts,^{189–192} understanding how HIF-1 suppresses lens growth is likely to have clinical relevance.

Communication between lens epithelial and fiber cells

The apical ends of the lens epithelial cells abut the apical ends of elongating fiber cells. It has been suggested that nutrients are provided to the underlying fiber cells through gap junctions linking the apposed ends of these cells.^{150,154,193} Other studies have questioned this interpretation, since gap junctions are rarely detected at the apical ends of central epithelial cells.^{153,194} Since the peripheral fiber cells contain a full complement of organelles, it is unclear whether transport from the epithelium is necessary for lens viability. The possibility that the lens does not require gap junction communication between the epithelial and fiber cells is supported by studies in which the main lens epithelial connexin, Cx43, was deleted in the lens and ciliary body. Although loss of this connexin in the ciliary epithelium reduced the production of aqueous humor, the lenses appeared normal.¹⁹⁵ However, damage to lens epithelial cells compromises the viability of underlying lens fibers.¹⁹⁶ Whether this is due to the absence of metabolites provided by the epithelium, or to some other role of the epithelium has not been determined.

Vascular support during lens development

Soon after it is formed, the lens becomes covered with a meshwork of capillaries. In the posterior of the lens this network, the tunica vasculosa lentis, arises from the hyaloid artery. The capillaries at the anterior of the lens arise from blood vessels of the developing iris stroma to form the anterior pupillary membrane. These capillary networks join with

each other near the lens equator. It has been assumed the fetal vasculature is important for normal lens development, although similar vessels are never present around the lenses of non-mammalian species. Deletion of vascular endothelial growth factor (VEGF-A) from the lens prevented the formation of the fetal vasculature, resulting in smaller lenses with transient nuclear cataracts.¹⁸³ Since mouse lens cells express functional VEGF receptors,¹⁹⁷ further studies are required to determine whether these cataracts were due to loss of VEGF signaling to lens cells, to the absences of the fetal vasculature, or both.

During the second trimester of human development, the capillaries of the tunica vasculosa lentis and the anterior pupillary membrane regress.¹⁹⁸ Decreasing levels of plasma-derived vascular endothelial cell growth factor may be one of the factors involved in the normal regression of these vessels.¹⁹⁹ Macrophages in the vitreous body also appear to play an essential role in capillary regression.^{198,200} In mice, these macrophages cause the programmed death of the endothelial cells by secreting the morphogen, Wnt7b.²⁰¹

A number of hereditary and acquired ocular diseases are accompanied by persistence of the fetal vasculature (see review²⁰²). At present, it is not clear why the fetal vasculature fails to regress in so many different syndromes and hereditary diseases. Better understanding of the factors that regulate vascular regression in normal ocular development is needed to address this question.

The lens as the organizer of the anterior segment

Studies performed in the 1960s and extended in the last decade show that the lens plays an important role in the development of the other tissues of the anterior segment.^{51,203–206} Absence of the lens at an early stage of embryogenesis leads to the absence of the corneal endothelium, abnormal differentiation of the corneal stroma, and absence of the iris, ciliary body, and anterior chamber.^{51,204–207} Therefore, the lens not only receives signals from its environment, but sends signals to nearby tissues that are essential for their normal development. The nature of these signals is unknown.

Special problems of lens cell metabolism

Overview

The lens, like all biological systems, is subjected to oxidative stress. Oxidation can be caused by molecular oxygen or free radicals. Oxygen free radicals are generated by the normal activity of mitochondria,²⁰⁸ by other metabolic processes, and by the absorption of light. To counteract the effects of oxidation, all cells maintain a reducing environment in their cytoplasm. The generation of reducing equivalents requires the expenditure of energy and, therefore, presents an especially difficult problem for the deeper lens fiber cells, which lack mitochondria. Enzyme systems in these deeper cells are also less active or inactive, since, in older lenses, they would have been synthesized decades earlier. For this reason, central fiber cells maintain a precarious balance between the catastrophic damage that would be caused by the unchecked

oxidation of membrane lipids and cytoplasmic proteins and the diffusion from the more superficial cells in the lens of molecules that protect against oxidative damage.^{209,210}

The unique structure of the lens creates special problems for the majority of fiber cells that do not contact the lens epithelium or capsule. Nutrients must reach these cells by diffusion, either between cells or through specialized cell-cell junctions. To reduce light scattering and maintain transparency, lens fiber cells must maintain a very small extracellular space. Therefore, nutrient and metabolite transport is more likely to occur through cells, rather than between them. This predicts that metabolites will accumulate in the center of the lens and that diffusion will limit the availability of nutrients and essential metabolites to cells deeper in the lens. Mature fiber cells do not synthesize proteins and must deal with the consequences of molecular senescence without the capacity for repair.

The lens derives much of its energy from glycolysis.^{211,212} The end product of glycolysis is lactic acid. As a result of lactate accumulation, intracellular pH drops significantly from peripheral to deeper fiber cells.^{213,214} As a result, pH-sensitive processes will be differentially affected in different regions of the lens.²¹⁵ Gap junction conductance is one of the systems in the lens that could be affected, since gap junction permeability is generally decreased at low pH. Interestingly, lens connexins do not decrease their conductance in response to the decreased pH in the mature fiber cells of the mouse lens.^{216,217} This adaptation preserves a diffusion pathway from the lens periphery to its center.²¹⁷ Other structural and metabolic adaptations to the standing pH gradient in the lens are likely to exist.

Another problem that the lens faces is the need to maintain protein stability for many decades. Once the lens is formed, proteins are synthesized only in the superficial fiber cells. Therefore, proteins made during embryogenesis in humans may have to last for more than 100 years. Accumulated damage leads to loss of enzymatic activity. Altering the structure of the crystallins, cytoskeletal proteins, and enzymes also increases their propensity for aggregation, a process that can lead to cataract formation.

Oxidants within and around the lens

All of the cells of the body exist in an oxidizing environment. Molecular oxygen is, directly or indirectly, the source of most oxidative damage. If cells could survive in an atmosphere free of oxygen, most oxidative damage could be avoided. For most cells this is not possible. However, human lenses can be maintained in an atmosphere of pure nitrogen for some time, as long as adequate amounts of glucose are provided.²¹⁸ This is possible because the lens obtains much of its energy from glycolysis.^{211,212}

The oxygen tension around the lens in the living eye is quite low, <15 mmHg (~2% O₂) just anterior to the lens and <9 mmHg (~1.3% O₂) near its posterior surface.^{219–224} Oxygen levels within the human lens are even lower (<2 mmHg).²²⁵ The low oxygen tension around and within the lens helps to protect lens proteins and lipids from oxidative damage. Even with this low level of oxygen, the lens normally derives a proportion of its ATP from oxidative phosphorylation,²¹¹ a process that, of necessity, generates free radicals.²⁰⁸

Hydrogen peroxide is another molecule that has been suggested to cause oxidative stress to the lens. Hydrogen peroxide is produced in mitochondria by the enzyme superoxide dismutase acting on superoxide anion, a byproduct of oxidative phosphorylation. Hydrogen peroxide can also be produced during the oxidation of ascorbic acid, which is present at high levels in the aqueous and vitreous humors (approximately 1.5–2.5 mM). Both processes may contribute to the hydrogen peroxide that has been reported within the intraocular fluids and lens.^{226,227} The level of hydrogen peroxide in the aqueous humor has been reported to average over 30 μM and to exceed 200 μM in about one-third of cataract patients.^{226,228} However, recent studies have suggested that, for methodological reasons, the level of hydrogen peroxide in aqueous humor was overestimated in these earlier studies.^{229–231} Ascorbate interferes with some assays of hydrogen peroxide and aqueous humor produces hydrogen peroxide when exposed to air.^{229,231} Careful re-examination of the levels of hydrogen peroxide around and within the human lens using methods not subject to these errors is needed.

The lens is exposed to solar irradiation throughout its life. Although the most energetic and potentially harmful ultraviolet light that reaches the eye is absorbed by the cornea, the remaining solar radiation could have harmful effects, especially on the metabolically vulnerable fiber cells.²³² If light is not absorbed, it produces no damage. However, ultraviolet light is readily absorbed by a number of cellular constituents, including DNA, proteins, nucleoside-containing metabolites, flavinoids and pigments. Flavonoids and pigments also absorb visible light, especially the shorter wavelengths of visible light. All of these interactions are potential sources of free radicals. Free radicals oxidize DNA, lipids, and proteins. Whether or not free radicals are produced by the absorption of light depends upon the chemical nature of the molecule that is interacting with light and the molecular environment.

In spite of its exposure to light throughout life and the presence of abundant targets for light damage, there is no evidence for the photo-oxidation of proteins in the central region of the lens, even in lenses from older individuals.^{233,234} It is likely that lens constituents are protected against the harmful effects of light-generated free radicals by the high intracellular concentration of reducing substances (see below), and by the low concentration of oxygen around and within the lens.^{221,222,224,225}

Protection against oxidative damage

Glutathione, a tripeptide of the amino acids glutamine, cysteine, and glycine, provides most of the protection against oxidative damage in the lens. It can prevent the oxidation of components of the lens cytoplasm because its concentration in the lens is very high, approximately 4–6 mM, and its sulphydryl group is readily oxidized. When glutathione levels have been lowered in lens epithelial cells or whole lenses, cell damage and cataract formation follow rapidly.^{235–237}

Lens epithelial and superficial fiber cells can synthesize glutathione and glutathione can be transported into lens from the aqueous humor.^{237–239} Reduced glutathione (GSH) is regenerated from oxidized glutathione (GSSG) by glutathione reductase and NADPH (Fig. 5.9).²³⁷ Much of the

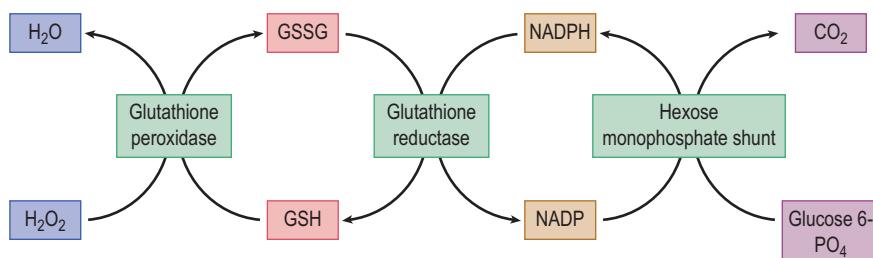

Figure 5.9 Diagram showing the major reactions responsible for the reduction of glutathione (right side) and the use of glutathione to reduce hydrogen peroxide (left side).

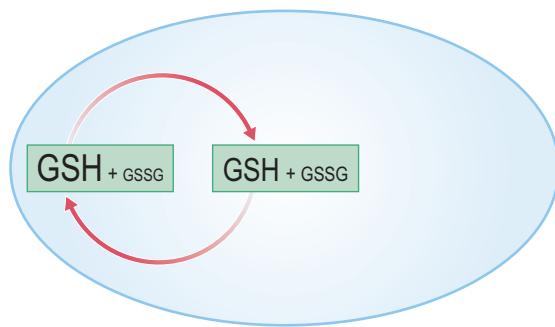

Figure 5.10 Diagrammatic representation of the distribution of reduced glutathione (GSH) and oxidized glutathione disulfide (GSSG) in the adult human lens. An increased fraction of glutathione is in the oxidized form in the center of the lens, a situation that is often increased in the aging lens.

NADPH in the lens is produced by the hexose monophosphate shunt, the activity of which is important for the continued production of reduced glutathione.²¹²

However, fiber cells deeper in the lens have minimal capacity for the synthesis or reduction of glutathione. They must obtain most of their reduced glutathione by diffusion from more superficial fiber cells.^{237,240} Glutathione can form disulfide bonds with the oxidized sulfhydryl groups of proteins. These glutathione-protein mixed disulfides can then be reduced by a second molecule of glutathione, a process that is facilitated by the enzyme thioltransferase.²⁴¹ This regenerates the protein sulfhydryl and forms GSSG (two molecules of glutathione linked by a disulfide bond). The GSSG that results from this process must then diffuse to more superficial layers of the lens where it can be reduced to regenerate GSH (Fig. 5.10). It is likely that this two-way diffusion is the rate-limiting step in maintaining a reducing environment in the center of the lens.^{209,210} The rate of diffusion between the superficial and deeper layers of the lens diminishes with age.²⁴⁰ Therefore, proteins and lipids in the nuclei of older lenses may be more susceptible to oxidative injury than those in younger lenses.

Ascorbic acid is also likely to protect the lens against oxidative damage. Ascorbate is actively transported from the blood to the aqueous humor by a sodium-dependent transporter located in the ciliary epithelium²⁴² and reaches concentrations in the aqueous humor that are 40–50 times higher than levels in the blood.²⁴³ The ascorbate levels in the lens and other intraocular tissues are also substantial.^{244,245} Dehydroascorbate, the oxidized form of ascorbic acid, enters lens cells by way of the glucose transporter, where it is reduced by glutathione-dependent processes.^{243,246} Like

glutathione, ascorbate is readily oxidized, forming dehydroascorbic acid in the process. Therefore, ascorbate can react with free radicals and other oxidants in the aqueous humor and the lens, preventing these molecules from damaging lens lipids, proteins, and nucleic acids. On the other hand, if dehydroascorbate accumulates in the lens, its metabolites can react with lens proteins, increasing lens color and decreasing protein stability.²⁴⁵ The high GSH levels in the lens are likely to maintain most ascorbate in its reduced state, thereby avoiding much of this potential damage.

The lens has two enzyme systems to detoxify hydrogen peroxide. Lens epithelial cells have abundant levels of catalase, which converts hydrogen peroxide to water,²⁴⁷ and glutathione peroxidase, an enzyme that couples the reduction of hydrogen peroxide to the oxidation of glutathione. Studies on cultured lenses and lens epithelial cells suggest that glutathione peroxidase provides most of the protection against the potential damaging effects of physiological levels of hydrogen peroxide, as catalase is only effective against relatively high concentrations of peroxide.²⁴⁸

Energy production in the lens

Due to the lack of blood supply, the oxygen concentration within and around the lens is much lower than in most other parts of the body.^{219,221,222,224,225} The lens, therefore, depends on glycolytic metabolism to produce much of the ATP and the reducing equivalents required for its metabolic activities.^{211,218} The glucose required for glycolytic metabolism is derived from the aqueous humor. Aqueous humor glucose levels are maintained by facilitated diffusion across the ciliary epithelium.

However, lens epithelial cells and superficial fiber cells also contain mitochondria. Therefore, cells near the surface of the lens use both glycolytic and oxidative pathways to derive energy from glucose. About 50 percent of the ATP produced by rabbit lens epithelial cells is derived from oxidative metabolism, while glycolysis accounts for nearly all the ATP produced in lens fiber cells.²¹¹

Water and electrolyte balance

Due to its high protein concentration and the lack of a blood supply, the lens faces special problems in regulating its water content and in providing nutrients and antioxidants to cells deeper in the lens.²⁴⁹ Protein concentration increases as one goes from the more superficial fiber cells to fiber cells deeper

in the lens.¹⁰ However, this protein gradient is not associated with a reciprocal gradient in the osmotic activity of water, because there is no tendency of water to flow into the cells of the lens nucleus. The mechanism by which this large potential osmotic gradient is neutralized is not known. Decreased protein osmotic activity might result from the increase in the short-range interactions between protein molecules that contributes to lens transparency.¹² The mechanism by which proteins can be concentrated in osmotically neutral manner remains an important unsolved question in the biophysics of the lens.

Several studies provide evidence for an ionic circulation within and around the lens. Vibrating electrodes detect gradients of electrical potential around the lens.^{250,251} Positive charges flow into the lens near the anterior and posterior sutures and out at the equator. Like most cells, the membranes of lens epithelial and superficial fiber cells contain sodium, potassium-activated ATPase activity. This Na⁺, K⁺-ATPase generates an electrochemical gradient across the surface membranes of the lens, with the interior of the lens more negative than the extracellular space. The electrochemical potential tends to drive positive charges, largely sodium ions, into lens cells. This appears to be the origin of the inward positive current at the sutures.^{250–252} The positive current flowing out at the lens equator is likely to be carried by potassium ions.²⁵²

A model that takes into account the electrical and biophysical properties of the lens predicted that water will follow the flow of ions into and out of the lens, creating an internal circulation system.²⁵³ While this is an appealing theory, direct evidence for water flow through the lens fiber cell cytoplasm has not been provided. Numerous studies in which fluorescent dyes were injected into fiber cells have, so far, failed to detect the directed, bulk movement of water that would be predicted by this model. Other studies detected inward flow of water across the lens epithelium and the whole lens, suggesting net flow of water from the anterior chamber to the vitreous body.²⁵⁴ The importance to lens physiology of this potential flow has not been tested.

The transmembrane potential of the human lens decreases steadily with age.²⁵⁵ This decrease is caused by an increase in the permeability of the fiber cell membranes to sodium and calcium ions through non-selective cation channels. It is not clear whether the increased cation permeability is due to increased numbers of these channels, to the appearance of the new type of channel, or to an increase in the activity (open probability) of pre-existing channels. The increase in cation permeability is balanced by an increase in the activity of membrane ATPases, which remove sodium and calcium from lens cells. In spite of the increased pump activity, free sodium and calcium levels increase in the cytoplasm of older lenses.²⁵⁵ Since the transmembrane potential of all cells indirectly provides the driving force for the transport of many metabolites and nutrients, the age-related decrease in the transmembrane potential of the lens may have important consequences for lens metabolism and ionic homeostasis. Elevated calcium levels can also lead to metabolic disturbances and destruction of cell components through the activation of calcium-sensitive proteases.²⁵⁶

Like all cells, lens epithelial and fiber cells maintain a much lower concentration of free calcium ions in their cytoplasm than is found in the extracellular space. However, free

calcium levels measured in fiber cell cytoplasm are substantially higher than the levels in epithelial cells.^{255,257} In addition, there appears to be a gradient of free calcium that decreases from the posterior to the anterior ends of lens fiber cells.²⁵⁷ These observations are consistent with the view that calcium slowly leaks into lens fiber cells and is removed by membrane pumps at the lens surface. The activity of these pumps in maintaining low cytoplasm calcium concentrations is important, because treatments that abruptly raise free calcium levels lead to rapid degradation of the lens fiber cell cytoskeleton, uncontrolled proteolysis, cell swelling, and opacification.^{256,258–262}

Lens epithelial cells transport nutrients into their cytoplasm from the aqueous humor. Although the transport of small molecules from epithelial cells to fiber cells has been demonstrated,^{154,193} the relative importance of this pathway in providing nutrients to the fiber cells, compared to transport directly across the surface membranes of superficial fiber cells, has not been determined. When metabolite transporters have been examined in lens fiber cells, these molecules have usually been found. The distribution of glucose transporters in the lens illustrates this issue. Lens epithelial cells express abundant levels of the glucose transporter, glut1, that is presumably used for the uptake of glucose from the aqueous humor.²⁶³ Although fiber cells express little glut1, they express large amounts of the higher-affinity glucose transporter, glut3. Therefore, fiber cells can transport glucose into their cytoplasm from the extracellular milieu, a finding that raises questions about the relative importance of the epithelial cells in providing glucose to the fiber cells.

Lens transparency and refraction

Vertebrate lenses are remarkably effective optical devices. An efficient lens must be transparent to the wavelengths of light that can be detected by the photoreceptors, have a focal point that is appropriate for the optical system in which it functions, and have a minimum of spherical and chromatic aberration. Lens transparency depends on the organization of the cells of the lens and of the distribution of the proteins within them. The precise organization of the fiber cells, their high protein concentration, and the absence of organelles from the fiber cells that lie in the optical axis assures that a minimum of scattering occurs as light passes through the lens.

The cellular and molecular interactions responsible for establishing and maintaining the curvature of the lens surfaces are not known. Studies in chicken embryos demonstrated that influences from outside the lens normally regulate its shape and rate of growth.³⁹ Lenses in different species range from nearly spherical (rodents) to an axial ratio of more than 2:1 (humans). As the human lens grows, the radii of curvature of its anterior and posterior surfaces decrease significantly.²⁶⁴ In spite of this, the focal point of the lens remains remarkably constant, suggesting that the refractive power of the lens cytoplasm changes in a way that compensates for the change in curvature of the refractive surfaces. Control of lens shape is one of the most fascinating unanswered (and little explored) aspects of lens biology.

The high protein concentration of the lens fiber cells causes the refractive index of the lens to be higher than that

of the fluid around it. Fiber cells close to the surface of the lens have a lower protein concentration than fiber cells deeper in the lens, creating a gradient of refractive index that at least partially corrects for spherical aberration.^{265–267}

Although the human lens is transparent to most wavelengths of visible light, it produces and accumulates chromophores that absorb the shortest wavelengths of the visible spectrum. At birth, the human lens is a pale yellow color. With increasing age the amount of yellow pigmentation in the lens increases. This pigmentation absorbs the shorter, more energetic wavelengths of light, preventing them from reaching the retina. The predominant yellow chromophores in the young human lens are metabolites of tryptophan, especially N-formyl kynurenine glucoside.¹⁴ With aging, an increasing variety of soluble and protein-bound chromophores are found in the lens fiber cells.^{268,269} When especially high concentrations of these chromophores accumulate, they can reduce visual acuity by increasing light absorbance, leading to the formation of what is termed a “brunescence” cataract. The factors responsible for the excessive accumulation of chromophores in some lenses are not known, although recent studies have suggested that the oxidative modification of proteins may play a significant role.²⁶⁸ Brunescence cataract is more common in rural areas and in developing countries, a factor that suggests that nutritional or environmental factors, like cooking smoke, may also be important.²⁷⁰

Changes in the lens with aging

Fiber cells in the center of an adult lens were produced during early embryonic life, while those at the surface of the lens may be weeks or months old. Many have touted the lens as a valuable model system for studying aging. However, unique properties of the lens, especially the lens fibers, make it an inappropriate model for aging in most cell types. Gene expression and protein synthesis cease at about the time that the fiber cells degrade their organelles.⁷ In nearly all other cell types, RNA and protein synthesis and turnover continue throughout life.

To follow changes in the composition of the lens that are related to age, one must correlate changes in fiber cells from lenses of different ages and from different layers of the same lens. Using this approach it was shown that, in the human lens, many of the soluble crystallins are sequentially truncated by proteolysis over a period of months to years.²⁷¹ Some of the β -crystallins are degraded relatively rapidly, while other crystallins much more slowly. However, by the end of the first 20 years of life, most of the crystallins appear to reach a steady state after which little additional degradation occurs. Therefore, in older lenses, crystallins in the center of the lens and crystallins a short distance from the surface of the lens show similar degrees of proteolysis.^{271–273} These studies only examined changes in soluble crystallins. Further studies may show that crystallins in the insoluble fraction are more extensively degraded.

The proteins of the lens are often characterized by their relative solubility, typically being separated into fractions that are water-soluble, urea-soluble, and “insoluble”. As one goes from more superficial to deeper fiber cells, an increasing percentage of the crystallins are found in the insoluble

fraction. In addition, when one separates the water-soluble crystallins by size, an increasing proportion is found in high molecular aggregates. Therefore, there is a general tendency for proteins to become aggregated and less soluble in the older fiber cells.^{274,275} Alpha-crystallin is a good example. In the lens nucleus from individuals of increasing age, one finds decreasing amounts of soluble α -crystallin. By age 45, no α -crystallin is detectable in the water-soluble fraction from the lens nucleus.^{276,277}

The gradual insolubilization of α -crystallin is likely to be related to its function as a molecular chaperone.¹⁰⁰ When lens proteins are partially unfolded, hydrophobic domains are exposed. Alpha-crystallin binds to these hydrophobic regions, presumably preventing uncontrolled protein aggregation. It seems likely that accumulated damage to the crystallins and other proteins leads to increased association with α -crystallin. Interestingly, in spite of the loss of soluble α -crystallin, one does not see a precipitous increase in the rate of protein aggregation in the lens nucleus after age 45.

Another age-related change seen in crystallin structure is the increasing racemization of aspartic acid, methionine and tyrosine, and the deamidation of glutamine and asparagine.^{272,273,278–280} Racemization and deamidation alter protein structure and/or charge. These changes correlate well with age, but do not differ significantly in clear and cataractous lenses of the same age.

Some components of the lens fiber cell cytoskeleton are disassembled in older fiber cells. Vimentin intermediate filaments are degraded in the deeper lens cortex, well after the loss of membrane-bound organelles.²⁸¹ Beaded filaments composed of phakinin and filensin persist into the lens nucleus and may last for the life of the lens.¹³³ Actin microfilaments also appear to survive in the oldest fiber cells, although the persistence and continued association of these filaments with the plasma membrane has been questioned.^{282–284} Proteolysis and insolubilization of the components of the cytoskeleton appear to contribute to their disassembly.^{133,281,284}

The structure and development of the lens sutures

Sutures form at the anterior and posterior poles of the lens where fiber cells growing from opposite sides of the lens abut at their apical and basal ends. In some species all fiber cells meet near the midline of the lens, forming an “umbilical” suture.²⁸⁵ In most species, the sutures form along planes. In human embryos, elongated lens fiber cells meet at three planes, forming an upright “Y” at their anterior ends (with respect to the superior-inferior axis of the eye) and an inverted “Y” posteriorly (Fig. 5.11A). As the human lens grows, the suture planes formed by more superficial shells of fibers become increasingly complex. The first evidence of this typically occurs soon after birth, when two new suture planes form at the ends of each of the three branches of the Y sutures (Fig. 5.11B). As new fibers are added during lens growth, the branch points of the newly formed sutures gradually “migrate” towards the center, eventually forming a six-pointed “star” suture (Fig. 5.11C).²⁸⁵ Branching again occurs at the tips of each of these six planes, eventually forming a total of 12 suture planes at the anterior and posterior

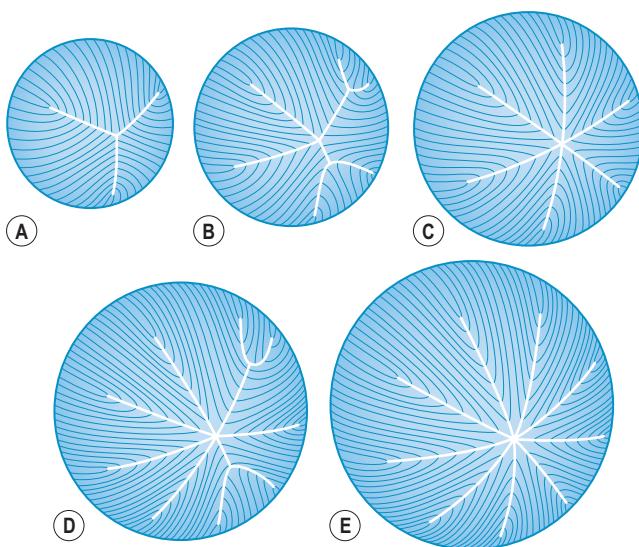

Figure 5.11 Diagram illustrating the increasing complexity of the sutures as the lens grows. The sizes of the lenses depicted are to scale. (A), (B), (C) The tripartite "Y" suture that forms during embryogenesis as a result of secondary fiber cell formation is converted into a six-pointed star suture by the continued deposition of new fiber cells. If one were to peel away the fibers from the lens depicted in (C), the initial tripartite suture pattern would be revealed. (D), (E) Further growth results in the formation of additional suture planes.

surfaces of the lens (Fig. 5.11D, E).²⁸⁵ The increasing geometric complexity of the suture patterns in older human lenses results in lenses with better optical properties than in species that maintain a simple Y suture pattern throughout life.²⁸⁶

The formation and orientation of the sutures provides a challenging problem for developmental, cell, structural and theoretical biologists. The lens appears to be radially symmetrical about the optical axis. Yet, the sutures form in a pattern that breaks this symmetry. The spatial cues that lead to the precise alignment of the suture planes with respect to the axes of the eye and body are not known.

The lens capsule

When the lens placode invaginates from the surface ectoderm early in embryonic life, it is already supported by a thin basal lamina.³⁵ This extracellular matrix surrounds the lens vesicle after it detaches from the surface ectoderm. The lens epithelial and superficial fiber cells continue to secrete the components of the basal lamina, which thickens to become the lens capsule.^{35,36} Examination of the lens capsule in the electron microscope shows that it is composed of multiple laminae, as if the basal lamina had been replicated many times.²⁸⁷ Studies of the synthesis of the lens capsule in experimental animals showed that newly synthesized capsular materials are originally deposited close to the basal ends of epithelial and fiber cells.²⁸⁸ With time, the labeled components of the capsule move farther away from the surface of the cells, as they are displaced by successive layers of newly synthesized capsular material.

Clinical observations have also supported the view that the human lens capsule is synthesized from the inside out.

In certain cases, foreign materials may be deposited in the capsule during its synthesis. These deposits can be viewed in slit lamp or Scheimpflug images.²⁸⁹ Eventually, these deposits disappear from the lens. One interpretation of this observation is that, as new layers are laid down on the inner surface of the capsule, capsular material is lost from the surface of the lens. If this interpretation is correct, the rate of synthesis of components of the capsule at its inner surface and the rate of degradation at its outer surface regulate its thickness. The capsule also must be remodeled during embryonic life, when the surface area of the lens is increasing rapidly.²⁹⁰ The enzymes that are responsible for the degradation or remodeling of the capsule have not been identified.

In keeping with its similarity to typical basal laminae, the lens capsule is composed predominantly of type IV collagen, laminin, entactin (nidogen), and heparan sulfate proteoglycans.^{33,37,287,291} However, studies have shown that some components of the capsule differ in the anterior, posterior, and equatorial regions of the lens.^{288,290,292} In the adult lens the capsule is significantly thicker over the epithelium and thinner over the basal ends of the superficial fiber cells. The factors that regulate the differential distribution and accumulation of the components of the lens capsule remain to be identified. Several diseases are associated with defects in the components of the capsule, including pseudoexfoliation syndrome (lysyl oxidase polymorphisms), Pierson syndrome (laminin- $\beta 2$ mutations) and Alport syndrome (collagen IV mutations).³⁷

The zonules

The zonules (suspensory ligament, zonules of Zinn) are composed of thin fibrils that suspend the lens in the anterior of the eye. Zonular fibers insert into the lens capsule near the equator and into the basal lamina of the non-pigmented layer of the ciliary epithelium (Fig. 5.12).²⁹³ It is likely that the ciliary epithelial cells synthesize the components of these fibrils.⁸ The primary structural protein in zonular fibers is fibrillin.^{8,9,294} Mutations in the fibrillin gene are responsible for Marfan syndrome, in which dislocation of the lens is a common clinical finding.^{295,296}

Examination of the insertion of zonular fibers into the lens capsule shows that these fibers are intimately interwoven with the components of the capsule.^{8,293,297} If, as suggested above, the capsule is continuously degraded at its outer surface, it is unclear how the zonular fibers and capsular fibers maintain their connections.

This is only one of the topological paradoxes associated with the synthesis and maintenance of the zonules. For example, it is also not clear how the components of the fibrils are originally inserted into the lens capsule, especially when they are under tension, or how the zonular fibers are physically attached to the basal lamina of the ciliary epithelial cells while being synthesized by these same cells. Presumably, the zonular fibers establish their attachment between the lens capsule and ciliary epithelium early in development when these basal laminae are in direct contact. If this assumption is correct, it would predict that the number of zonular fibers should not change throughout life. If it is not correct, a mechanism must exist for these fibrils to be assembled across the space between the ciliary

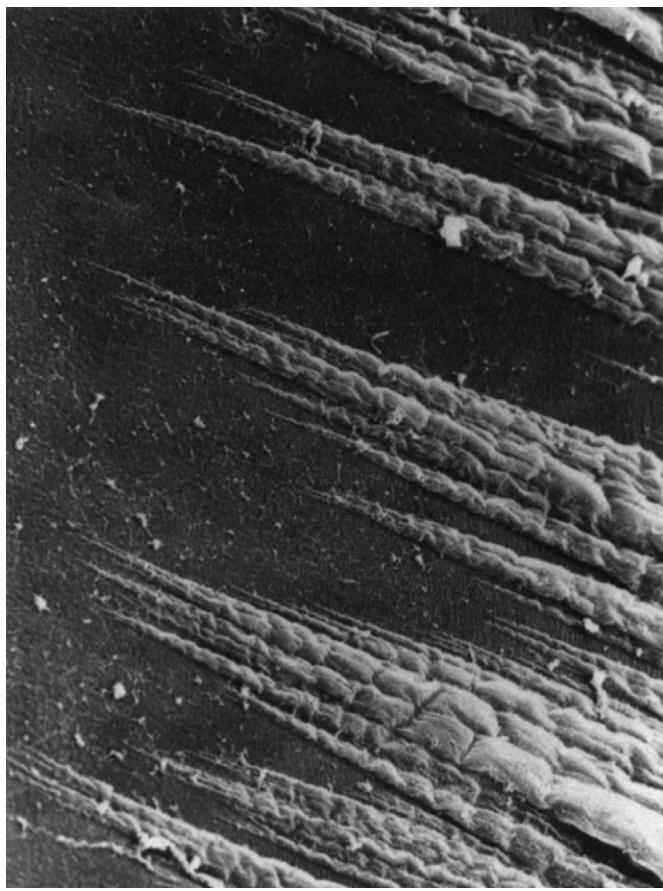

Figure 5.12 Scanning electron micrograph showing tapering bundles of zonular fibers inserting into the lens capsule (magnification $\times 780$). (Reproduced with permission from Streeten, B.W., The zonular insertion: a scanning electron microscopic study. Invest Ophthalmol Vis Sci, 1977. 16(4): p. 364-75. Reproduced with permission from Association for Research in Vision and Ophthalmology²⁹³)

epithelium and the lens capsule, a remarkable feat of bioengineering.

As the lens grows, the position of insertion of the zonules shifts anteriorly.²⁹⁷ Since the zonules are believed to maintain a fixed point of insertion into the lens capsule, this shift has been interpreted as evidence for a relative increase in capsule synthesis at the lens equator.²⁹⁷ It is possible that the age-related anterior shift in the zonular insertion point alters the forces applied on the lens during accommodation and may contribute to presbyopia.²⁹⁷

Cataracts

A cataract is any opacification of the lens. Cataracts are considered to be clinically significant when opacification interferes with visual function. Loss of lens transparency can be due to an increase in light scattering or light absorption. Increased light scattering can be caused by disruption of the structure of lens fiber cells, increases in protein aggregation, phase separation in the lens cell cytoplasm, or by a combination of these processes.

Age-related cataracts are classified based on the region of the lens that is affected (Fig. 5.13). The most common types

of age-related cataracts are nuclear, cortical, and posterior subcapsular. Nuclear cataracts occur in the oldest fiber cells near the center of the adult lens – those formed during embryonic and fetal life. Cortical cataracts occur in cells formed later in life. These cataracts typically begin in a sector of the lens cortex, affecting mature cells that have already degraded their organelles. Posterior subcapsular cataracts result from light scattering by a plaque of swollen cells at the posterior pole of the lens.

In addition to age-related cataracts, there is a wide variety of less common cataracts that are usually classified based on their etiology. These include the opacification of the posterior lens capsule that sometimes occurs following cataract surgery, referred to as secondary cataracts, after cataracts, or posterior capsular opacification (PCO).

Cataract epidemiology

The risk factors associated with different types of age-related cataracts provide clues to the environmental factors that promote cataracts or protect against them. Therefore, before considering the mechanisms that may cause age-related cataracts, it is useful to consider the factors that influence the risk of cataracts in human populations. Although epidemiologic factors are often difficult to identify with certainty, especially for a disease that occurs late in life, those factors that are frequently associated with cataracts in human populations are likely to be relevant to the disease mechanism.

General risk factors

Not surprisingly, age is the primary risk factor for the most common kinds of cataract. There is an exponentially increasing incidence of cataract after age 50. One risk factor common to most kinds of cataract is lower socioeconomic status and/or lower education. Since lower socioeconomic status may predispose to nutritional deficiencies, increased exposure to diseases, poor general health status, and increased occupational exposure to cataractogenic agents, it is difficult to determine the specific aspects of lower socioeconomic status that are important for cataract formation.

Sex is also an important influence on the incidence of cataract. Women are at increased risk for most kinds of cataract.²⁹⁸⁻³⁰⁴ Conversely, studies have suggested that estrogen protects against cataract formation in humans and animals and that cataracts may be delayed by late menopause.³⁰⁵⁻³¹⁰ Lowering estrogen function with the anti-estrogen tamoxifen increased the risk of cataracts when used for long duration.^{311,312} The protective effect of estrogen suggested by these studies makes the increased overall levels of cataract in women harder to understand. If estrogen is protective, other factors, as yet unknown, must strongly predispose women to cataract formation. Alternatively, higher levels of male sex steroids may be protective against cataract.

When the influences of age, sex and socioeconomic status are removed, specific risks for different types of cataracts are revealed. Smoking and high alcohol consumption have been identified in several studies as dose-dependent risk factors for nuclear and, in some cases, cortical cataracts.^{304,313-315} Dark iris color is often associated with a higher incidence of all types of lens opacities,^{304,316,317} a finding that may also be related to higher levels of cortical cataract in blacks than whites.³⁰⁰ Exposure to anti-inflammatory steroids and

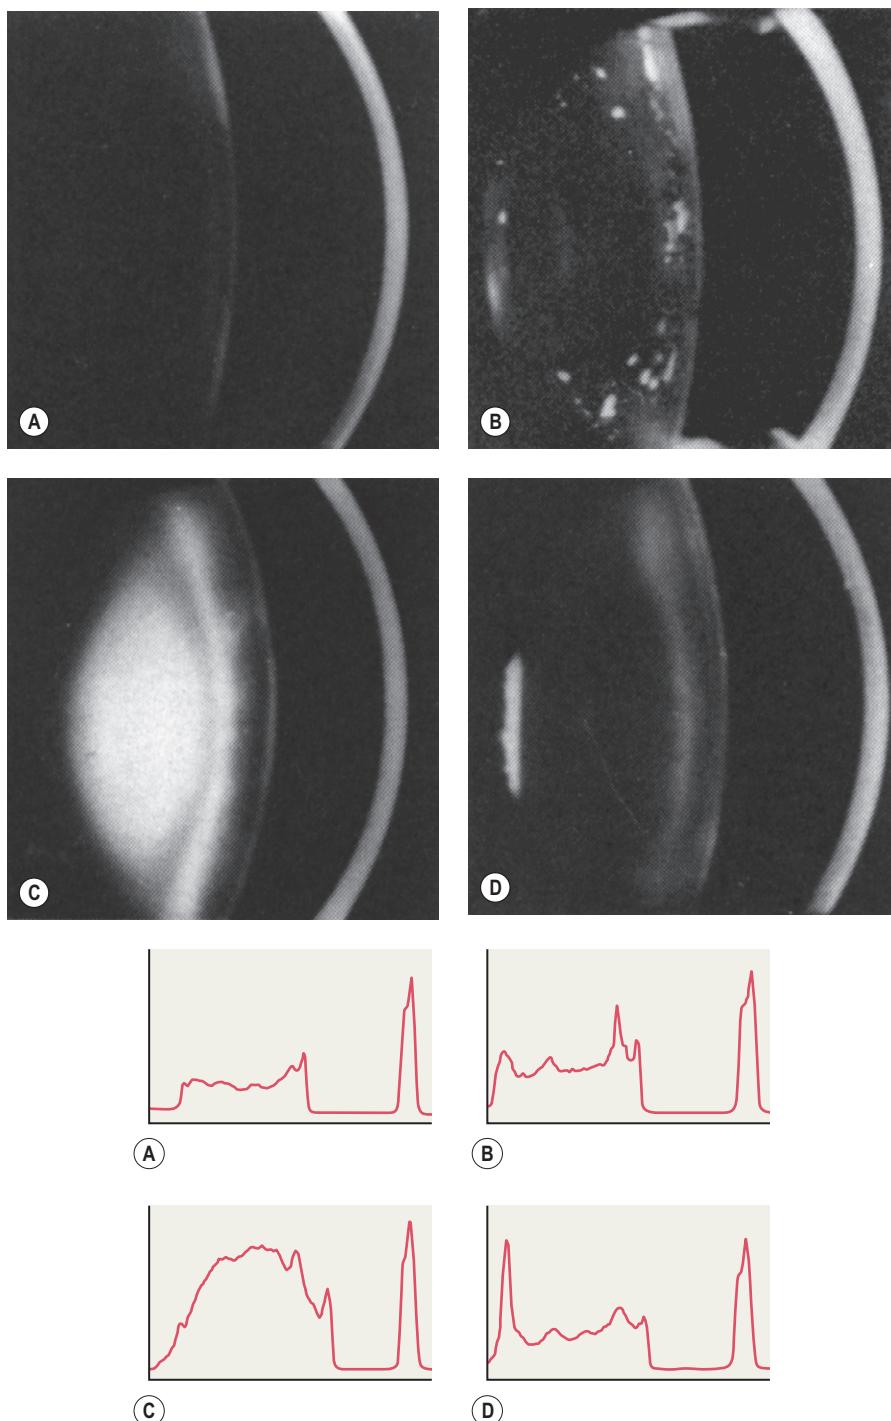

Figure 5.13 Photographs taken using a Scheimpflug camera of the anterior portion of human eyes. Light scattering from the cornea, the lens capsule-epithelium and any opacity in the lens can be seen in the photographs. Scattering intensity is shown in scans of the photographs made with a densitometer. (A) Normal lens. (B) Cortical cataract. (C) Nuclear cataract. (D) Posterior subcapsular cataract.

ionizing radiation are well-recognized risks for posterior subcapsular cataracts. Few additional risk factors have been consistently identified for PSCs. However, this could be the statistical consequence of the generally lower frequency of PSCs than of other types of cataract. Numerous epidemiological studies have identified additional risk factors for cataracts. These are not detailed here, either because their association with cataract was not especially strong, or because they have not been seen in the majority of epidemiological studies of cataract.

Several studies have found an interesting association between cataracts and increased mortality. When confounding

variables, including smoking, age, race, and sex were removed, the presence of clinically significant cataracts remained as a strong, independent predictor of mortality, especially in younger patients with cataract.^{318–321} These findings suggest a connection between cataracts and systemic phenomena influencing survival. Considered in another way, behavioral, nutritional and biochemical factors that prevent age-related cataract formation may lengthen life span. However, other studies failed to find an association between cataract and increased mortality.^{320,322} A recent 5-year follow-up of patients undergoing cataract surgery in the UK in 2000–2001 revealed lower mortality than in the

general population.³²² This paper also provides a thorough compilation of previous studies of cataract and mortality.

Several studies found an association between lens thickness and the most common types of age-related cataract. In the Beaver Dam Eye Study, a comprehensive evaluation of ocular disease in a US population of northern European ancestry, cortical cataracts correlated with thinner and nuclear cataracts with thicker lenses.¹⁸⁹ Five-year follow-up of subjects that initially had clear lenses revealed that having a thinner lens was a risk for developing cortical cataract. Thicker lenses at baseline were associated with increased risk of developing nuclear cataract.¹⁹⁰ Studies in Singapore and India subsequently found similar associations between lens thickness and age-related cataract.^{191,192} Possible reasons for these associations are discussed below in the sections on nuclear and cortical cataracts.

Age-related nuclear cataracts

In the US and most Western countries, nuclear cataracts are most often associated with increased light scattering in the nuclear fiber cells. In many developing countries brunescent nuclear cataracts are more common. These opacities are associated with increased lens color and light absorption. Whether due to light scattering or absorption, nuclear cataract is the most common type in most countries or regions, typically accounting for more than 60 percent of cataract surgery. However, cortical cataracts predominate in some countries or regions, particularly in Asian populations living in temperate climates.

There is abundant evidence that nuclear cataracts are associated with increased oxidative damage to lens proteins and lipids.^{228,237,323–325} The formation of disulfide bonds between protein subunits can lead to aggregation and increased light scattering,²³⁷ although other forms of protein–protein interactions also occur. There is also evidence that crystallins may associate with lens fiber cell membranes in increased amount in nuclear cataracts.^{326–329} The factors responsible for increased oxidation in nuclear cataracts are not fully understood. However the marked age dependence of nuclear cataracts and the concurrent increase in oxidized glutathione in the lens nucleus suggests that the balance between protein and lipid oxidation and glutathione-dependent reduction are likely to be involved (see Box 5.3).^{237,240,330}

Persuasive evidence for an association between oxidation, age, and cataract formation was provided by studies of patients treated with hyperbaric oxygen to alleviate the complications of peripheral vascular disease.³³¹ These individuals were exposed to 2.0–2.5 atmospheres of pure oxygen for one hour each day for up to three years. Of the 25 patients treated in this study, all but one had increased light scatter in the lens nucleus and nearly half developed frank nuclear cataracts. All of the individuals who showed increased light scattering or opacification in the nucleus were over 50 years old. The individual who did not show increased light scatter was 24 years old. Patients of slightly older average age with the same presenting symptoms, but not treated with hyperbaric oxygen, served as the control group. None of the individuals in the control group developed cataracts over the study period. After the termination of treatment, some of the patients who had been treated with hyperbaric oxygen and had developed increased light scatter showed improvements

Box 5.3 Nuclear sclerotic cataracts; oxidation is the key

Nuclear cataract is associated with the oxidative damage to the proteins and lipids, leading to hardening of the lens nucleus and increased light scattering. Hardening of the lens nucleus increases its refractive power, causing a “myopic shift” which is later followed by cataract formation. The lens normally exists in an extremely hypoxic environment. Patients treated with long-term hyperbaric oxygen therapy develop a myopic shift and, eventually, nuclear cataracts. Removal of the vitreous body during retinal surgery increases oxygen levels at the posterior of the lens and leads to rapid-onset nuclear cataracts. Retina surgery performed without vitrectomy avoids cataract formation. The high level of ascorbate (vitamin C) that is present in the ocular fluids reacts with oxygen, reducing oxygen exposure to the lens. Age-related degeneration of the vitreous body is associated with lower ascorbate levels, slower oxygen consumption and increased risk of nuclear cataract. Protecting the lens from exposure to oxygen or preserving the gel structure of the vitreous body could prevent the formation of nuclear cataracts.

in their visual acuity and decreases in the amount of light scattering in their lenses. This result suggests that, even in older individuals, the lens has the capacity to reverse oxidative damage to the components of the nucleus.³³¹

The onset of nuclear cataract formation is often associated with an increase in the refractive power of the lens.³³² For hyperopic patients this “myopic shift” temporarily causes an improvement in their near visual acuity, a phenomenon that is often called “second sight.” This increase in refractive power is associated with hardening of the lens nucleus. It is not surprising that the term “nuclear sclerotic cataract” is used to describe the opacities that soon follow.

Patients treated with hyperbaric oxygen also experience significant myopic shift. As with the light scattering described above, these increases in lens refractive power usually reversed during treatment or soon thereafter.^{331,333,334} This suggests that the hardening of the lens and its increased refractive power, as occurs in nuclear sclerotic cataracts, are caused by oxidative damage to the proteins and lipids of central lens fiber cells. In this case, reducing the source of oxidative damage (hyperbaric oxygen) permitted the lens to recover much of its normal refractive properties.

Isolated lenses and experimental animals have also been treated with hyperbaric oxygen. The results of these studies are in general agreement with the findings in patients receiving hyperbaric oxygen therapy, although frank nuclear opacities are rarely seen. These animal models provide useful tools to study the earlier biochemical effects of oxidative stress on cataract formation.^{335–337}

Studies of patients treated with hyperbaric oxygen suggest that molecular oxygen or a metabolite derived from molecular oxygen contributes to nuclear sclerosis and nuclear cataract formation. Studies of the effect of hyperbaric oxygen on the lens also provide some of the strongest evidence that the cells of the lens nucleus are in a delicate balance between their ability to prevent or reverse oxidative damage and the tendency for oxidation to occur. The fact that hyperbaric oxygen leads to opacification of the lens nucleus, but not the more superficial lens fiber cells, shows that the central fibers

are more susceptible to oxidative damage, even though they are farther away from the source of oxygen. Age-associated decrease in the rate of diffusion of glutathione to the lens nucleus is likely to be part of the reason for this increased susceptibility.^{209,210,237,240,330,338}

Nuclear cataracts occur frequently in older patients within 6 months to 3 years after vitrectomy. Several studies have reported that the incidence of cataracts is as high as 95% 2 years after the removal of the vitreous body.³³⁹⁻³⁴⁷ Evidence is accumulating which suggests that study of post-vitrectomy cataracts may help to understand the general mechanism responsible for the formation of age-related nuclear cataracts.

The appearance of the lens in post-vitrectomy nuclear cataracts is similar to typical age-related nuclear cataracts, the only difference being the rapidity of onset of cataracts after vitrectomy. If one assumes that the etiology of the cataracts in both cases is the same, there is likely to be an increase in oxidative damage in the lens following vitrectomy. The lens is usually not touched during vitrectomy and the time between surgery and cataract formation is at least several months. Therefore, the high incidence of nuclear cataracts after this procedure is probably due to changes in the environment around the lens, not to direct damage to the lens during surgery. Measurement of oxygen near the lens after vitrectomy showed that oxygen levels increased greatly during surgery and remained significantly elevated in the eyes of patients who returned for a second retinal surgery months or years later.²²² When retinal surgery could be performed without damaging the vitreous gel, cataract was prevented, even 5 years after the initial surgery.³⁴⁸ In a related study, eye bank eyes with a greater degree of vitreous degeneration (liquefaction) were more likely to have nuclear opacities than eyes with a more intact vitreous gel. In eyes between 50 and 70, the extent of vitreous liquefaction was a stronger predictor of nuclear opacification than age. Diabetics, who have lower levels of oxygen in the vitreous,²²⁴ also progress to cataract surgery more slowly after vitrectomy than non-diabetics.³⁴⁹ These studies suggest that the vitreous gel protects against nuclear cataract, probably by protecting the lens from exposure to oxygen from the retinal vasculature.

The high concentration of ascorbate in the vitreous body also appears to protect the lens from exposure to oxygen.³⁵⁰ There is usually ~2.0 mM ascorbate in the human vitreous.^{350,351} Degeneration of the vitreous body or prior vitrectomy was associated with a ~40 percent decrease in the mean ascorbate concentration. An endogenous catalyst enabled the ascorbate in the vitreous to react with oxygen. Presumably, ascorbate-dependent oxygen consumption reduces the exposure of the lens to oxygen. When the level of ascorbate or the catalyst in the vitreous fluid decreased, the ability of the vitreous to consume oxygen also decreased.³⁵⁰ Therefore, excessive vitreous degeneration or vitrectomy lowers the concentration of ascorbate in the vitreous, which would be expected to increase the exposure of the lens to oxygen (Fig. 5.14).

The increased light scattering associated with nuclear cataract formation could be due to protein aggregation or to changes in the organization of the fiber cell structure. Examination of the fiber cells in the lens nucleus with the electron microscope suggests that nuclear cataract formation is usually not associated with a gross disruption of cell membranes, obvious protein aggregation, phase separation, or

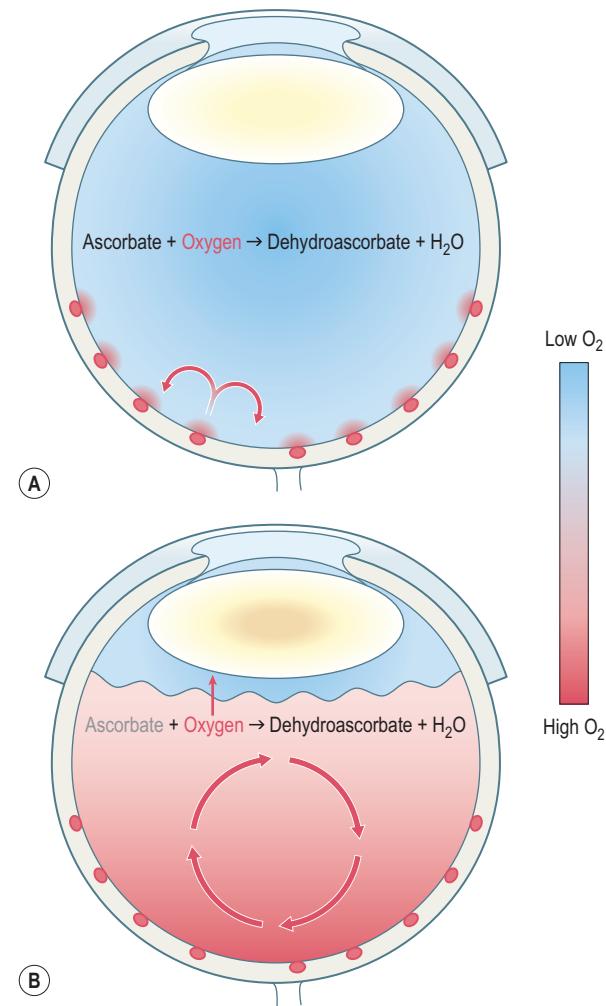

Figure 5.14 Diagram illustrating the role of the gel vitreous body and ascorbate in the vitreous fluid play in protecting the lens from excessive exposure to oxygen from the retinal vasculature. The gel state of the vitreous body prevents stirring of the contents of the vitreous chamber, allowing the uptake of oxygen by adjacent retinal cells. Increased mixing of the vitreous fluids after vitreous degeneration or vitrectomy increases exposure of the fluids to oxygen, which increases the degradation of ascorbate, allowing more oxygen to reach the lens. The chemical reactions summarized in the figure show the initial reactants (ascorbate and oxygen) and the end products (dehydroascorbate and water). Hydrogen peroxide is an intermediate product in this reaction, which is degraded to water and oxygen by the enzyme, catalase. If not taken up by cells, dehydroascorbate is rapidly hydrolyzed to yield several additional degradation products.

with increased granularity of the fiber cell cytoplasm (Fig. 5.15).³⁵²⁻³⁵⁴ Techniques aimed at detecting subtle alterations in the organization of the fiber cell cytoplasm did not detect significant differences between clear lenses and the majority of lenses with nuclear cataracts.³⁵⁴ More subtle changes in the organization of the cytoplasm, whether they are due to protein aggregation or microscopic phase separation, cannot be ruled out. It is important to recognize that only a small fraction of the protein in the lens fiber cell cytoplasm needs to be aggregated in order to increase light scattering dramatically.³⁵⁵ This makes it difficult to identify the changes that lead to opacification among the many alterations of lens proteins that occur with aging.

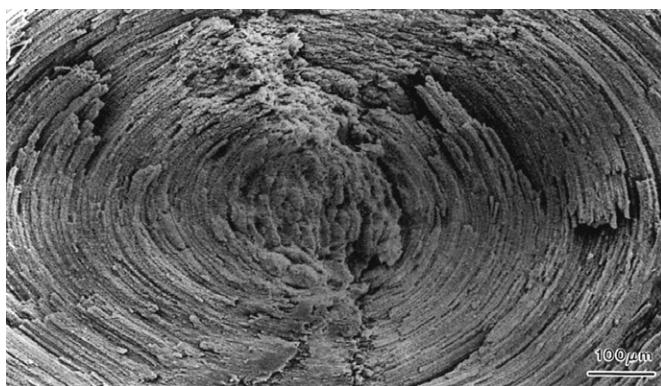

Figure 5.15 Scanning electron micrograph of the lens fiber cells in the embryonic nucleus of a lens from an 80-year-old. The fiber cells are still well organized and intact. (Courtesy of Dr. J. Kuszak)

During life, the nuclei of clear human lenses become up to 1,000 times harder or stiffer than at the time of birth.^{356,357} The increased hardness that typically accompanies nuclear cataract formation is superimposed upon this age-related increase.³⁵⁶ As described above, since nuclear cataract involves increased oxidative damage, oxidation of the components of the nucleus is likely to contribute to the stiffening of the lens cytoplasm that characterizes these “sclerotic” cataracts. Whether oxidative modification of crystallins is also involved in the age-related stiffening of clear lenses is not known.

In summary, it is likely that the aging lens is susceptible to oxidative damage, due to the increased difficulty in maintaining the cytoplasm of the lens nucleus in the reduced state.²⁰⁹ Any increase in oxidative load or further decrease in the ability of the lens nucleus to cope with the normal level of oxidation is likely to lead to nuclear cataract formation. In addition, experiments with animals, mentioned in the section on lens growth, showed that exposure of the lens to increased oxygen increased the rate of lens growth.¹⁸⁷ Since larger lenses are associated with increased risk of nuclear cataracts, exposure to oxygen may indirectly increase nuclear cataracts formation by increasing the size of the lens. Therefore, increased exposure of the lens to oxygen, as a result of hyperbaric oxygen therapy, after vitrectomy, or following age-related degeneration of the vitreous body, is likely to play a significant role in the formation of nuclear cataracts.

Age-related cortical cataracts

The cells that are affected in cortical cataracts are mature fiber cells that lie close to the surface of the lens. Cortical cataracts most often occur in the inferior half of the lens, with a tendency for these cataracts to occur in the inferior nasal quadrant.^{358,359} Cortical opacities usually begin in small regions of the lens periphery and may spread around the circumference of the lens over a period of years. Early stage cortical cataracts are usually not clinically significant, since the opacity does not impinge on the visual axis. As the cataract progresses and the opacity spreads towards the visual axis, it may eventually interfere with vision. However, an individual may have a superficial cortical opacity for years without experiencing a diminution of visual function.

The superficial lens fiber cells that are involved in cortical cataracts, like all mature lens fiber cells, span the thickness of the lens from the posterior to the anterior suture. Therefore, the peripheral opacities that are characteristic of early-stage cortical cataracts occur only in the central part of the affected fiber cells, with the apical and basal ends of these cells remaining transparent.^{360,361} The spread of the cortical cataract around the lens circumference involves progressive damage to an increasing number of lens fiber cells of similar age, while the extension of a cortical cataract into the visual axis involves progressive opacification of the extremities of the same cohort of fiber cells. It is remarkable that the central region of a group of fiber cells can be opaque while the tips of these same cells remain transparent. Extension of the opacity along the lengths of a small cluster of fiber cells leads to the formation of the “cortical spokes” that are frequently described in these cataracts.³⁶²

In contrast to the subtle morphological changes that occur during nuclear cataract formation, the damage found in cortical cataracts is catastrophic. Examination of the affected regions of lens fiber cells in a cortical cataract reveals almost complete disruption of cell structure.^{361,363,364} Plasma membranes are ruptured and many whorls and vesicles of membrane-like material can be found in the cytoplasm. Cytoplasmic proteins are typically aggregated to such an extent that the cytoplasm takes on a chalky appearance when the cataractous region of the lens is disrupted during cataract surgery or during dissection of the lens postmortem.

Only a small group of cells is affected in the early stages of cortical cataract formation. One can imagine several mechanisms that could lead to the formation of this initial opacity, including physical or chemical damage to the fiber cell plasma membrane, inhibition of the ion pumps or transporters in these membranes, damage to the system responsible for calcium homeostasis or the local loss of protective molecules like glutathione. Any one of these damaging occurrences would be likely to lead to all the others, making it particularly difficult to identify the initiating event in cortical cataract formation.

No matter what the initiating event, loss of calcium homeostasis could underlie the radial and circumferential spread of opacification. Cytoplasmic calcium levels are abnormally high in the damaged cells of cortical cataracts.^{364–366} As mentioned above, lens fiber cells typically maintain their intracellular calcium concentration in the low micromolar range. Experimental elevation of lens cytoplasmic calcium levels leads to widespread proteolysis.³⁶⁵ If adjacent fiber cells are joined by membrane fusions, it may be difficult to prevent the eventual spread of high levels of calcium into adjacent cells.

The mechanism that initially prevents the spread of damage from the central portion of the lens fiber cell towards its basal and apical ends must involve the creation of a barrier between the central, cataractous region of the cell and the transparent, distal regions. Numerous membrane blebs and vesicles are seen in the opaque regions of cortical cataracts, a phenomenon that has been termed “globular degeneration.”³⁶⁷ If, during cataract formation, the cytoplasm were to fragment into such vesicles, it is likely that the proximal ends of the fiber cells, adjacent to the damage, would be sealed by fusion of the plasma membrane. This could “wall off” the damaged region of the cell, thereby slowing the

Box 5.4 Cortical cataracts; common opacities of obscure etiology

Cortical cataracts occur in mature fiber cells near the lens equator. These opacities only impair vision when they extend into the visual axis. Although they are a common cause of age-related cataracts, the mechanisms responsible for their formation are not clear. Cortical cataracts first appear after the onset of presbyopia. It has been suggested that they may be caused by physical damage occurring at the interface between the stiffer lens nucleus and softer cortex. Physical stresses may be focused in this region of the lens during attempted accommodation. Factors that increase the risk of cortical cataracts, like greater sunlight exposure, poorly controlled diabetes or having a thinner lens, could increase the stiffness of the lens nucleus, weaken fiber cell membranes or increase the force exerted on the lens during accommodation.

spread of damage.³⁶⁴ Since fiber cells are connected to their neighbors by gap junctions all along their lateral membranes, "walling off" the central region of the cell would not isolate the tips of the cell from the rest of the lens, permitting the passage of nutrients and antioxidants into and out of the transparent portions of the fiber cells.

The presence of a protective mechanism to prevent the spread of damage along the length of a fiber cell in typical age-related cortical cataracts is also evident in traumatic cataracts. Local physical damage to the lens, caused by traumatic injury to the eye or by touching the lens during surgery, usually leads to the formation of a local opacity. Such opacities may be restricted to the affected cells for many years, becoming buried deeper in the lens as new fiber cells are added, or the opacity may slowly spread to adjacent fiber cells in a manner that appears similar to the progression of non-traumatic cortical cataracts.³⁶⁸

The strong association between thinner lenses and increased risk of cortical cataract suggests a physical mechanism for the initiation of cortical cataracts.^{189–191} Cortical cataracts typically occur after the lens has lost most or all of its ability to accommodate. However, even in older individuals accommodative stimuli cause contraction and relaxation of the ciliary muscle and, therefore, changes in the tension on the zonules, even though the lens may not change shape appreciably. Presbyopia is accompanied by continued hardening of the lens nucleus, while the cortex remains relatively soft. This results in lenses with increasingly steep gradients of stiffness between the nucleus and cortex.^{357,369,370} It is likely that the forces generated during accommodation are focused at the interface between these layers, close to the location at which cortical cataracts occur.^{362,371–373} In smaller lenses, there may be increased tension on the zonules during disaccommodation, due to the greater distance between the lens equator and the ciliary body. Influences that increase the stiffness of the lens nucleus, including higher levels of protein glycation in diabetics or increased sunlight exposure, could account for some of the increased risk of cortical cataract associated with these factors (see Box 5.4).

Posterior subcapsular cataracts

Posterior subcapsular cataracts (PSCs) are caused by light scattering in a cluster of swollen cells at the posterior pole

of the lens, just beneath the capsule.^{374–376} Because the opacity produced by these cells is in the optical axis, posterior subcapsular cataracts are particularly disabling. Careful examination has shown that, in lenses with PSCs, the most superficial fiber cells are disorganized in localized regions at the lens equator. A "stream" of epithelial-like cells leads from the affected region of the equator to the opacity at the posterior pole.³⁷⁴ This suggests that PSCs result from the abnormal migration of lens epithelial cells or the aberrant differentiation of fiber cells.

Opacities can also occur at the posterior pole due to swelling of the posterior ends of the fibers along the suture planes. These "sutural" cataracts can sometimes resemble PSCs. However, sutural opacities are typically associated with inherited cataracts and are not common in age-related cataract.

"Pure" PSCs (PSCs not associated with another kind of cataract) are less common than either age-related nuclear or cortical cataracts, typically accounting for less than 10 percent of cataracts in humans. However, PSCs may occur in conjunction with nuclear or cortical opacities.

Although specific risk factors associated with PSC formation are known, we have less information about the cellular or molecular defects that lead to the formation of these cataracts in humans. An animal model of steroid-induced cataract provided some insight into this process, suggesting that defects in the adhesion of differentiating fiber cells may lead to PSC formation.³⁷⁷ Experimentally induced radiation cataracts also provide a relevant model. Cortical and posterior subcapsular opacities develop over weeks to months after exposure to sufficient levels of ionizing radiation.^{378–381} These opacities are preceded by increased death in the germinative zone epithelial cells and disorganization of the fiber cells that develop from those epithelial cells that survive the radiation damage.^{382–384} Increasing use of intravitreal steroids has led to an increase in PSCs. These cataracts may provide useful material for further study of the mechanisms underlying this disease.

Mixed cataracts

Cataract patients sometimes have a combination of nuclear, cortical, and/or posterior subcapsular cataracts. It is not clear whether having one kind of cataract predisposes a person to developing an additional kind of cataract, although it seems likely that such an association would have been noticed. This is particularly likely in the case of a pre-existing cortical cataract, which may be detectable, but clinically insignificant for many years. However, the author is not aware of studies showing that the presence of a cortical cataract is a risk factor for the later formation of a nuclear cataract or PSC. In the case of mixed cataracts, it is possible that the factors that led to the formation of one kind of cataract also contributed to the formation of the second or third type.

In most developed countries cataracts are removed as soon as they become visually disabling. However, if a cataract is not removed, it may progress to a "total," "white" or "Morgagnian" cataract. There is no specific etiology for total cataracts. They are simply the result of the progression of a more localized cataract to the point at which it affects the entire lens.

Secondary cataracts

There are two general strategies for the removal of cataracts. The most common approach taken is to remove a portion of the anterior lens epithelium and capsule exposing the underlying fiber mass, extract the nuclear and cortical fiber cells, often using instruments for "phacoemulsification," and implant a plastic intraocular lens (IOL) in the capsular bag. This method of cataract removal is a form of "extracapsular" cataract extraction. Before intraocular lenses were available, the entire lens was removed to remove the cataract. This is called "intracapsular" cataract extraction.

A frequent complication of extracapsular cataract extraction is the formation of secondary cataracts, also called "after cataracts" or "posterior capsular opacification" (PCO). Removal of the cataractous fiber mass leaves the posterior capsule free of cells. Lens epithelial cells near the lens equator persist after cataract surgery and can migrate beneath the IOL onto the denuded posterior capsule. Epithelial cells that remain close to the equator may differentiate into a mass of fiber-like cells, forming a band called "Soemmering's ring" around the equator.³⁸⁵ If the epithelial cells migrate further onto the posterior capsule they may differentiate into small "lentoid bodies," also called "Elschnig's pearls," or they may form fibrotic plaques. Both Elschnig's pearls and fibrotic plaques scatter light, degrade the visual image, and result in secondary cataract formation (see Box 5.5).

The cells found in Elschnig's pearls resemble the large, swollen cells seen in posterior subcapsular cataracts.³⁸⁶ They are likely to result from lens epithelial cells that were stimulated to undergo aberrant fiber cell differentiation. Instead of forming precisely organized, elongated lens fibers, they form small, rounded clumps of cells that act as miniature lenses, thereby degrading the image produced by the implanted intraocular lens.

Fibrotic plaques are the most common cause of PCO. They contain contractile, myofibroblast-like cells in an abundant extracellular matrix, thereby resembling in many ways the fibrosis seen in anterior polar cataracts (see below).³⁸⁷⁻³⁹⁰ Myofibroblasts are contractile cells found during wound healing in many parts of the body. They

express the contractile protein α -smooth muscle actin and secrete an abundant collagenous extracellular matrix, properties that may be important in wound healing. In addition to the light scattered by the cells and matrix in these plaques, the contractile cells wrinkle the posterior capsule, further contributing to light scattering.

The cytokine TGF- β has been implicated as a stimulant of the capsular fibrosis seen in secondary cataracts.^{391,392} Lenses and lens epithelial cells treated with activated TGF- β form plaques of myofibroblast-like cells similar to those seen in secondary cataracts.³⁹³⁻³⁹⁵ However, there are no published studies showing that TGF- β is required for lens fibrosis and cataract formation.

Other studies have suggested that the migration or spreading of lens epithelial cells on the posterior capsule may, by itself, contribute to myofibroblast differentiation.³⁹⁶ Since active TGF- β is likely to be found in the eye after cataract surgery and cataract surgery always provides a surface on the posterior capsule for the migration of lens epithelial cells, it is possible that both of these conditions contribute to the formation of myofibroblasts after cataract surgery.

Less common types of cataract

Congenital cataracts are cataracts that are present at birth or that appear soon after birth. They can include early-onset hereditary cataracts or cataracts caused by infectious agents. Most congenital cataracts are total, although some may affect specific regions of the lens. In most cases, the etiology of congenital cataracts is not known, although the presence of a family history of congenital cataracts suggests a genetic component.

One infectious cause of congenital cataracts is rubella infection in early pregnancy.³⁹⁷ The rubella virus has been isolated from the lenses of affected individuals and experimental infection of early-stage human lens tissue with the rubella virus has been demonstrated. It is likely that the lens is susceptible to infection only early in gestation, prior to the separation of the lens vesicle from the overlying ectoderm. After this stage of lens development, the capsule appears to prevent the entry of the virus into the lens tissue.³⁹⁸ Immunization against rubella in industrialized countries has reduced the incidence of rubella cataracts and the other types of birth defects associated with this disease. However rubella cataracts are still common in non-immunized populations.

One of the cytological characteristics of lenses infected with the rubella virus is the failure of organelle degradation in lens fiber cells.³⁹⁹ The mechanism by which the rubella virus prevents organelle loss is not understood. However, several genetic and transgenic mouse models of cataract also show a failure of organelle degradation,^{132,400} suggesting that inhibition of organelle loss may be a non-specific side effect of a variety of factors that perturb fiber cell differentiation.

Anterior polar cataract (APC) is another type of congenital or early-onset cataract. Anterior polar cataracts typically involve the formation of an opaque plaque near the center of the lens epithelium. Although they are usually rare, a recent hospital-based study found that prevalence of anterior polar cataracts in Koreans was 6 percent. The mean age in this study was 53 and 87 percent were male.⁴⁰¹ It is unclear whether the early onset, high risk in males and overall high prevalence is due to genetic or environmental effects.

Box 5.5 Posterior capsular opacification (PCO), a possible barrier to the introduction of advanced intraocular lenses (IOLs)

The opacities that sometimes form on the posterior capsule after cataract surgery are caused by the migration of lens epithelial cells across the newly denuded posterior capsule and their differentiation to "myofibroblast-like" cells. The migration and transdifferentiation of these cells is a kind of wound healing response. Opacification is caused by the excessive amount of extracellular matrix secreted by these cells and their tendency to cause wrinkling of the posterior capsule. PCO can be greatly reduced by preventing the migration of the cells onto the capsule by incorporating a square edge at the posterior of the IOL. However, newer types of "accommodating IOLs" do not effectively block the migration of lens epithelial cells and are subject to high rates of PCO. New biological or technical solutions to this problem are needed to permit advances in IOL technology.

Microscopic examination of the anterior plaques in APC shows spindle-shaped lens epithelial cells embedded in a large amount of extracellular matrix, the plaque taking on the appearance of a connective tissue. The fiber cells that lie beneath these plaques are often disrupted, a factor that may contribute to the opacity. The spindle-shaped lens cells in these plaques express several of the proteins characteristic of myofibroblast cells, including α -smooth muscle actin, fibronectin, type I collagen, transforming growth factor- β (TGF- β) and connective tissue growth factor (CTGF).^{391,392,402} Experimental studies have shown that exposing lenses to TGF- β in vivo or in vitro can trigger the formation of myofibroblast-like cells and plaques that resemble those seen in anterior polar cataracts,^{394,395} although it has not yet been shown that anterior polar cataracts in humans are associated with exposure of the lens to high levels of TGF- β .

Mutations in several lens-specific genes have been implicated in hereditary cataracts in humans. These include genes encoding α A- and α B crystallin,^{115,403} members of the β/γ -crystallin superfamily,^{404–406} the lens-specific connexins α 3 and α 8,^{407,408} and the lens-specific intermediate filament proteins, phakinin and filensin.^{136,137} To date, nearly all mutations identified in these genes have a dominant mode of inheritance.

The association of cataract and mutations in these genes does not necessarily demonstrate that the proteins they encode are essential to the function of the lens. For example, deletion of one copy of the genes encoding either of the two lens-specific connexins in mice does not result in cataract formation.^{152,154} However, if one allele of these genes is mutated in humans, cataract can result.^{407,408} Similarly, one mutant allele of any of several of the genes encoding members of the β/γ superfamily of crystallins is sufficient to cause cataracts.^{400,404,406,409} In these cases, the mutant allele produces a protein that interferes with the function of the normal protein or other proteins in the lens, thereby disrupting their function and leading to cataract formation.

There are numerous hereditary syndromes that include cataracts as one of their characteristic features. The genes responsible for these syndromes are known in several cases, including the ocular-cerebral-renal syndrome of Lowe (a protein similar to inositol polyphosphate 5-phosphatase),⁴¹⁰ neurofibromatosis type 2 (a member of the ERM family of cell membrane-associated proteins),⁴¹¹ galactokinase deficiency (galactokinase 1),⁴¹² galactosemia (galactose-1-phosphate uridylyltransferase),⁴¹³ hyperferritinemia (ferritin light chain),⁴¹⁴ Werner syndrome (recQ-related helicase),⁴¹⁵ and myotonic dystrophy (six-5 homeobox gene),^{416,417} and several others. For most of these diseases, knowing the gene responsible has not provided an obvious explanation for why cataracts are part of the phenotype. Understanding the molecular and biochemical mechanisms underlying cataract formation in these syndromes may provide information about the mechanisms of age-related cataract formation and the importance of these genes in other tissues that are part of the disease syndrome.

Exceptions to this generalization include galactosemia and galactokinase deficiency, in which galactose accumulates to high levels in the body. High levels of galactose lead to the accumulation of the polyol galactitol in the lens fiber cell cytoplasm. This is due to the activity of the enzyme

aldose reductase, which converts galactose to galactitol. Accumulation of galactitol leads to osmotic swelling of lens fiber cells, damage to fiber cell membranes, and cataract formation. The possible role of aldose reductase in the formation of cataracts seen in diabetics will be discussed further below.

Exposure of the eye to several kinds of electromagnetic radiation can lead to cataract formation. The best studied of these are cataracts caused by ionizing radiation.⁴¹⁸ In experimental animals, x- or γ -irradiation causes characteristic changes in the cells of the lens, leading to posterior subcapsular and cortical cataracts. The initial insult in the cataractogenic process may be damage to the proliferating cells in the germinative zone of the lens epithelium, which leads to extensive cell death in this region.^{380,382,419–421} Exposure of only the central epithelial cells and mature fibers to very high levels of x-irradiation does not lead to cataract formation, as long as the germinative zone is protected from irradiation.⁴²² Furthermore, animals in which cell division in the lens can be stopped by environmental or experimental means are resistant to radiation cataracts.^{423,424} Cell death in the germinative zone is followed by a delay in cell division and a wave of compensatory mitosis. When the epithelial cells that resulted from this increased proliferation begin to differentiate, the usually precise organization of the fiber cells is disrupted.⁴²¹ As they elongate, these fiber cells become distorted and may appear swollen, although their average cell volume is unchanged.³⁸² The appearance of fiber cell swelling may be due to the presence of distended and attenuated regions along the length of a fiber, instead of the uniform geometry of normal fiber cells. The nuclei of these elongating fibers, instead of remaining in a compact arc (the "lens bow"), move posteriorly. The posterior movement of the nuclei probably reflects the flow of the entire cytoplasm of these cells. Eventually, these abnormal fibers form "balloon cells" or "Wedl cells" at the posterior pole, resulting in the formation of a posterior subcapsular cataract. During the later stages of this process there is evidence of increased membrane permeability in the affected lens fibers. Glutathione levels decrease, the potassium concentration in the cytoplasm declines, the sodium concentration increases, and the synthesis of proteins slows.^{425,426}

Exposure to x- or γ -radiation is a risk factor for cortical and PSC formation in humans. Radiologists routinely seek to minimize the exposure of the lens to ionizing radiation. In cases in which this is not possible or advisable, cataracts often follow and must be dealt with surgically.

Non-ionizing radiation can also contribute to cataract formation. The effects of UV light on the eye have been most intensively studied. Epidemiological studies have linked high lifetime exposure to UV light with the formation of cortical cataracts in humans.^{359,427–430} The effects of UV light have been most clearly demonstrated in individuals who are exposed to high levels of UV as a consequence of their occupation.^{427,431} The risk of developing cortical cataracts is only slightly increased in individuals who receive higher than normal levels of UV, but whose occupation does not routinely expose them to high levels of ultraviolet light (see Box 5.6).⁴²⁹ The same studies have suggested that the shorter wavelengths of UV light reaching the eye, UV-B, and not the longer, less energetic UV-A, is likely to be responsible for increased risk of cortical cataract.⁴³¹ However, studies in

Box 5.6 Sunlight exposure and cataract; not as important as often believed

Sunlight exposure is widely thought to be a major contributor to cataract. Careful epidemiological studies have demonstrated increased risk of cataracts in individuals with higher lifetime sunlight exposure. However, most studies have found that only cortical cataracts are associated with increased exposure to sunlight, not nuclear or posterior subcapsular opacities. In a typical population, the increased risk of cortical cataracts attributable to sunlight is only about 10%. That added risk can be avoided by relatively simple means: wearing plastic glasses or a brimmed hat. Many other variables, like sex or a family history of cataracts, are more significant risk factors for cortical cataract than sunlight. The mechanism by which sunlight increases the risk of cortical cataracts is not understood. For example, the region of the lens most often affected in cortical cataracts is the part that is best protected from direct exposure to sunlight. Therefore, while exposure to excess sunlight is an avoidable risk factor, avoiding sunlight protects against only a small part of the total risk of age-related cataracts.

diurnal animals exposed to UV-A suggest that these longer wavelengths can also contribute to cataract formation (see below).

The mechanism by which UV exposure leads to cataract formation in humans has not been identified. Studies in experimental animals, on lenses cultured in vitro, and on isolated lens proteins, have been used to examine the potential damaging effects of UV light on the lens or lens components. While these studies have suggested that UV-generated free radicals can damage components of the lens in a similar manner to that seen in cataract formation, these studies often do not fully take into account the biology of the human lens. For example, most studies of the effects of UV light on the lens in experimental animals have been performed in rodents or rabbits. These are nocturnal animals that are not adapted to high levels of light exposure. Many potential protective mechanisms found in the human eye, like the high ascorbic acid content of the aqueous humor, are not present in these species. Furthermore, treatment of the isolated lenses or lens proteins with UV light has usually been performed at ambient oxygen concentrations (21 percent), not the low levels of oxygen that are typically found around the lens *in vivo* (less than 2 percent).²²¹ Experiments performed under these conditions may yield results that are substantially different from what is found as the result of light exposure in the eye. Finally, UV exposure in experimental animals is often acute, employing high levels of UV light. This differs significantly from the chronic, lower level of exposure over a lifetime that is typical in humans.

In a few cases, the effects of UV light on the lens were tested in diurnal species chronically exposed to more physiological levels of light over a substantial proportion of their lifetime. In contrast to epidemiological studies of human populations, these experiments indicated that UV-A light might also be a risk for cataract formation.⁴³² UV-A light can be absorbed by several chromophores into the lens, a process that may lead to the generation of free radicals.^{268,433} These studies suggest that protection against free radical generation or the effects of free radicals might help reduce the incidence

of cataracts. They also suggested that the role of UV-A light in human cataract formation is worthy of further study.

One of the paradoxical findings concerning the role of UV light in cataract formation is that the cells that are affected are those that are best protected from light exposure. As indicated above, epidemiological studies have associated UV light with the formation of cortical, not nuclear cataracts. Cortical cataracts form in superficial fiber cells. Superficial fiber cells and the peripheral epithelial cells that give rise to them, because they lie behind the densely pigmented iris epithelium, are better protected from light exposure than any other part of the lens. This is especially true in bright light when the iris is maximally constricted and the size of the pupil is small. Conversely, epidemiological and experimental studies indicate that the fiber cells in the center of the lens, those directly exposed to light entering the eye through the pupil, are not damaged by exposure to light.^{234,427,429}

Studies using model eyes have suggested that light entering the eye from the temporal side of the head may be focused by the curvature of the cornea onto the cortical fiber cells on the opposite (nasal) side of the lens.^{358,434} While this hypothesis might provide an explanation for the higher frequency of cortical cataract formation on the naso-inferior side of the lens, it would not appear to account for the higher frequency of cortical cataracts in the remainder of the inferior half of the lens.⁴³⁵ Studies are needed to explain the selective effects of light exposure on cortical fiber cells and to better understand the proposed role of ocular sunlight exposure in cortical cataract formation. As discussed above, it seems possible that sunlight exposure may increase the hardness of the lens nucleus, indirectly promoting cortical cataracts by focusing the stress of accommodation in the cortex. Modeling studies and non-invasive measures of lens hardness may be helpful in testing this possibility.^{369,436,437}

Long-term exposure to infrared light and focused, high-energy microwaves can also cause cataracts. Evidence that infrared light can cause cataracts comes mostly from epidemiological studies in individuals exposed as a result of their occupation.^{438,439} This type of cataract is also called "glass-blowers cataract." High-energy microwaves appear to cause cataracts by directly damaging lens fiber cell membranes.⁴⁴⁰⁻⁴⁴² It seems unlikely that either kind of cataract will provide significant insight into the etiology of more common types of cataracts, although lifetime exposure to increased ambient temperature has been suggested as a risk factor for nuclear cataracts.⁴⁴³

Diabetics are at increased risk for early-onset cataracts and the lens has provided a useful system with which to study diabetic complications. Like other organ systems affected in diabetes, damage to the lens seems to be due entirely to high levels of glucose. It is the mechanism by which elevated glucose leads to cellular damage that remains as the central question. Investigators studying diabetic cataracts have been leaders in illustrating the potential importance of the enzyme aldose reductase in diabetic complications.^{444,445} Aldose reductase catalyzes the reduction of a wide variety of aldehydes, including glucose and galactose. These sugars are relatively poor substrates for the enzyme, but their metabolism by aldose reductase may become significant when concentrations exceed normal levels. Species that have high levels of aldose reductase in the lens seem to be particularly susceptible to diabetic cataract formation.⁴⁴⁶ Inhibitors of

aldose reductase protect these animals against diabetic cataracts.^{444,446,447} Mice, which have low levels of aldose reductase in the lens, are not susceptible to diabetic cataracts. However, when aldose reductase is over expressed in the lenses of transgenic mice, these animals become very susceptible to hexose-induced cataract formation.⁴⁴⁸ These studies convincingly show that a high level of aldose reductase in the lens is sufficient to cause diabetic cataracts in this species. Humans have relatively low levels of aldose reductase in the lens, a situation that has led to controversy about the relative role of aldose reductase in human diabetic cataracts.

It has been suggested that aldose reductase causes cataracts in diabetics because of the accumulation of the polyol sorbitol in lens fiber cells. Sorbitol accumulation could lead to osmotic damage. However, since aldose reductase uses reducing equivalents from NADH to produce polyols, it is possible the high glucose flux through the polyol pathway could also create oxidative stress in lens fiber cells.

There are three hypotheses that are currently favored to explain diabetic complications in affected organs. Increased flux through the polyol pathway mediated by aldose reductase is one of these. The second mechanism is the glucose-mediated activation of a specific isoform of protein kinase C.⁴⁴⁹ A third mechanism is the generation of increased amounts of advanced glycation end products (AGEs).⁴⁵⁰ AGEs are produced by the non-enzymatic reaction of aldehydes, like glucose, with a wide variety of chemical species. Diabetics and animals with experimental diabetes accumulate increased levels of AGEs in connective tissues and within cells. Treatments that block each of these three biochemical pathways have been shown to reduce or prevent diabetic complications in one or more experimental systems. A recent study suggested that the three major pathways thought to be responsible for diabetic complications might be explained by a single mechanism – the effect of high glucose on mitochondrial oxidative phosphorylation.⁴⁵¹

In spite of the long association between diabetes and cataracts, more recent studies suggest that patients with reasonable control of blood glucose are not at increased risk for age-related cataract and that the types of cataracts that occur in these patients are similar to age-matched non-diabetics in the same population.⁴⁵² More effective management of this disease may reduce its impact on cataract prevalence and other systemic complications.

Overview of age-related cataract formation

As described above, excessive oxidative damage to lens crystallins and fiber cell membranes remains an attractive explanation for nuclear cataract formation. Increased oxidative damage in the lens nucleus must result from an imbalance between the factors that protect lens proteins from oxidative damage and increases in oxygen and free radicals that may occur with age. The age-related decrease in the diffusion of glutathione to the center of the lens is likely to be of central importance in this balance,^{209,240} while degeneration of the vitreous body is an age-related change that appears to increase the delivery of oxidants to the lens.⁴⁵³

Cortical cataracts are associated with gross disorganization and disruption of fiber cells. This makes it even more

difficult to identify the initiating insult for this type of cataract, since the wreckage that ensues obscures the early damage. While many possible inciting factors have been suggested, a comprehensive hypothesis that explains the subcellular and anatomical location of the damage in cortical cataracts (initial involvement of only the center of affected fiber cells, preferential location in inferior half of the lens) is lacking. While epidemiological studies suggest that light exposure contributes to cortical cataract formation, there is no evidence to indicate whether the damage to the lens results from the interaction of light with the affected cells or with other parts of the eye. For example, light could cause the release of substances from the iris that contribute to cortical cataract formation,⁴⁵⁴ a possibility that seems consistent with the increase in cataract in persons with dark iris color.^{304,316,317} It seems increasingly likely that physical forces acting on the aging lens, like those generated during accommodation, could rupture fiber cell membranes and initiate the formation of cortical cataracts (see Box 5.6).

Perspectives for preventing cataract blindness

One of the most unusual aspects of the lens is its continued growth throughout life. Since fiber cells are not replaced once they differentiate and epithelial cells continue to divide to produce new lens fibers, the number of fiber cells in the lens increases steadily with age, approximately doubling between birth and age 90. Although the rate of addition of new fiber cells is slow in postnatal life, most of the cells in the outer part of the lens, including the fiber cells that are involved in cortical cataract formation, are produced after childhood.

There is strong epidemiologic evidence supporting the possibility that the rate of growth of the lens plays a role in cataract formation. Individuals with larger lenses are more likely to have nuclear cataracts and those with smaller lenses are much more likely to have cortical cataracts.¹⁸⁹ Individuals with clear lenses at initial observation were more likely to develop nuclear or cortical cataracts over 5 years if they initially had larger or smaller lenses, respectively.¹⁹⁰ Could nuclear cataract formation be prevented or slowed by reducing the rate of lens cell proliferation? Recent studies support this view, since the rate of lens growth can be accelerated by supplying the adult lens with more oxygen and increased lens size and exposure to oxygen are likely to contribute to the formation of nuclear cataracts.^{187,190,222,224,455} Would slowing the growth of larger lenses delay the onset of presbyopia? Why are smaller lenses at increased risk of cortical cataracts? These questions could be approached if there were an experimental means to slow or stop the formation of new lens fiber cells.

It is presently not possible to effectively slow lens growth in most mammals. However, in amphibians, removing the pituitary gland stops lens cell division. This approach was used to show that x-ray-induced cataracts could be avoided if cell division were halted, even if the pituitary gland were removed after the lens had been irradiated.^{384,423,456} Restoration of lens cell growth by hormone supplementation led to cataract formation if the lenses had been irradiated prior to hypophysectomy.^{384,457} These studies provide tantalizing support for the possibility that reducing the rate of lens

growth could slow or prevent some kinds of cataract formation.

Another area that is likely to provide important information about cataract formation is the study of the genetics of human cataracts. Some of the genes responsible for congenital cataracts were described in a previous section. It is not surprising that the known genes that cause cataracts without affecting other parts of the body encode proteins that are expressed selectively and at high levels in the lens. Once a hereditary cataract is mapped close to one of these "lens-specific" genes it is relatively easy to connect the disease to a change in the sequence of that gene. However, several loci responsible for hereditary cataracts do not map close to the genes encoding known lens-specific proteins.^{458–460} Identification of these genes and study of their function in the lens may give important clues about the factors required to maintain lens transparency.

Of even greater potential significance will be the identification of genes that predispose the lens to cataracts in middle or later life. Some of these adult-onset hereditary cataracts are likely to be caused by mutations in genes that protect the lens from cataract-causing damage over a lifetime. Studies of twins have suggested that heredity accounts for about 50 percent of the factors responsible for age-related cortical cataracts and 35 percent of the risk of nuclear cataracts.^{461,462} Other statistical analyses of epidemiological data support these conclusions and suggest that a relatively small number of genes determine the probability of developing nuclear and cortical cataracts.^{463,464} One recent study found a mutation in the cell-recognition receptor, EPHA2, to be associated with a rare, recessive form of juvenile cataracts. Further analysis showed that single nucleotide polymorphisms in the EPHA2 gene were significantly associated with age-related cortical cataracts, suggesting that variants of this protein may predispose individuals to cortical cataract formation.⁴⁶⁵ Interestingly, deletion of the ephrin-A5, the ligand for EphA2 in the mouse, causes disruption of lens fiber cell organization.⁴⁶⁶ These studies are among the first to identify candidate genes that may increase susceptibility to age-related cataracts.

Since degeneration of the vitreous body is a risk factor for nuclear cataracts,⁴⁵³ it seems reasonable to broaden attention from lens-specific genes to the genetic variations that are responsible for maintaining the normal environment around the lens in older individuals. If one were to identify genes that alter stability of the vitreous gel, for instance, it might be possible to develop therapies to delay cataractogenesis by altering the pathways in which these genes work.

Cataract blindness is a serious and growing problem in the countries of the developing world. The early onset and higher incidence of cataracts in these populations suggests that basic nutritional, environmental, and hygienic factors contribute to cataract formation. Elimination of these predisposing conditions could preserve the vision of millions of individuals who would otherwise be deprived of their sight and productivity for a substantial proportion of their lifetime. The World Health Organization, through its program "Vision 2020: The Right to Sight," has developed plans to eliminate preventable blindness by the year 2020. Cataract blindness will be addressed in this program by providing increased access to affordable cataract surgery.⁴⁶⁷ Although greatly increased numbers of cataract surgeries will

be essential to the goals of this project, concomitant improvement of basic living conditions may reduce the rate of cataract formation, and along with it, a host of other diseases.

There are numerous epidemiological studies suggesting that nutrition plays an important role in cataract formation (see review⁴⁶⁸). There have been several interventional studies to test whether supplementation with specific nutrients can protect against cataract formation or progression. The AREDS study, a large-scale clinical trial of the effects of selected vitamin and nutrient supplementation on the progression of eye diseases, found that supplementation with known antioxidant vitamins did not provide measurable protection against cataract.⁴⁶⁹ However, an interesting follow-up paper revealed that the multivitamin supplement offered to about two-thirds of the participants in this trial was associated with protection against "all cataracts" and, in subgroup analysis, nuclear cataracts.⁴⁷⁰ This result is similar to that obtained in the Linxian Cataract Study, which provided supplements to a nutritionally deprived population in China.⁴⁷¹ In this case, supplementation was associated with a substantially decreased risk of nuclear, but not other types of cataract. However, supplementation with beta-carotene and vitamins C and E in a nutritionally deprived population in India demonstrated no protection against cataract.⁴⁷² Nuclear opacities were less common in a large group of older subjects receiving a multivitamin/mineral supplement in Italy.⁴⁷³ However, this benefit was accompanied by increased incidence of posterior subcapsular opacities.

These and other clinical trials caution that consumption of higher levels of selected nutrients are likely to have marginal benefit and may even have adverse consequences.⁴⁷⁴ Studying the importance of individual components of the diet on cataract incidence and progression may even obscure the larger picture. The message that seems to underlie most studies of the relationship between nutrition and cataract is one that is echoed in many studies of nutrition and disease; a moderate diet with abundant fruits and vegetables is likely to provide an effective foundation for good visual health and good health in general.

Secondary cataracts, the opacities that appear on the posterior capsule following extracapsular cataract surgery and IOL implantation, remain an important clinical problem. These opacities are routinely treated by ablating the posterior capsule with a laser – a procedure that is costly, depends on advanced technology, and is associated with increased risk of serious complications.⁴⁷⁵ The frequency with which secondary cataracts develop depends on the age of the patient and the type of IOL that is implanted. Children have a high incidence of secondary cataract formation, a fact that complicates and limits the options for treating congenital or traumatic cataracts in children. Designs that limit the ability of lens epithelial cells to migrate behind the IOL can prevent this complication, but may require more complicated surgical procedures.⁴⁷⁶ In older patients, the composition and design of the IOL can significantly influence the need for laser surgery after cataract extraction.^{477–479} However, changes in IOL design to achieve other goals (smaller incision size, accommodative IOLs, for example) may increase the frequency of secondary cataracts. Further understanding of the biologic factors responsible for secondary cataract and its prevention could simplify pediatric cataract surgery and reduce the need to treat secondary cataracts in adults.

New technologies, such as accommodating IOLs, are likely to provide valuable advances in cataract surgery. Such improvements could increase the demand for replacement of the lens even before cataract formation. Although cataract surgery is now a relatively simple surgery, new technologies are likely to further simplify and speed this common procedure. Drugs to prevent or delay cataract formation have not been widely sought by the pharmaceutical industry. This may be due to the relatively low cost of cataract surgery coupled with the cost and potential risk of anti-cataract medications that may need to be taken for many years. Better understanding of the etiology of cataracts may point to therapies that are effective, minimally invasive, and inexpensive.

Cataract has been thought to be inevitable if one is fortunate enough to live a long life. However, better understanding of the cell biology, genetics, biophysics and physiology of the lens is beginning to suggest strategies to prevent or significantly delay this most common disease.

Acknowledgments

Many thanks to the colleagues, students, residents and fellows whose stimulating discussions and healthy skepticism helped me to formulate some of the ideas expressed in this chapter. I especially thank Drs. Steven Bassnett, Ying-Bo Shui, Nancy Holekamp, George Harocopos, Toshiyuki Nagamoto, Carmelann Zintz, Joram Piatigorsky, and Leo Chylack. Cheryl Armbrecht provided expert assistance with graphics and Dr. Jer Kuszak generously contributed figures. Support for preparing this manuscript was derived from Research to Prevent Blindness, NIH Grants EY04853, EY07528 and EY015863 and Core Grant EY02687 from the National Eye Institute to the Department of Ophthalmology and Visual Sciences at Washington University.

The Vitreous

Henrik Lund-Andersen & Birgit Sander

Introduction

The vitreous body makes up approximately 80% of the volume of the eye and thus is the largest single structure of the eye (Fig. 6.1). In the anterior segment of the eye, it is delineated by and adjoins the ciliary body, the zonules, and the lens. In the posterior segment of the eye, the vitreous body is delineated by and adjoins the retina.

The vitreous body has many normal physiological functions. This chapter focuses on the most important physiologic relationships, especially those that have a close clinical correlation. As background for the understanding of the physiology and the pathophysiology of the vitreous body, we focus on the main features of the anatomy, biochemistry, and biophysics.

The investigation of the vitreous body and its structure and function is hampered by two fundamental difficulties. Firstly any attempts to define vitreous morphology are in fact attempts to visualize a tissue, which by design is intended to be invisible. Secondly the various techniques that have previously been employed to define the structure of the vitreous body are combined with artifacts that make interpretations difficult in terms of the true *in vivo* physiological situation.

Anatomy

Embryology

Structural considerations of embryology

In the early stages the optic cup is mainly occupied by the lens vesicle. As the cup grows the space formed is filled by a system of fibrillar material, presumably secreted by the cells of the embryonic retina. Later, with the penetration of the hyaloid artery, more fibrillar material apparently originating from the cells of the wall of the artery and other vessels contribute to filling the space. The combined mass is known as *primary vitreous*.^{22,23,39,110,127}

The *secondary vitreous* develops later, appearing at the end of the sixth week, and is associated with the increasing size of the vitreous cavity and the regression of the hyaloid vascular system. The main hyaloid artery remains for some time, but it eventually disappears and leaves in its place a

tube of primary vitreous surrounded by the secondary vitreous, running from the retro Lentil space to the optic nerve (area of Martegiani). The tube is called *Cloquet's canal* (Fig. 6.1); this is not a liquid-filled canal, but simply a portion of differentiated gel devoid of collagen fibrils.

The term *tertiary vitreous* is related to the fibrillary material, which develops as the suspensor fibrils, the zonules, of the lens. During childhood the vitreous undergoes significant growth. The length of the vitreous body in the newborn eye is approximately 10.5 mm, and by the age of 13 years, the actual length of the vitreous increases to 16.1 mm in the male.¹⁰⁷ In the absence of refractive changes, the mean adult vitreous is 16.5 mm.^{30,91}

Molecular and cellular considerations of embryology

The two main components of the vitreous, collagen and hyaluronic acid, are produced in the primary and secondary vitreous. In the primary vitreous, however, there is initial production of substances other than hyaluronic acid, such as galactosaminoglycans; later hyaluronic acid becomes the predominant constituent.^{27,41,111,127}

The primary vitreous contains cells which in the secondary vitreous differentiate as hyalocytes and fibroblasts. The hyalocytes are believed to be involved in the production of glycosaminoglycans, especially hyaluronic acid, a non-sulfated glycosaminoglycan.¹¹¹

Although the function of the fibroblasts is not known exactly, they are probably involved in the formation of collagen. The retina may also be a source of collagen synthesis.^{88,108} The hyalocytes are found in the vitreous cortex, approximately 30 µm from the internal limiting membrane (ILM), with the highest density near the vitreous base and the posterior pole.⁹

Anatomy of the mature vitreous body

The mature vitreous body is a transparent gel which occupies the vitreous cavity. It has an almost spherical appearance, except for the anterior part, which is concave, corresponding to the presence of the crystalline lens. The vitreous body is a transparent gel; however, it is not completely homogeneous (Fig. 6.2). The outermost part of the vitreous, called the cortex, is divided into an anterior cortex and a posterior

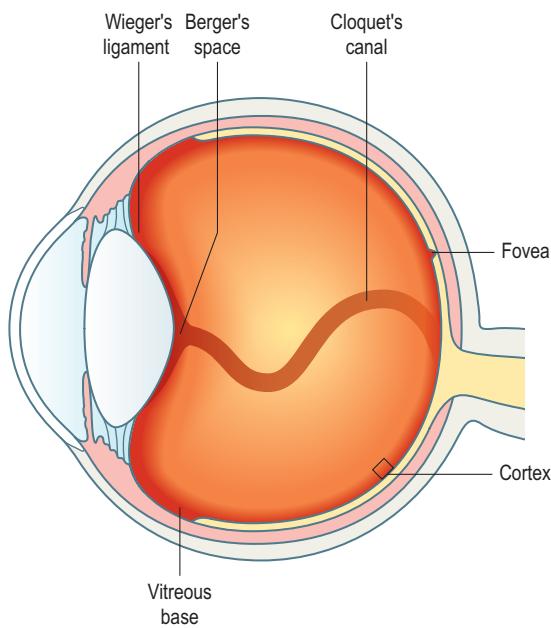

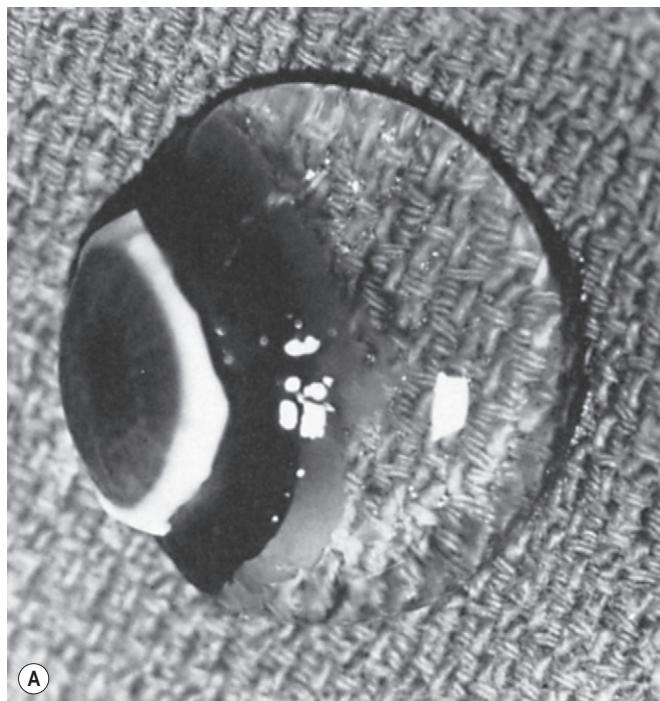

Figure 6.1 Sketch of the primate eye showing the vitreous body and its relations. Wieger's ligament is the attachment of the vitreous to the lens. Berger's space and the Cloquet's canal are the former sites of the hyaloid artery. (From Heegaard 1997.⁴⁵)

cortex, the latter being approximately 100 µm thick (Fig. 6.3). The cortex is also called the *anterior* and the *posterior hyaloid*. The cortex consists of densely packed collagen fibrils (Fig. 6.4). The vitreous base (see Fig. 6.1) is a three-dimensional zone. It extends approximately from 2 mm anterior to the ora serrata to 3 mm posterior to the ora serrata, and it is several millimeters thick. The collagen fibrils are especially densely packed in this region.

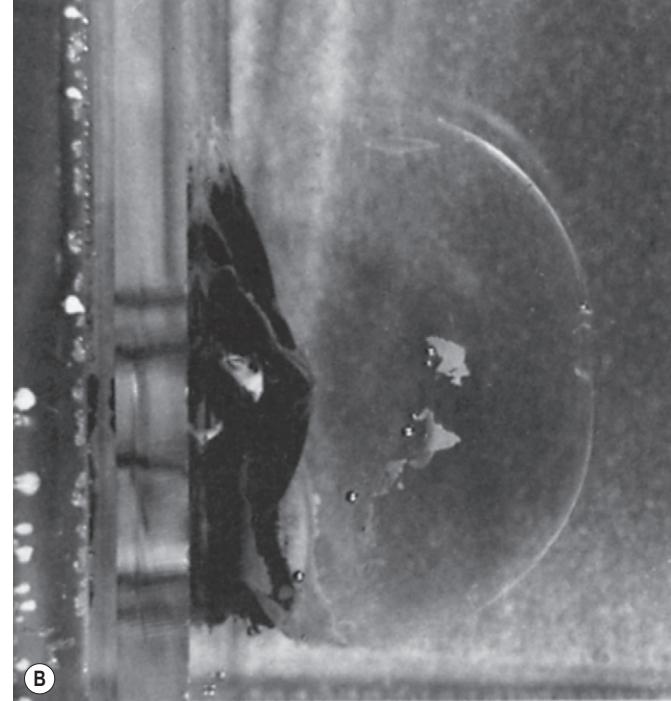

The vitreoretinal interface

The vitreoretinal interface can be defined from electron microscopy as the outer part of the vitreous cortex (posterior hyaloid), including anchoring fibrils of the vitreous body and the ILM of the retina (Fig. 6.5).^{29,34,44–46,93} The ILM is a retinal structure between 1 and 3 µm thick, consisting mainly of type IV collagen and proteoglycans.¹¹⁷ It contains several layers and can be considered the basal lamina of the Müller cells, the foot processes of which are in close contact with the membrane.

The vitreous cortex is firmly attached to the ILM in the vitreous base region, around the optic disc (Weiss ring), at the vessels, and in the area surrounding the foveola at a diameter of 500 µm.^{48,106} Under normal conditions, the connection between the fibrils of vitreous cortex and the ILM is looser than in the rest of the vitreoretinal interface. The adhesion is strong in young individuals, and dissection of

(A)

(B)

Figure 6.2 Human vitreous dissection. (A) Vitreous of a 9-month-old child. The sclera, choroid and retina were dissected off the vitreous, which remains attached to the anterior segment. A band of gray tissue can be seen posterior to the ora serrata. This is peripheral retina that was firmly adherent to the posterior vitreous base and could not be dissected. The vitreous is solid and although situated on a surgical towel exposed to room air maintains its shape because at this age the vitreous is almost entirely gel. (B) Human vitreous dissected off the sclera, choroid and retina are still attached to the anterior segment. The specimen is mounted on a lucite frame using sutures through the limbus and is then immersed in a lucite chamber containing an isotonic, physiologic solution that maintains the turgescence of the vitreous and avoids collapse and artefactual distortion of vitreous structure. (Reprinted with permission from Sebag & Balazs 1984.¹¹⁴)

the retina from the vitreous often leaves ILM tissue adherent to the vitreous cortex.^{47,60,108,109} Under pathologic conditions, the tight connections between the vitreous cortex and the ILM play an important role, as is discussed later in this chapter.

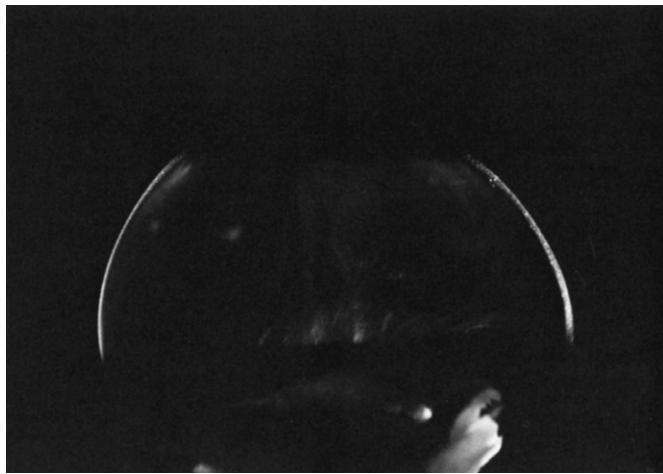

Figure 6.3 Human vitreous structure during childhood. This view of the central vitreous from an 11-year-old child demonstrates a dense vitreous cortex with hyalocytes. The posterior aspect of the lens is seen below, though dimly illuminated. No fibers are present in the vitreous.

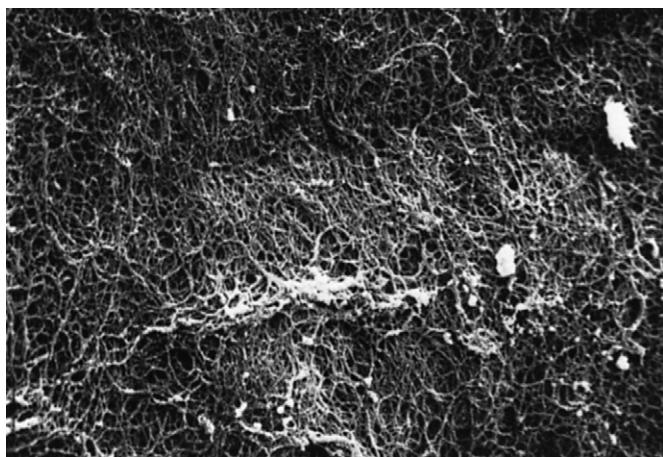

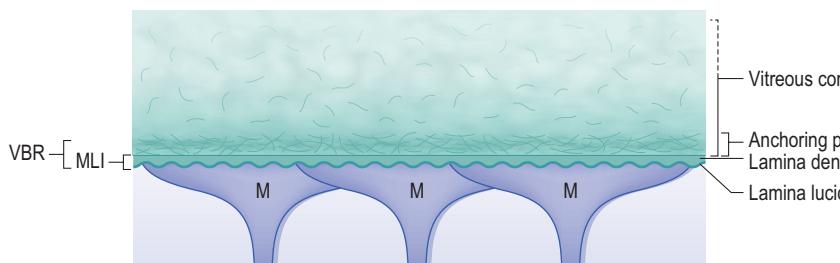

Figure 6.4 Ultrastructure of human vitreous cortex. Scanning electron microscopy demonstrates the dense packing of collagen fibrils in the vitreous cortex. To some extent this arrangement is exaggerated by the dehydration that occurs during specimen preparation for scanning electron microscopy (magnification = $\times 3750$).

Ultrastructural, biochemical, and biophysical aspects

Ultrastructural and biochemical aspects

The vitreous contains more than 99% water; the rest is composed of solids. The vitreous acts as a gel (i.e. an interconnected meshwork) that surrounds and stabilizes a large amount of water compared with the amount of solids. The gel structure of the vitreous results from the arrangement of long, thick, non-branching, collagen fibrils suspended in a network of hyaluronic acid, which stabilize the gel structure and the conformation of the collagen fibrils (Figs 6.6 and 6.7).^{8,10,107}

In the human eye the major part of the glycosaminoglycan is hyaluronic acid, with a molecular weight of $3\text{--}4.5 \times 10^6$.¹¹¹ The volume of non-hydrated hyaluronic acid is $0.66 \text{ cm}^3/\text{g}$, in contrast with the volume of the hydrated molecule, which is $2000\text{--}3000 \text{ cm}^3/\text{g}$.⁸ The molecule forms into large, open coils, with the anionic sites spread apart. This arrangement of small-diameter fibers, separated by highly hydrated glycosaminoglycan chains, permits the transmission of light to the retina with minimal scattering.¹¹ The collagen fibrils in the vitreous are thin, with diameters of approximately 10–20 nm. Collagen fibrils are mostly of collagen type II. They are composed of three identical α -chains, which form a triple helix. The helix is stabilized by hydrogen bonds between opposing residues in different chains.¹¹¹ Collagen type IX is also present and may function as a bridge, linking type II collagen fibrils together.^{10,32,120} Collagen V/XI is integrated with collagen II in the collagen fibers.⁸¹ The collagen fibrils seem to interconnect with the hyaluronic acid, most likely via bridging glucoproteins.¹¹¹ The viscoelastic properties of the vitreous gel are neither due to hyaluronic acid or collagen alone but to the combination of the two molecules.¹²⁸

Dissolved in the water of the vitreous gel are inorganic and organic substances as shown in Table 6.1, where plasma values are given for comparison.

According to Table 6.1, it appears that gradients exist in both directions between vitreous and plasma.^{3,79,82,97,98} These gradients are a result of several mechanisms: presence of the blood–ocular barriers (i.e. active and passive passage across the barriers), metabolism in retina and ciliary body, and diffusion processes in the vitreous body (Box 6.1).

The values in Table 6.1 represent mean values for the whole vitreous. The methods used to quantitate vitreous concentrations are difficult and may differ between studies in absolute numbers. However, regional differences within the vitreous have been measured for some substances.¹²

Figure 6.5 Sketch of the vitreoretinal interface / vitreoretinal border region (VBR). The VBR consists of two major components: the anchoring fibrils of the vitreous body and membrana limitans interna (MLI). The MLI is composed of three structures: the fusing point of the anchoring vitreous fibrils, lamina densa and lamina lucida. M = Müller cell. (From Heegaard 1997.⁴⁵)

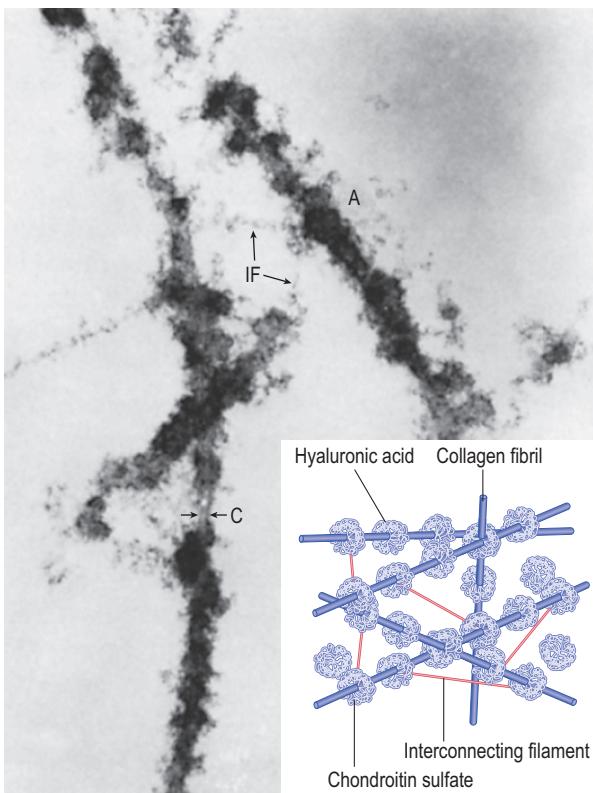

Figure 6.6 Ultrastructure of hyaluronic acid/collagen interaction in the vitreous. Specimen was fixed in glutaraldehyde/paraformaldehyde and stained with ruthenium red. Collagen fibrils (C) are coated with amorphous material (A) believed to be hyaluronic acid. The amorphous material may connect to the collagen fibril via another glycosaminoglycan, possibly chondroitin sulfate (see inset). Interconnecting filaments (IF) appear to bridge between collagen fibrils, inserting or attaching at sites of hyaluronic acid adhesion to the collagen fibrils (bar = 0.1 μm). (Reprinted with permission from: Asakura A. Histochemistry of hyaluronic acid of the bovine vitreous body as studied by electron microscopy. Acta Soc Ophthalmol J 1985; 89:179.)

Figures 6.8 to 6.10 show the regional difference for glucose (Fig. 6.8), lactate (Fig. 6.9), and oxygen (Fig. 6.10). The fall in vitreous oxygen tension towards the center, corresponding to the upper curve in Figure 6.10, was also found by Sakaue¹⁰⁰ and seems to result from an oxygen flux from the retina towards the vitreous corresponding to arterioles; the flux goes in the opposite direction corresponding to the venules (lower curve). Several studies have found an increase in preretinal oxygen after photocoagulation, indicating that the oxygen supply to the inner retina improves after destruction of the outer retina and a concomitant decrease in tissue metabolism and oxygen needs.^{40,85,94,122–124}

Box 6.1 Vitreous – aging and ocular pathology

- The concentration of salts and organic substances of the vitreous differ substantially from plasma due to the blood-aqueous and blood-retinal barrier
- Small molecules move through the vitreous gel by diffusion
- Vitreous fluorometry is useful for evaluation of the vitreal morphology, the fluorescein profile is an indicator of physiologic aging such as vitreous liquefaction
- The aging process leads to posterior vitreous detachment, easily visualized by optical coherence tomography (OCT)
- Vitreoretinal traction may lead to formation of a macular hole and the traction can be conducted through the retinal layers
- Vitreoretinal traction is also implicated in some cases of macular edema
- In diabetes, the high glucose speeds up metabolism before visible retinopathy
- Increased demand for oxygen and capillary closure leads to retinal ischemia and an increased production of VEGF
- Increased leakage through the blood-retinal barrier leads to macular edema
- VEGF inhibition and steroids decrease macular edema

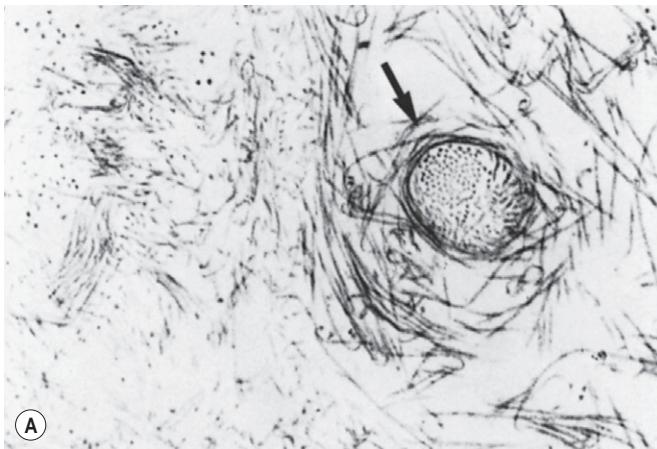

Figure 6.7 Ultrastructure of human vitreous. (A) Specimens were centrifuged to concentrate structural elements, but contained no membranes or membranous structures. Only collagen fibrils were detected. There were also bundles of parallel collagen fibrils such as the one shown here in cross-section (arrow). (B) Schematic diagram of vitreous ultrastructure, depicting the dissociation of hyaluronic acid (HA) molecules and collagen fibrils. The fibrils aggregate into bundles of packed parallel units. The HA molecules fill the spaces between the packed collagen fibrils and form “channels” of liquid vitreous. *Human data from McNeil et al 1999.⁸²**Porcine data from Andersen 1991.³All other values are rabbit data from Reddy & Kinsey 1960;⁹⁷ with modification from Kinsey 1967.⁵⁹

Figure 6.8 Glucose concentration in different parts of the vitreous body and in plasma. All values are in $\mu\text{mol/g}$ tissue weight (mean \pm standard deviation, $n = 20$). (From Bourwieg et al 1974.¹² Reproduced with permission from Association for Research in Vision and Ophthalmology.)

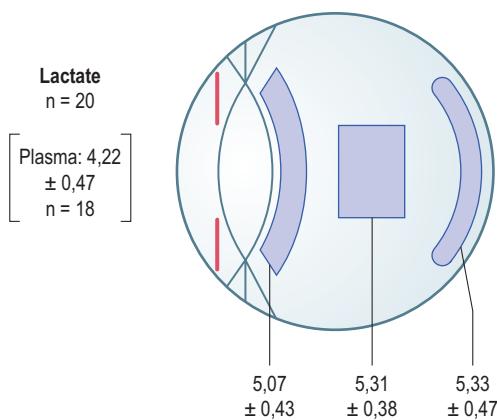

Figure 6.9 Lactate concentration in different parts of the vitreous body and in plasma. All values are in $\mu\text{mol/g}$ tissue weight (mean \pm standard deviation, $n = 20$). (From Bourwieg et al 1974.¹² With kind permission of Springer Science + Business Media.)

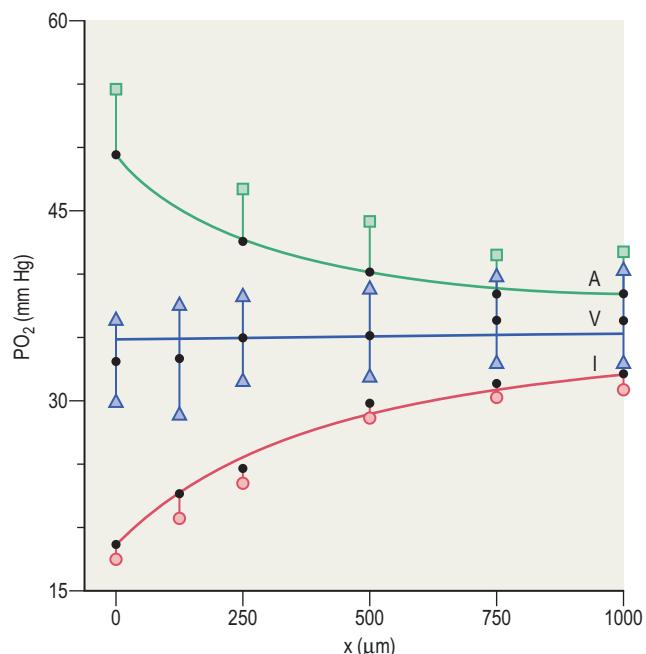

Figure 6.10 Heterogeneity of the PO_2 in the preretinal vitreous of a non-photocoagulated eye. Graphic representation of the PO_2 (\pm SEM) recorded when the O_2 -sensitive microelectrode was withdrawn from the vitreal surface of the retina ($x = 0$) towards the vitreous. Curve A: opposite an arteriole; curve I: opposite an intervacular zone; curve V: opposite a vein. These results are averages of measurements made on one or both eyes of 11 miniature pigs. (From: Mohar I. Effect of laser photocoagulation on oxygenation of the retina in miniature pigs. Invest Ophthalmol Vis Sci 1985; 26:1410. Reproduced with permission from Association for Research in Vision and Ophthalmology.)

Biophysical aspects

The gel structure acts as a barrier against movement of solutes. Basically, substances may move by two different processes: diffusion or bulk flow. The diffusion process can be illustrated in humans by using fluorescein as a tracer substance for the biophysical behavior of the gel. The fluorescein concentration in the vitreous body can be estimated by vitreous fluorophotometry. After intravenous (IV) injection of fluorescein, a certain amount (in healthy humans only a very small amount) passes through the ocular barriers

into the anterior chamber and into the vitreous body. The ILM, the vitreoretinal interface, and the vitreous cortex cannot be regarded as a diffusion restriction to smaller molecules (Box 6.1). In the vitreous the distribution versus time occurs according to the diffusion properties of a particular molecule in the vitreous gel.

An analysis of the fluorescein concentration gradient in the posterior part of the vitreous can be made with the aid of a simplified mathematical model of the relationship between the vitreous body and the blood-retinal barrier, as shown in Figures 6.11–6.14.⁷⁸

In the model the vitreous body is considered as a globe with an outer delineation corresponding to the blood-retinal barrier (Fig. 6.11). Fluorescein passes the barrier passively with permeability P. Diffusion in the vitreous gel takes place with a diffusion coefficient D. The time-dependent plasma fluorescein concentration is given by $C_0(t)$ and the concentration in the vitreous body dependent on time (t) and distance (r) from the center of the eye is given by $C(r,t)$.

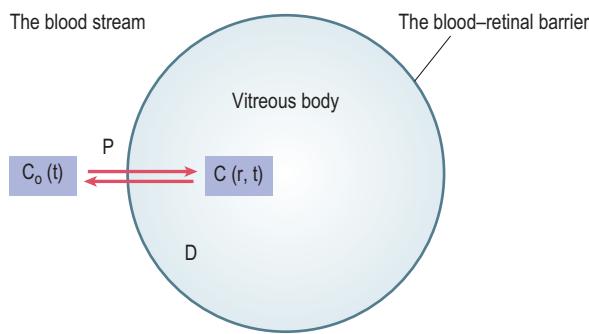

Figure 6.11 Simplified model of the eye used for the computerized calculation of a blood-retinal barrier permeability and vitreous body diffusion coefficient for the substance fluorescein. $C_0(t)$: concentration of free (not protein-bound) fluorescein in plasma at time (t); $C(r,t)$: concentration of fluorescein in the vitreous body at time (t) and at the position (r) from the center of the eye. P: permeability of the blood-retinal barrier, symbolized by a single spherical shell; D: diffusion coefficient in the vitreous body. (From Lund-Andersen et al 1985.⁷⁸ Reproduced with permission from Association for Research in Vision and Ophthalmology.)

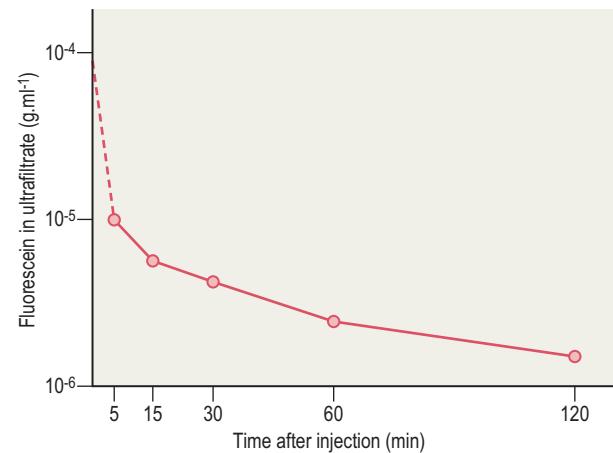

Figure 6.12 Concentration of free (non-protein bound) fluorescein in ultrafiltrate of plasma versus time after IV injection of the dye. The data were obtained in a normal subject. Fluorescein was injected at time 0. The first blood sample was obtained at 5 min, then 15, 30, 60 and 120 min after the injection. The concentration during the first min of injection was not directly measured, but calculated (dotted line) – see method. (From Lund-Andersen et al 1982.⁷⁵)

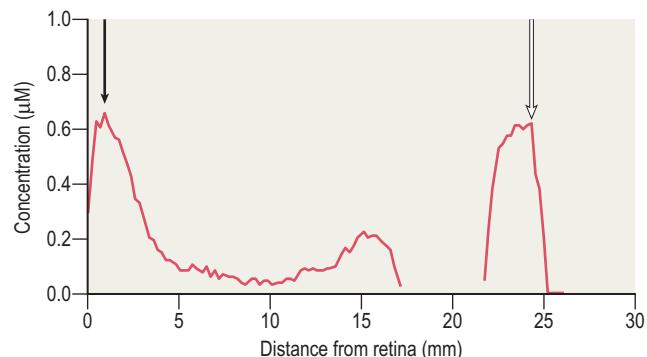

Figure 6.13 Vitreous fluorophotometry scan along the optical axis of the eye obtained 60 min after injection of fluorescein. The black arrow indicates the retina, the open arrow the fluorescein concentration in the anterior chamber. The autofluorescence signal from the lens has been removed. Note a small peak behind the lens (~15 mm from the retina) due to fluorescein leaking from the anterior chamber into the vitreous body. (From Sander et al 2001.¹⁰² Reproduced with permission from Association for Research in Vision and Ophthalmology.)

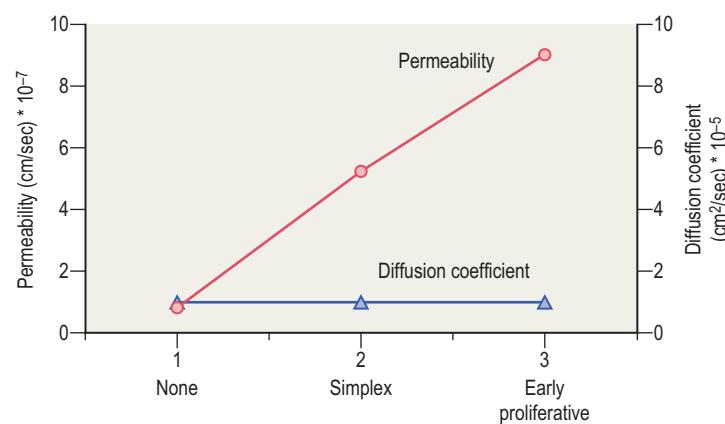

Figure 6.14 Diffusion coefficient for fluorescein in the vitreous body and fluorescein permeability of the blood-retinal barrier in diabetic patients with three different degrees of retinopathy. (Redrawn with permission from Lund-Andersen et al 1985.⁷⁷)

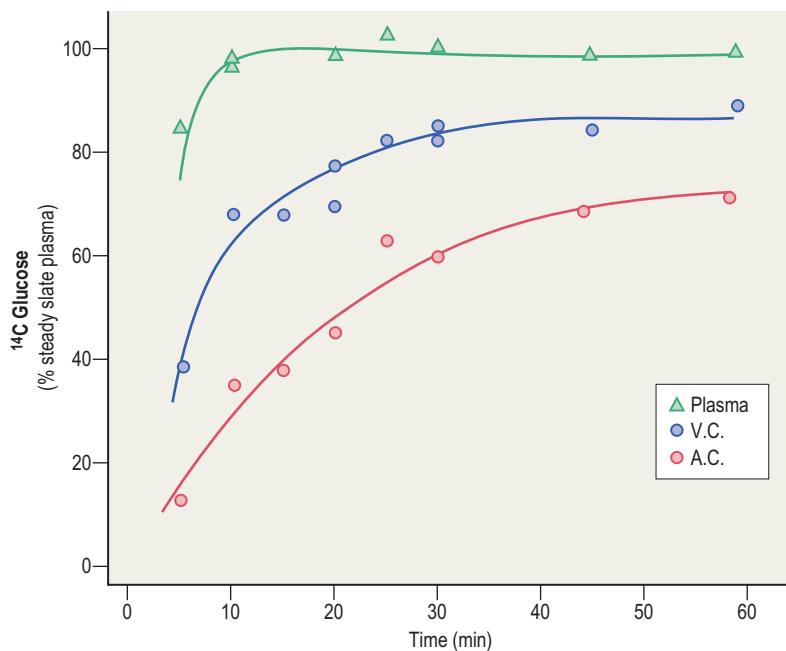

Figure 6.15 Entry of ^{14}C -glucose from the blood into the aqueous (A.C.) and vitreous (V.C.) humors. Blood and aqueous humor samples were fractionated on Sephadex columns before counting to separate glucose from its metabolic products. Curves are hand-fitted to the data; 6 animals were used. (From Riley 1972.⁹⁸ Reproduced with permission from Association for Research in Vision and Ophthalmology.)

The basic equations and the mathematical formalisms are as follows:⁷⁸

$$C(r, t) = \int_0^t C_o(t-s) * F(r, s; a, D, P) ds \quad (1)$$

where

$$F(r, s; a, D, P) = \frac{aP}{r\sqrt{D}} * \left[G\left(\frac{a-r}{2\sqrt{D}}, s; k\right) - G\left(\frac{a+r}{2\sqrt{D}}, s; k\right) \right] \quad (2)$$

In equation (2), G is given by

$$G(x, s; k) = e^{-x^2/4s} / \sqrt{\pi s} - k * e^{k(x+k*s)} \operatorname{erfc}(k\sqrt{s} + x/2\sqrt{s}) \quad (3)$$

where $k = (P\sqrt{D}) - (\sqrt{D}/a)$ and erfc is the complementary error function. Radius [a] of the eye is determined experimentally. P and D are calculated from a set of experimental data by minimizing

$$S = \sum_{i=1}^N w_i [C_m(r_i, t) - C(r_i, t)]^2 \quad (4)$$

where $C_m[r_i, t]$ is the measured value at $r = r_i$, and c is the corresponding value given by equation (1).

Equation (4) indicates that each point of the vitreous concentration profile is weighed equally during the fitting procedure. In the paper by Larsen et al⁶⁷ another weighing procedure was suggested. However, this procedure adds too much weight to the low values towards the center of the eye and, accordingly, the present equal weighting procedure is preferred.

Figure 6.12 shows the fluorescein concentration in the bloodstream versus time after IV injection.⁷⁵ Figure 6.13 shows the fluorescein concentration in the vitreous body and the anterior chamber 60 minutes after the injection as determined by vitreous fluorophotometry. A combination of plasma and vitreous values by aid of the simplified mathematical model results by curve fitting in a diffusion coefficient of approximately $6 \times 10^{-6} \text{ cm}^2/\text{sec}$. This is close to a diffusion coefficient that would be expected in an unstirred

gel; experimentally, the diffusion coefficients for mannitol and inulin have been found to be 2.4 and $2.0 \times 10^{-6} \text{ cm}^2/\text{sec}$ respectively.^{74,76}

The diffusion coefficient for fluorescein in the vitreous in diabetic patients with different degrees of retinopathy is shown in Figure 6.14. Although the permeability of the blood-retina barrier increases in relation to the degree of retinopathy, the diffusion coefficient is unchanged, indicating that the spread of fluorescein in the vitreous gel occurs with the same kinetics and rate during the earlier phases of diabetic retinopathy.

The permeability for the blood-retinal barrier relates to low-molecular-weight substances and ions; is low in the healthy eye, as shown here for fluorescein; and is close to the permeability of the blood-brain barrier.^{13,131} The blood-aqueous barrier (i.e. the barrier in the ciliary body and the iris) is looser, although it is still tighter than capillaries elsewhere, such as in the muscles.¹⁹

The presence of the ocular barriers and the "slow" diffusion process have the consequence that transient changes in the bloodstream are reflected slowly in the total vitreous body (Fig. 6.13). The slow change of the vitreous body concentration can be used in some aspects of legal medicine regarding postmortem diagnosis.⁸² The time constants for many substances (Figs 6.15 and 6.16) are of the same magnitude as those describing glucose transport between blood and brain; that is, half of the maximum is achieved in approximately 10 minutes.⁷³

Bulk flow through the vitreous cavity as a result of a possible pressure gradient from the anterior part of the eye toward the posterior pole does not play any significant role in the distribution of low-molecular-weight substances in the intact vitreous; this aspect was not included in the mathematical model. However, high-molecular-weight substances or large particles are moving through the vitreous as a result of bulk flow (i.e. the flow of liquid that enters the vitreous body from the retrozonular space and leaves through the retina, as

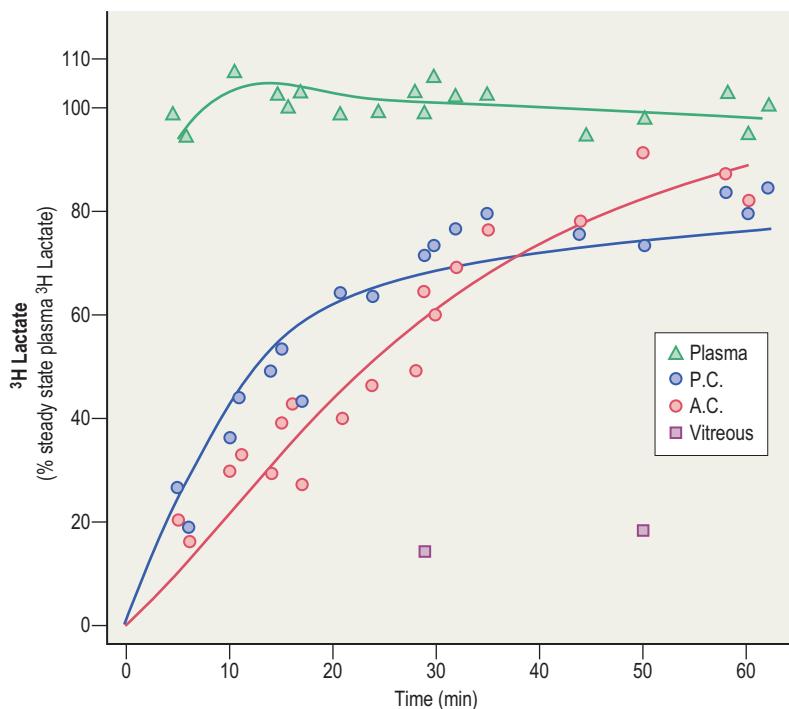

Figure 6.16 Entry of H-lactate from the blood into the aqueous (A.C., anterior chamber; P.C., posterior chamber) and vitreous humors. The two lower curves in this figure are best fit lines obtained by analog computer analysis in accordance with the theory of aqueous humor dynamics derived by Kinsey & Reddy. (From Riley 1972.⁹⁸ Reproduced with permission from Association for Research in Vision and Ophthalmology.)

described by Fatt²⁸). If such a compound is placed in the anterior part of the vitreous, it moves slowly toward the retina; the diffusion process is virtually zero for large molecules. In contrast, diffusion is more rapid for the movement of small molecules. Low-molecular-weight substances move faster, diffusing in all directions, and are virtually unaffected by bulk flow; if placed in the vitreous, a low-molecular-weight substance will also be found in the anterior chamber.

Aging of the vitreous

The vitreous body goes through considerable physiological changes during life; changes that have great significance for its function. There is a sliding transition between the physiological aging changes and actual degenerative changes (retinitis pigmentosa, Wagner's disease).

The normal postnatal vitreous body is a homogeneous gel developed and biochemically composed as described above. The fundamental aging change is a disintegration of the gel structure, the so-called liquefaction or synchysis, especially notable in the center of the vitreous where the collagen concentration is lowest.^{119,127,128} Liquefaction starts early in life, and a linear increase in the volume of vitreous liquid is found with age.^{8,118}

Molecular mechanisms in aging

The mechanisms behind the liquefaction are not known exactly but could be linked to conformational changes in the collagen.² The apparent molecular weight of vitreous collagen increases with age because of the formation of new covalent cross links between the peptide chains equivalent to the aging process in collagen elsewhere in the body.¹ Bundles of collagen fibrils become biomicroscopically visible as coarse fibrous opacities.¹¹³ The common aging

processes, such as the cumulative effect of light exposure and non-enzymatic glycosylation, seem to be important. Both hyaluronic acid and collagen may be affected by free radicals in the presence of a photosensitizer such as riboflavin (which is present in the eye) after irradiation with white light.² Enzymatic and non-enzymatic cross-linking have also been demonstrated.^{115,116,134} Non-enzymatic glycosylation is well known from other tissues with a slow turnover of proteins, such as the lens.^{58,125} Proteins are cross-linked due to the Maillard reaction with formation of a covalent binding between an amino group and glucose leading to insolubilized proteins (advanced glycation end-products – AGEs). The process is modulated by ultraviolet light and accelerated in persons with diabetes mellitus.¹⁰¹ The vitreous glucose concentration is doubled in persons with diabetes compared with that of healthy subjects.⁷⁹ Sebag et al have found that collagens in the vitreous are cross-linked due to non-enzymatic glycation.^{111,116,133}

Other mechanisms are probably involved. The network density of collagen decreases in childhood due to the growth of the eye, which could destabilize the gel. On the other hand, the hyaluronic acid concentration is increased and leads to gel stabilization.¹¹¹ The concentration of electrolytes, soluble protein and other substances such as metalloproteinase may change.^{15,52} The soluble protein concentration increases with age due to an increase in the leakage through the blood–retina barrier, which may play a role both in the normal aging process and in pathologic conditions such as diabetic retinopathy.¹²⁷

Structural changes

Regardless of the exact nature of the molecular changes, the structure of the gel is dissolved and replaced with aqueous lacunae, which melt together over time. The hyaluronic acid is redistributed from the gel to the liquid vitreous with

concomitant conformational changes.⁵ The liquefaction is qualitatively shown in Figures 6.17 and 6.18 and quantitatively in Figure 6.19.

Human vitreous structure can be observed using dark-field microscopy.^{108,110,113,116} With this technique, the vitreous is optically empty in the young apart from the vitreous cortex. With time, fine parallel fibers appear, with anterior-posterior fibers attached to the vitreous base and ora serrata. Peripheral fibers are circumferential with the vitreous. The fibers probably correspond to aggregated collagen fibers no longer separated by hyaluronic acid and with increasing age the fibers become thickened and associated with pockets of liquid vitreous (lacunae).

In a series of investigations using India ink injection in the vitreous body, Worst argued that the adult vitreous body is composed of a number of cisterns (Fig. 6.20),^{54,55,137} the lining of the cisterns corresponding to the fibers found by Sebag. A funnel-shaped cavity, the bursa premacularis, was found in front of the macula. Using fluorescein staining, Kishi has described a similar structure termed the posterior precortical vitreous pocket (PPVP).⁶¹ In this study the anterior part was found to be lined by the vitreous gel proper and the posterior part by the posterior hyaloid membrane.

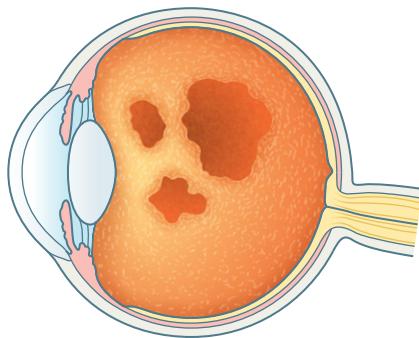

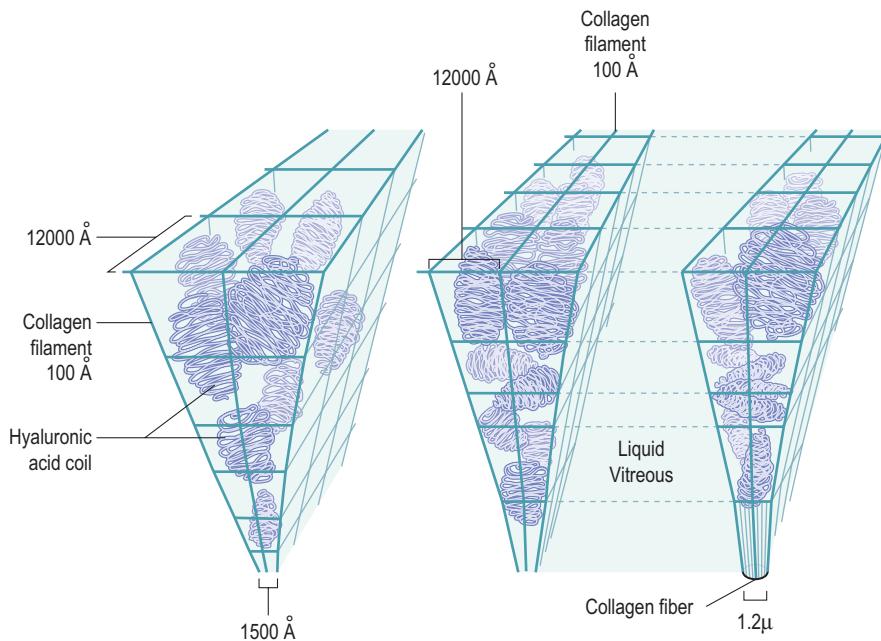

Figure 6.17 Schematic illustration of the vitreous body with lacuna. (From Kanski J 1989.⁵⁷)

Sebag et al^{113–116} found a premacular hole in the cortex and observed herniation of the vitreous gel through the hole. The presence or absence of vitreous cortex in close apposition to the fovea is disputed and might be dependent on the age of the donor eye and the technique used.^{41,60,61,112,127} Worst proposed that anterior-posterior traction of the collagen fibrils lining the cisternae is significant for the formation of macular holes.¹³⁷

Vitreo-retinal interface imaging

Optical coherence tomography (OCT) is a clinical technique that is suitable both for measurement of retinal thickness and for imaging of the vitreo-retinal interface (Fig. 6.21).^{6,80,42,43,96} Measurements of retinal thickness are comparable to stereoscopic viewing and reproducible, even in the presence of cataract.^{49,80,126} The axial resolution of the technique is 3–10 µm and the distinction between high-reflectivity intravitreal membranes and non-reflective vitreous is favorable,^{18,136} although the exact nature of intravitreal strands cannot be deduced from the image. Anterior-posterior membranes will theoretically be more difficult to detect due to the minimal backscatter from the small cross-section of such fibers.

The aging process of the vitreo-retinal interface has been studied with the OCT in 209 healthy subjects (age 31–74 years).¹³² Preretinal strands, presumably posterior cortex, were found in 60 percent of these non-symptomatic cases without biomicroscopic evidence of posterior vitreous detachment (PVD). Persistent attachment was found to the fovea, optic nerve head and mid-periphery. The study demonstrates that partial PVD demonstrated by OCT is frequent in healthy subjects.

Diffusion kinetics as an indicator of the biophysical status of the vitreous

Using fluorophotometry examination of the fluorescein diffusion profile in the vitreous reveals three different profiles. These profiles provide information on how the vitreous

Figure 6.18 Schematic picture of the fine structure of the vitreous gel showing network reinforced with hyaluronic acid molecules. Left: Random distribution of the structural elements. Figure 6.21 Optical coherence tomography scan from a healthy subject (6 mm scan through the fovea). The optically empty vitreous is in the top of the picture. The thin foveal center is seen in the middle of the scan and facing the vitreous, the retinal nerve fiber layer is visible (stippled arrow). The signal from the photoreceptors is relatively low (black or blue) while the reflectance from the retinal pigment epithelium is high and seen as red/white (repeated arrow). Also the junction of the inner and outer photoreceptor segments gives a highly reflecting line (full-drawn arrow). The vessels in choriocapillaris are partly visible.

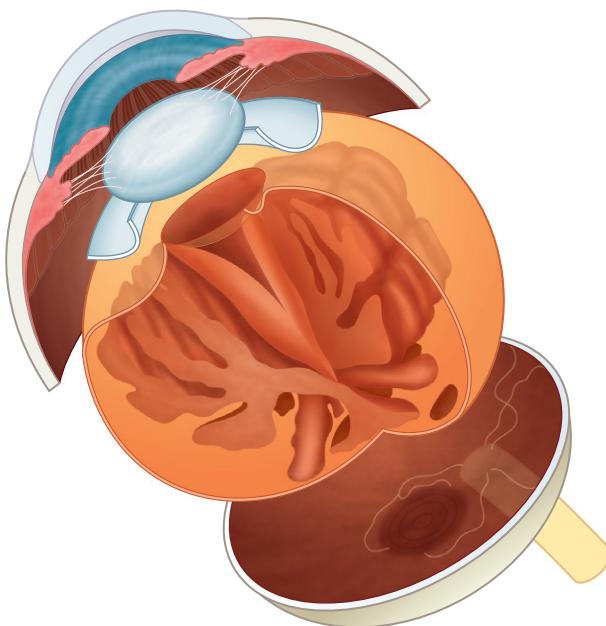

Figure 6.20 Schematic diagram of Worst's interpretation of vitreous structure. "Cisterns" are visualized using white India ink to fill areas of the vitreous that take up this opaque dye. There are retrociliary, equatorial, and perimacular cisternal rings and a bursa premacularis. (From Jongebloed & Worst 1987.⁵⁵)

body behaves during aging from a diffusion-kinetic point of view.^{77,83} The three different diffusion kinetic relationships are shown in Figures 6.22 to 6.24 from a study of patients with retinitis pigmentosa in different stages of the disease. The upper curve (see Fig. 6.22) shows a diffusion profile comparable to a normal vitreous body, in which the shape of the diffusion profile corresponds to the diffusion in an intact gel, and the diffusion coefficient corresponds to diffusion in a gel (see above). Figure 6.23 shows that there is no diffusion profile, as is the case when degeneration and liquefaction of the vitreous body are present, as observed in

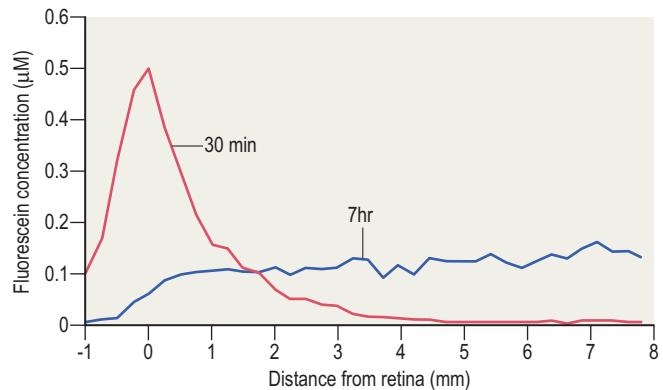

Figure 6.22 Pre-retinal vitreous concentration profiles for fluorescein in a patient with retinitis pigmentosa measured after 30 min and 7 h, which enables determination of passive permeability and outward, active transport. (From Moldow et al 1998.⁸³ With kind permission of Springer Science + Business Media.)

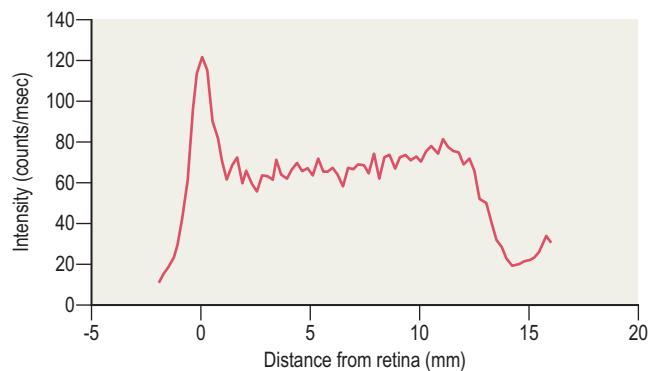

Figure 6.23 Fluorescein profile in the vitreous recorded at 30 min after fluorescein injection from a patient with retinitis pigmentosa. The absence of a preretinal gradient after 30 minutes indicates a significant vitreous detachment/liquefaction and the patient was excluded from the study. (From Moldow et al 1998.⁸³ With kind permission of Springer Science + Business Media.)

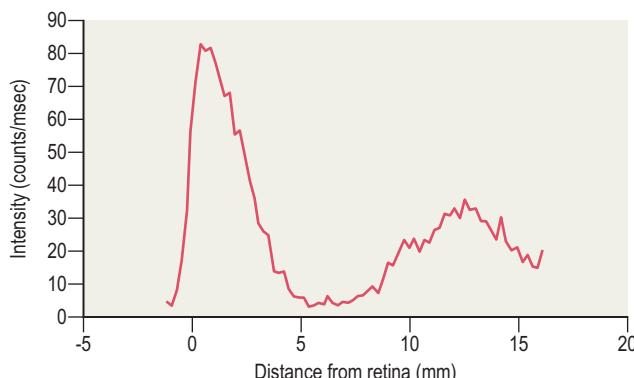

Figure 6.24 Vitreous profile recorded from a patient with retinitis pigmentosa 30 minutes after injection. The figure illustrates a typical “camel hump” which has no visual influence on the pre-retinal gradient. (From Moldow et al 1998.⁸³ With kind permission of Springer Science + Business Media.)

cases of retinitis pigmentosa. Figure 6.24 gives a diffusion profile interrupted by a convex hump, which can be related to a lacuna in the vitreous with high fluorescein concentration in the center (Box 6.1).

In studies where the diffusion kinetic relationships were compared with a clinical evaluation of the vitreous body, a good correlation between the diffusion kinetic and the clinical evaluation was reported.^{95,99}

Physiology of the vitreous body

In the following the most essential physiological and pathophysiological relationships of the vitreous body will be illustrated. The normal physiology of the vitreous body can be divided into four main groups:

- Support function for the retina and filling up function of the vitreous body cavity
- Diffusion barrier between the anterior and the posterior segments of the eye
- Metabolic buffer function
- Establishment of an unhindered path of light

A. Support function for the retina and filling up function of the vitreous body cavity

Normal conditions

An intact vitreous body, which fills up the entire vitreous cavity, may retard or prevent the development of a larger retinal detachment. Presumably, the vitreous body can also absorb external forces and reduce mechanical deformation of the eye globe. The intact vitreous body supports the lens during trauma to the eye. However, this mechanical support is only of limited significance. Thus eyes in which the vitreous has been removed during vitrectomy can still have a normal function, and the retina is not detached.

Pathological/pathophysiological correlations

Posterior vitreous detachment

As previously mentioned, degeneration of the vitreous body is a normal physiologic aging phenomenon. When the

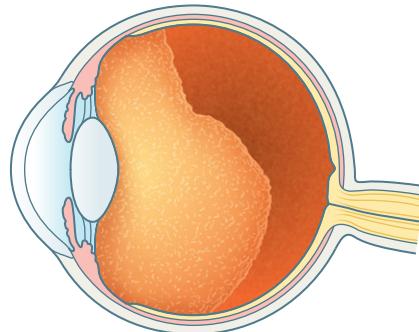

Figure 6.25 Schematic illustration of the vitreous body cavity with a posterior vitreous detachment. (From Kanski 1989.⁵⁷)

central degeneration is sufficiently large, this leads to a collapse of the rest of the vitreous body, which causes the cortex to sink into the center of the vitreous body. This leads to the condition PVD (Figs 6.25 and 6.26).

PVD is the most common pathophysiologic condition of the vitreous body and is considered a normal physiologic aging phenomenon that might be related to a decrease in anchoring fibrils at the vitreoretinal interface.^{46,47,132,139} Vitreous detachment leads to opacities in the vitreous body, but otherwise it typically has no clinical consequences. However, if there is a strong attachment between the posterior hyaloid and the ILM, a PVD can result in a retinal tear. This is the first step in a rhegmatogenous retinal detachment.

PVD can also induce traction on the retina, especially in the foveal region, if there is a strong attachment between the vitreous cortex and the ILM. This is seen especially in eyes with diabetic retinopathy. A shrinking of the posterior cortex when it is attached to the ILM can induce various forms of surface retinopathy, such as macular holes or macular edema.

Perifoveal vitreous detachment has been argued as a primary pathogenic event in idiopathic macular hole formation. However, this phenomenon may be secondary to the formation of the macular hole.

Gass^{35,36} has postulated a centrifugal retraction of retinal receptors as an early event that might be caused by an early vitreoretinal degeneration of foveal Müller cells and the overlying vitreous cortex with subsequent split of the Müller cells. According to this hypothesis, the photoreceptors are still present in the cuff around the hole and the large improvement in visual acuity often found after vitrectomy is to be expected.

Other studies, using OCT and B-scan ultrasonography, indicate that vitreous change is the primary event.^{37,53} Both techniques show a partial PVD, with attachment to the fovea, optic nerve and midperiphery in early stages of macular holes. As the vitreous shrinks, a traction develops in the anterior-posterior direction from the vitreous cortex to the fovea. An OCT image from the fellow-eye of a patient with a full-thickness macular hole in the other eye is shown in Figure 6.27A&B and clearly demonstrates the attachment sites of the posterior cortex. Discrete changes and a small break are seen in the outer retinal layers and the anterior-posterior traction might be conducted to the outer retinal layers through the thin, vertical fiber (probably Henle's fibers) in the middle of the central cyst. A similar picture, now with

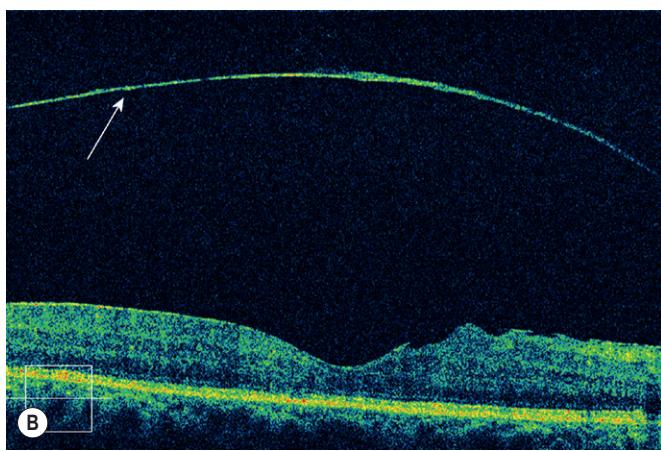

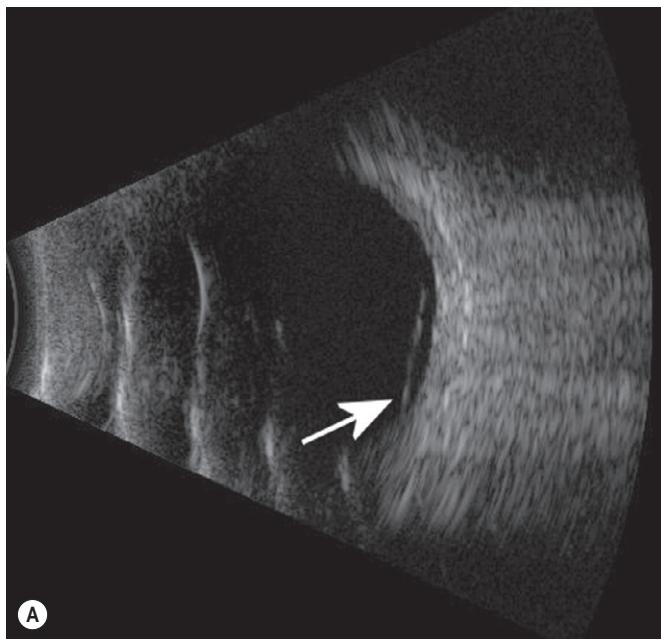

Figure 6.26 Posterior vitreous detachment as shown schematically in Figure 6.25. (A) Ultrasound B-scan of a posterior vitreous detachment in a diabetic patient, in this case the partial detachment is located just anterior to the fovea (arrow). (B) OCT of the same case, the vitreous cortex is thick and reflects strongly (arrow). The retina is stretched out, giving a false impression of a strong curvature of the posterior cortex. Epiretinal fibrosis is seen on the right side of the foveal center.

dehiscence of the photoreceptors, is seen in Figure 6.27C. Though clearly seen in Figure 6.27, PVD is not found in all cases and the etiology may not be the same in all patients (Box 6.1).^{38,43,50,62,63,89}

Intravitreal string formation may also be implicated in macular hole or retinal edema formation and a vitreal schisis may represent a type of anomalous PVD as described by Sebag.^{18,108,118}

Tangential forces cannot be excluded in the pathogenesis of macular holes.^{6,86} Traction is well known from proliferative diabetic retinopathy, and the posterior vitreous is often attached to the optic nerve and to the midperiphery. A slack shape of the posterior cortex may present evidence for an argument in favor of an antero-posterior traction and against tangential traction.^{17,37,53,86}

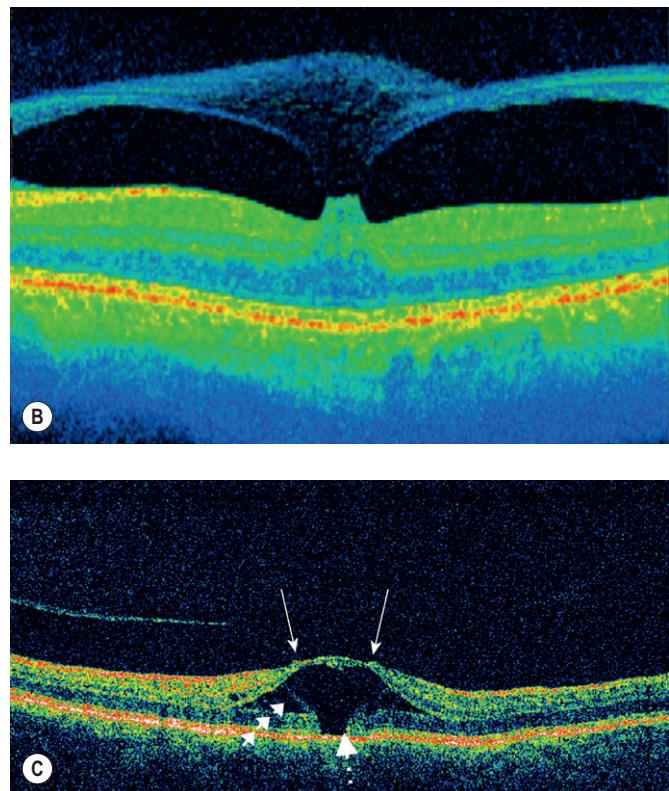

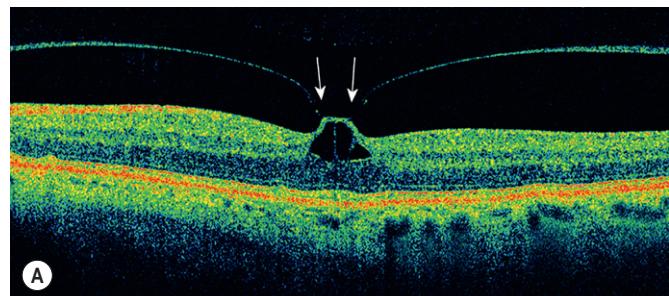

Figure 6.27 (A) Optical coherence tomography scan from the fellow eye in a patient a with full-thickness macular hole in the other eye. The posterior vitreous cortex is clearly attached to the fovea (arrows), though the signal intensity from anterior–posterior structures as usual in OCT is weaker than for nearby transversal structures. A cystic formation is seen in the fovea, the vertical lines may originate from Henle's fibers or remaining Müller cells. Beneath the cyst, a discrete break seems to be present in the outer photoreceptor layer and the otherwise highly reflecting line from the junction of inner and outer segments. (B) A 3D picture of the same eye. The vitreo-retinal traction clearly forms a circular ring, attaching to the foveal center. (C) Prehole in another patient than in (A). The vitreo-retinal traction is very similar to the case shown in the previous figure, with vitreo-retinal traction (arrows) and a vertical line within the central cystic area (repeated arrow), indicating a conduction of the vitreo-retinal traction through the neuroretina. The cystic area expands into a split at the level of the outer plexiform layer. A dehiscence is seen of the photoreceptors (stippled arrow).

Development of macular edema

The basic principles behind the pathogenesis of macular edema are illustrated in Figure 6.28. The factors involved are related to the blood–retina barrier, that is, the passive permeability and the active transport correlated to blood flow and metabolic dysfunction with formation of osmotic

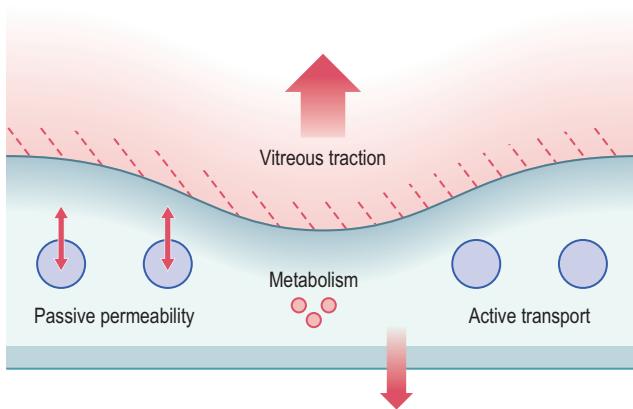

Figure 6.28 Factors related to the development of diabetic macular edema: vitreous traction, passive permeability, active transport (from the retina to the blood) and metabolism.

equivalents. Under normal conditions, the blood-retinal barrier is tight (low passive permeability). An increase in the passive permeability or a decrease in the outward active transport may lead to edema formation (see Table 6.2 below), and an increased passive permeability is predictive for later photocoagulation as well as substantial visual loss, though an increased leakage may not lead to an immediate increase in retinal thickening (Box 6.1).^{104,105} Retinal ischemia seems to be a major cause of the pathophysiological changes leading to macular edema. As shown by Linsenmeyer, the oxygen tension in the inner retina of diabetic cats is nearly zero even before visible capillary dropout.⁷² In diabetic patients without retinopathy, an acute increase in glucose leads to a faster impulse transduction (implicit time), as shown by electrophysiology, and the blood flow is increased, indicating an increased metabolism and oxygen demand.^{16,64} In addition, in cases of capillary closure and drop out of the retinal vessels, the inner retina will be in a hypoxic state, which in turn induces production of vascular endothelial growth factor (VEGF) and an increased permeability. As a consequence, long-standing severe edema is now treated with VEGF inhibitors or steroid injection; both treatments decrease vascular permeability (Box 6.1).^{7,31,135}

Vitreous traction is probably involved in some cases of macular edema and in diabetic patients OCT tomograms might have patterns similar to those seen in eyes with a macular hole (Fig. 6.29) (Box 6.1).⁵⁶ In several studies, eyes with otherwise untreatable edema have been shown to have partial PVD and vitrectomy seems to improve visual acuity in these eyes.^{6,71,129,130,138} However, vitrectomy has also been helpful in cases without evidence of vitreomacular traction.⁶⁶

As indicated above, the clinical significance of the tractive forces is complicated and difficult to quantitate, and the pathogenesis of these maculopathies is still a matter of debate.

B. Diffusion barrier between the anterior and the posterior segments of the eye

Normal conditions

The vitreous body is, as previously mentioned, a gel and in that context it has a considerable barrier function for bulk

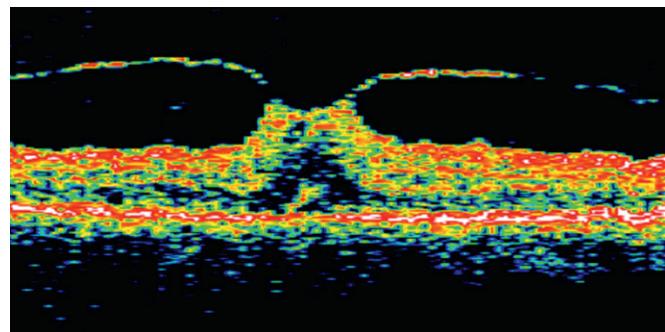

Figure 6.29 Optical coherence tomogram of a diabetic patient. The vitreous cortex is firmly attached to the fovea and the vascular arcades (not shown). After vitrectomy, normal anatomy and visual acuity were restored.

movements of substances between the anterior and posterior parts of the eye.

Substances that are liberated from the anterior segment of the eye will have difficulty reaching high concentrations in the posterior part of the eye when the vitreous body is intact because diffusion is slow and movement by bulk flow is very limited in a gel. An intact vitreous gel will also prevent topically administered substances reaching the retina and the optic nerve head in significant concentrations. Entrance of antibiotics from the bloodstream to the center of the vitreous will also be impeded by the normal vitreous.

Pathological/pathophysiological correlations

If the vitreous body is partly removed/degenerated/collapsed the exchange between the anterior and posterior part of the eye will be much faster and easier. This is the case when the lens is removed and anterior vitrectomy has been performed. Substances that are produced in the anterior segment of the eye or given topically enter the vitreous body through the less tight barrier systems in the anterior part of the eye (blood-aqueous barrier) and can be expected to reach the retina in higher concentrations than in eyes with an intact vitreous and an intact irido-lenticular barrier (Figs 6.30 and 6.31). The same is the case for topically administered pharmacologically active substances. Whether this has any clinical significance or not is not known, but the condition of the vitreous should always be taken into consideration in discussions on ocular pharmacokinetics, both for topically and systemically applied substances.

The preretinal oxygen tension is improved in diabetic patients after vitrectomy, indicating that oxygen transport increases with faster fluid currents.¹²² This is of clinical relevance because retinal neovascularization and macular edema regress.

C. Metabolic buffer function

Normal conditions

The ILM and the posterior cortex do not act as diffusion barriers for smaller molecules. Because of the close anatomic relationship to the ciliary body and the retina, the vitreous body can act as a metabolic buffer and, to a certain degree, a reservoir for the metabolism of the ciliary body and especially the retina, as indicated in the oxygen profiles in Figure 9.10. Because of the tight blood-retina barrier, water-soluble

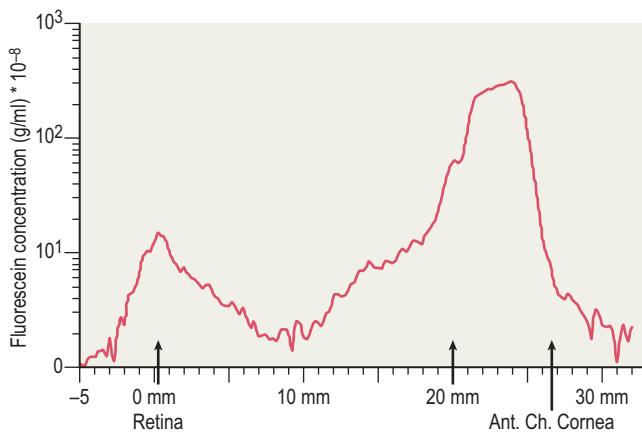

Figure 6.30 Fluorophotometric scan (30 minutes) in a patient after extracapsular cataract extraction with posterior chamber pseudophakos. Note the falling concentration of dye from the anterior and posterior towards the central vitreous. (From Ring et al 1987.⁹⁹)

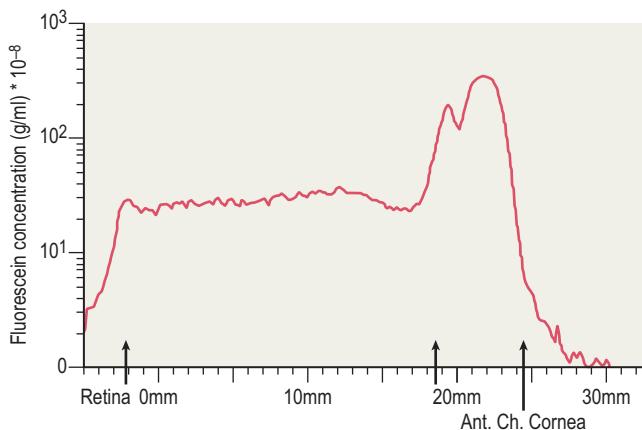

Figure 6.31 Fluorophotometric scan (30 minutes) in a patient after intracapsular cataract extraction with anterior chamber pseudophakos. There is a high concentration of dye uniformly throughout the vitreous cavity caused by gross vitreous detachment. (From Ring et al 1987.⁹⁹)

substances located in the retina have easier access to the vitreous cavity than to the bloodstream if the transport across the barrier is limited.

Substances present in or produced in the retina are thus diluted by diffusing into the vitreous body. Likewise glucose and glycogen in the vitreous body can supplement the metabolism of the retina, especially during anoxic conditions. The foot plates of the Müller cells also have close contact with the vitreous body. The vitreous body can thus act as a buffer in the physiological function of the Müller cells, for example in the potassium homeostasis of the retina.^{10,14,87}

Vitamin C is also present in the vitreous body in relatively high concentrations, where it can act as a reservoir of antioxidants in stress situations, protecting the retina from metabolic- and light-induced free radicals (see Table 6.1).

Pathological/pathophysiological correlations

Because normal function of the retina can be obtained after total vitrectomy, the metabolic buffer functions of the vitreous do not seem to play an important role.

However, the condition of the vitreous may play a role for the effect of pathogenic factors produced in the retina. The concentration of vasoproliferative factors (produced in the retina and appearing in the vitreous body) near the retina depends on the condition of the vitreous body. If the vitreous acts as a diffusion barrier to these substances, they are retained in high concentrations close to the retina. Accordingly, one can speculate that vitrectomy can cure this condition, as can be seen in some aggressive cases of proliferative diabetic retinopathy. In other cases vitrectomy can lead to rapid movement of vasoproliferative factors from the posterior pole to the anterior pole, thus leading to neovascularization in the anterior segment of the eye (neovascular glaucoma).

D. Establishment of an unhindered path of light

Normal function

The normal physiological function of the vitreous body allows an unhindered passage of light to the retina, when visible light passes through the vitreous body. An important function for the vitreous body is to maintain this optimal transparency, which is primarily due to the low concentration of structural macromolecules (<0.2 % w/v)¹¹⁸ and soluble proteins.³³ The transparency may also be maintained by the specific collagen/hyaluronic acid configuration, in analogy with the cornea. The scattering properties of the vitreous are anisotropic and the scatter decreases when the vitreous swells.¹¹

Pathological/pathophysiological correlations

Degeneration of the vitreous body (as described in the section “Aging of the vitreous” above) with generation of opacities, so-called muches volantes, interferes with the path of light. This is also seen in connection with PVD as has already been mentioned. Synchysis scintillans, asteroid degeneration, hemorrhages, inflammatory material, fibrous tissue in the vitreous body, and lack of regression of the hyaloid artery are examples of pathological conditions which all interfere with the normal path of light through the vitreous body.¹²¹

The vitreous body as a sensor for the physiology of surrounding structures

As previously described neither the posterior cortex nor the internal limiting membrane can be regarded as diffusion barriers for smaller molecules. Due to the close anatomical relationship between the vitreous, the retina and the ciliary body, changes in concentrations of substances in the vitreous body will mirror processes in these tissues. Typically, fluorescein is used as a tracer of salt (and water) movement. In vitro studies have shown both passive and active outward transport through the blood–retina barrier (from the retina to the blood).^{20,65,140,141} The passive movement (permeability) is bidirectional and probably due to fenestrations and/or leakage through tight junctions.^{4,51} The outward transport from the retina to the blood, measured with fluorescein, is significantly reduced by metabolic and competitive inhibitors and is considered an active, carrier-mediated

transport from the retina to the blood.^{24,25,65,140} The active transport thus could be related to the metabolic activity of the pigment epithelium.

Determination of the blood-retinal barrier, passive permeability and active transport for fluorescein in humans, based upon concentration changes in the vitreous body

Mathematical models that are able to determine the blood-retinal barrier permeability in passive or active transport have been developed. The models are based on the assumption that the vitreous body is a globe surrounded by a homogeneous blood-retinal barrier. The following assumptions are made: The diffusion of fluorescein in the vitreous body takes place in accordance with conventional diffusion kinetics with a diffusion coefficient (D) the passive permeability of fluorescein through the blood-retinal barrier (P_{passive}) follows the usual passive permeability rules, and the active transport ($T_{\text{out,active}}$) is carrier mediated and non-saturable within the concentration range expected to be found in the vitreous body.

After IV injection of fluorescein, the concentration of fluorescein is determined in the bloodstream as the ultrafiltrated part in the plasma, and the concentration of fluorescein in the vitreous body is determined by vitreous fluorophotometry. The passive permeability and the diffusion coefficient are calculated as described earlier, based on diffusion profiles obtained up to 60 minutes after fluorescein injection.^{21,67,68,69,70,74,77} The outward, active transport is calculated from the preretinal fluorescein concentration curve 8–10 hours after fluorescein injection (Fig. 6.22). The basic equation is as follows:

$$J = P_{\text{passive}} * C_p(t) - T_{\text{out,active}} * C_r(t)$$

where J is the flux, P_{passive} the permeability, T is the outward, active transport and C is the fluorescein concentration in the plasma and vitreous.

Many hours after fluorescein injection, the plasma concentration is low and the first term small. Thus the outward (active) transport may be estimated from the preretinal gradient:

$$(D * dC/dx) * C_r^{-1}$$

where dC/dx is the pre-retinal fluorescein gradient and C_r^{-1} is the fluorescein concentration at the retina.^{25,26,102}

The calculation of outward transport is not possible earlier than approximately 5–7 hours after fluorescein injection, when the preretinal gradient is reversed (Fig. 6.22). The time of reversal will vary according to the passive and active transport in the individual patient, and the equation above does not take into account the non-steady state of the whole diffusion process. With a mathematical model, the vitreous concentration curves can be simulated despite the non-steady state of the system.¹⁰² In contrast to earlier studies,^{90,92,140–143} the system is based on in vivo measurements of fluorescein isolated from the contribution of the fluorescent metabolite fluorescein-glucuronide. The model in Figure 6.32 is based on a spherical geometry of the eye; however the experimental and theoretical curves with this model did not fit in patients with high passive permeability.

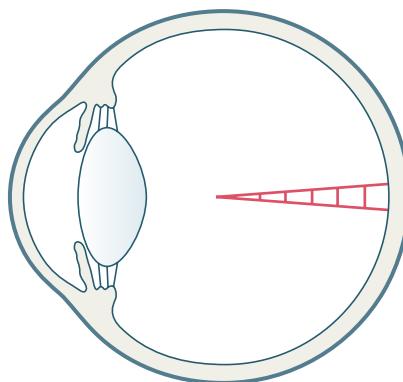

Figure 6.32 Simplified spherical model of the blood-retina barrier. The distance from the retina to the center of the eye is divided into a large number of conical cells. The fluorescein concentration in the cell next to the retina is estimated from the plasma fluorescein concentration curve and passive and active transport estimates. (From Sander et al 2001.¹⁰² Reproduced with permission from Association for Research in Vision and Ophthalmology.)

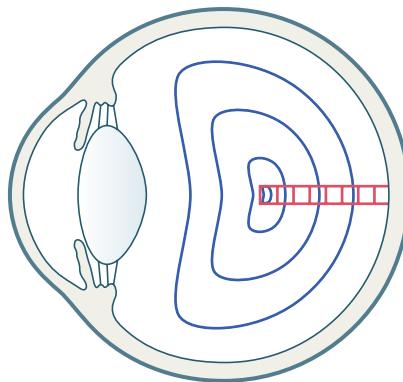

Figure 6.33 Simplified cylindrical model of the blood-retina barrier. Assuming diffusion from the anterior part of the eye into the vitreous and low leakage in the peripheral of the retina compared to the posterior pole, the concentration gradients will form ellipsoid curves in the vitreous (thin lines). The major direction of fluorescein flux is orthogonal to the concentration. (From Sander et al 2001.¹⁰² Reproduced with permission from Association for Research in Vision and Ophthalmology.)

With a cylindrical model (Fig. 6.33) the match to experimental curves improved. In the final model a correction for diffusion of fluorescein from the anterior chamber was also included, as the concentration in anterior chamber often exceeds the posterior concentration up to several hours after injection and diffuses into the vitreous. The concentration profiles versus time with the final model are shown in Figure 6.34. By curve fitting it is possible to estimate the outward, active transport of fluorescein transport in the individual patient. The results are shown in Table 6.2.

It appears that the permeability for fluorescein in the normal person is very low and that the capacity of active transport process from vitreous to the blood is much larger than the passive permeability.^{20,25,65,102,103,141} The passive permeability for fluorescein glucuronide equals that of fluorescein despite a large difference in lipid solubility between these two substances, indicating that the transport is related to water-filled pores.

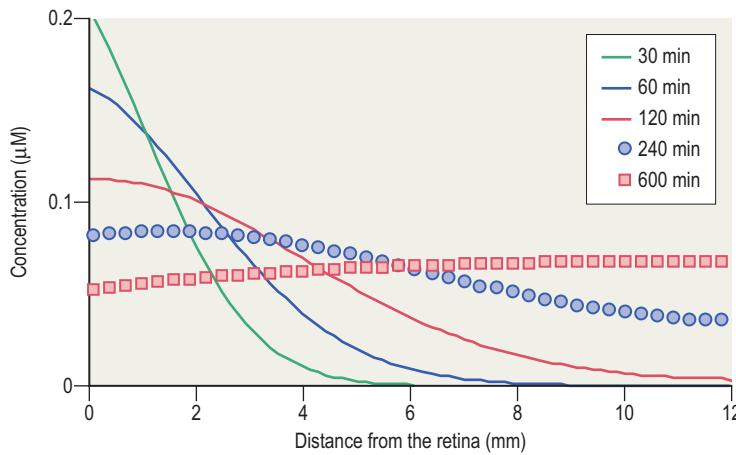

Figure 6.34 Vitreous curves calculated with the spherical model from 30 minutes to 8 hours after fluorescein injection. Input data (P_{passive} 2.5 nm/sec; T_{active} 25 nm/sec) correspond to a healthy subject. (From Sander et al 2001.¹⁰² Reproduced with permission from Association for Research in Vision and Ophthalmology.)

p < 0.05 compared to no CSME.

In healthy subjects, the passive permeability has been found to be 1.9 nm/sec, the active, outward transport is 43 nm/sec.^{84,102} The same parameters in the condition of diabetic patients with and without macular edema are shown in Table 6.2. The passive permeability increases significantly with macular edema, whereas the active transport is unaffected by edema, although it appears to increase in patients with early diabetes compared with persons with healthy eyes.¹⁰² The significance of this is unknown but could be related to an activation of the retinal pigment epithelium pump due to an increase of ions/non-ionic compounds in the retina of diabetic patients.

Concluding remarks

Although the vitreous body can be removed and almost normal function of the eye will still be maintained, the vitreous body plays an important role in the physiology and pathophysiology of the eye. The “silent” vitreous body exerts many important physiologic functions with close parallel to pathophysiology. An important implication for the future will be intravitreal drug application and release; a further understanding of the physiology of the vitreous body will be important for the development of rational applications of this new modality. The condition of the vitreous body is also important for movement of drugs within the eye and should be considered in discussions regarding the possibility

that topically applied drugs will induce effects or side effects in the posterior segment of the eye.

Acknowledgments

We thank Drs. Ulrik Christensen, Kristian Krøyer and Mads Kofod for Optical Coherence Tomography images.

The Extraocular Muscles

Linda McLoon

The extraocular muscles (EOM) are found within the bony orbit. They function in conjugate eye movements, maintenance of primary gaze position, and motor fusion – maintaining corresponding visual elements within the binocular field on corresponding retinal loci. In addition, the eyes must be able to follow moving objects (smooth pursuit) and accomplish rapid changes in fixation (saccades). This is accomplished by a very complex oculomotor control system, and the EOM are the final effector tissues. Understanding how the EOM adapt to changing visual demands is critical to the development of improved treatment strategies to realign the eyes when the system fails, as in strabismus or nystagmus.

The EOM have many distinct and complex properties that distinguish them from non-cranial skeletal muscles, many of which are normally associated with developing or regenerating muscle. This includes a population of multiply- and polynuronally innervated myofibers, and retained expression of the immature subunit of the acetylcholine receptor, neural cell adhesion molecule, and “immature” myosin heavy chain isoforms. The EOM also have the capacity to continuously remodel throughout life. From a clinical perspective, the EOM have a distinct propensity for or sparing from a number of skeletal muscle diseases. EOM share some of their unusual characteristics with other craniofacial muscles, such as the laryngeal muscles, and the potential developmental basis for their unusual properties and disease profiles is presented.

The bony orbit

The eyes are protected in deep bony orbits that are roughly pyramidal in shape (Fig. 7.1). The orbit is largest just inside the orbital margin at its anterior extent and smallest at its posterior extent, the apex. The orbital margins are composed of the frontal bone superiorly, the zygomatic process of the frontal bone and the frontal process of the zygomatic bone laterally, the zygoma and the maxillary bone inferiorly, and the frontal process of the maxillary bone, the lacrimal bone and the maxillary process of the frontal bone medially (Fig. 7.1). However, direct impact to the bony margin can result in fracture (see Box 7.1). The orbit has a thick bony roof composed of frontal bone and a portion of the lesser wing of the sphenoid bone. The lateral wall is composed of the zygomatic bone and the greater wing of the sphenoid. A

relatively thin floor is composed of the maxillary bone, a small and variable part of the palatine bone, and the zygomatic bone. The thin medial wall is composed of the maxillary, the lacrimal, ethmoid, and sphenoid bones.¹ As a result of this bony configuration, the globe is somewhat protected from injury caused by direct impacts to the face, particularly if there are no bony fractures.

An understanding of the geometry of the bony anatomy relative to maintenance of eye position is critically important. The medial walls are parallel to each other, while the plane of the lateral wall in each orbit is 45° from the sagittal plane formed by the medial wall (Figs 7.1 and 7.2). Additionally, the geometry of the orbital bones requires that both globes be partially adducted in primary gaze. Maintenance of eye position in primary gaze requires a constant steady-state resting level of tension in all the EOM, referred to as tonus.²

The apex of the bony orbit has three major foramina: the optic foramen, and the superior and inferior orbital fissures. The nerves and blood vessels to the majority of structures within the orbit enter through these foramina. A number of small foramina also open into the orbit, allowing entry and exit of nerves and vasculature to a wide array of structures in the orbit and head.³

Normal extraocular muscles

Gross anatomy

There are six EOM in each orbit whose function is to move the eyes: four rectus muscles, superior, medial, inferior, and lateral; and two oblique muscles, inferior and superior (Fig. 7.3). In addition there is a seventh skeletal muscle in each orbit, the levator palpebrae superioris, which inserts into the upper eyelid and functions in elevating the palpebral fissure. While its cranial nerve innervation is similar to the EOM, functionally and metabolically it is distinct, and will not be discussed further in this chapter.

The four rectus muscles take their origin in part from the bones at the apex of the orbit, but also from the tendinous annulus. They course anteriorly to insert into the sclera anterior to the equator of the globe, a key factor when considering their functional effects on eye movements. Classically this insertion is described as external to the ora serrata; however, recent studies demonstrate that insertions of the

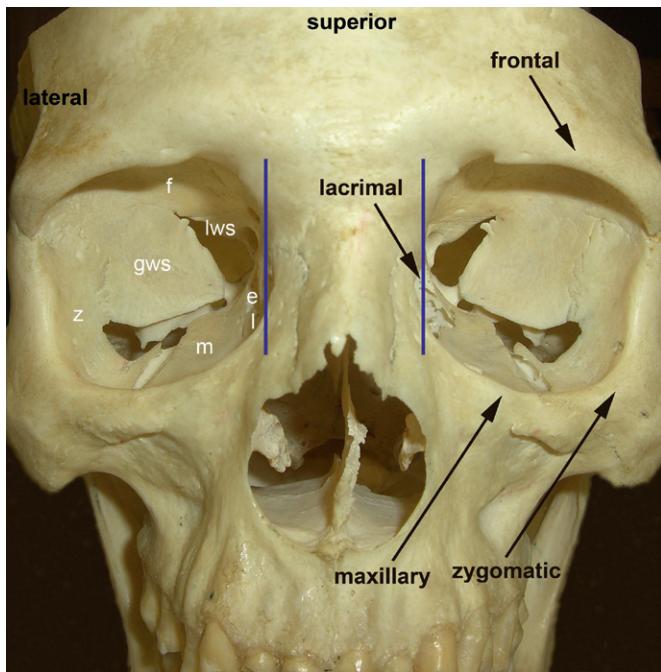

Figure 7.1 Bony orbit (anterior view). Medial walls of the two orbits are parallel to each other and in the sagittal plane (blue vertical lines). The walls form a pyramidal shape with the apex pointing posteriorly. f, frontal bone; lws, lesser wing of the sphenoid; gws, greater wing of the sphenoid; m, maxillary bone; l, lacrimal bone; e, ethmoid bone.

Box 7.1 Blowout fractures

Bony fractures of the thin orbital walls can occur with blunt impact to the orbital margins. The increased force causes the bone to "blowout" into the sinuses, with the inferior and medial walls most susceptible to fracture. Sometimes the EOM become entrapped at the fracture site, as evidenced by restricted movements in the range of function of the entrapped muscle. These must be surgically repaired.¹

rectus muscles range from 2.25 mm posterior to 2.25 mm anterior to the ora serrata, with 90 percent of the insertions within 1 mm.⁴ Generally considered to be tendinous at the insertion site, the medial and lateral rectus muscles in humans may contain myofibers that extend directly to the sclera,⁵ an important consideration for incisional strabismus surgery. The insertions of the four rectus muscles increase in distance from the corneal limbus circumferentially, with the medial rectus closest and the superior rectus furthest. The distances were originally determined on cadaveric material;⁶ however, recent analyses on living adult patients during strabismus surgery show that the average distances from the corneal limbus to the rectus muscle insertions have large interindividual variations.^{7–10} In part, this explains the disparate measurements seen in the literature. One typical study measured the distances from the limbus to muscle insertion as 6.2 ± 0.6 mm for the medial rectus, 7.0 ± 0.6 mm, for the inferior rectus, 7.7 ± 0.7 mm for the lateral rectus, and 8.5 ± 0.7 mm for the superior rectus.¹⁰ Distances can vary up to 4 mm, even between the same muscles in both eyes of one

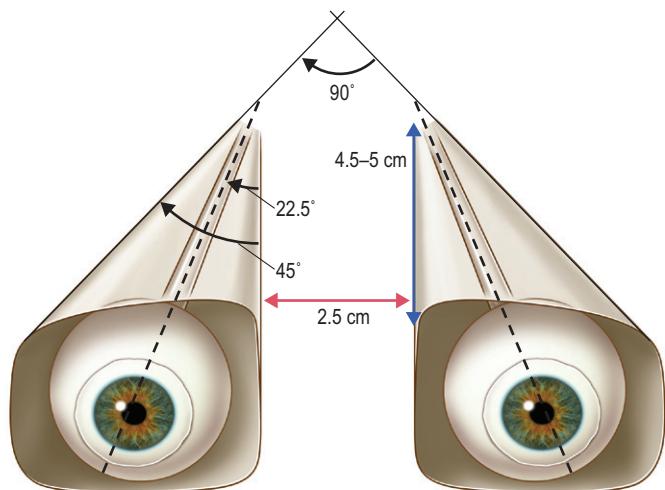

Figure 7.2 Geometry of the orbit. The orbit is a pyramidal-shaped structure with the base anterior and the apex posterior. The medial walls of the two orbits are parallel to each other and in the sagittal plane. The lateral walls are angled 45° relative to the medial wall. The lateral walls of both orbits form a 90° angle. The optic nerve emerges at an angle of 22.5° from the medial wall. The eyes in the primary gaze position results in adduction of 22.5°. The orbital volume is 30 ml, with 6.5 mL filled by the globe.

patient, and does not correlate with primary position of the eye or surgical success for strabismus patients.¹¹ Thus, there is a significant amount of variation in rectus muscle insertions, and this variability has important consequences for incisional surgery of the EOM.

The superior and inferior oblique muscles have distinct paths compared to the rectus muscles. The superior oblique takes its origin from the dense connective tissue periosteum lining the orbit just superior and medial to the attachment of the tendinous annulus, and courses anteriorly along the border between the orbital roof and the medial orbital wall. Approximately 10–15 mm posterior to the orbital margin it becomes tendinous and enters the trochlea, a cartilaginous and dense connective tissue structure attached to the orbital periosteum. Emerging from the trochlea, the superior oblique muscle passes posteriorly at a 51° angle to the axis of the eye in primary position and inserts into the sclera. The trochlea thus serves as the "de facto" origin, creating the vector of force that moves the globe. The insertion of the superior oblique is on the superior pole deep to the superior rectus muscle, but in contrast to the rectus muscles, posterior to the equator of the globe (Fig. 7.3). The inferior oblique muscle is the only EOM that does not take its origin from the apex of the orbit; instead originating from the anteromedial orbital floor. The inferior oblique muscle courses posteriorly and inferior to the inferior rectus and inserts into the sclera posterior to the equator of the globe.

The shape, size, and orientation of the EOM from origin to insertion form the basis for the eye movements that result from their contraction (Table 7.1). While the effect of contraction of each EOM will be described separately, it is important to remember that they work in a coordinated fashion, maintaining significant tension or "tonus" even when the eye is in primary position and thus presumably "at rest".^{2,12}

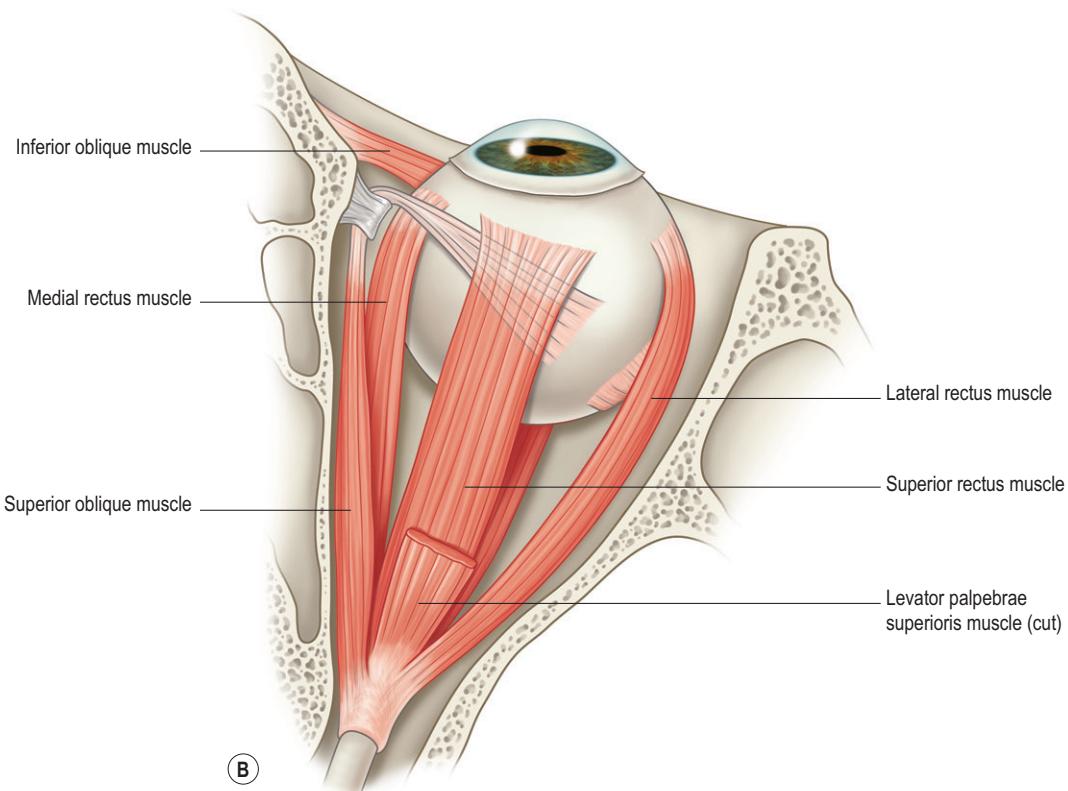

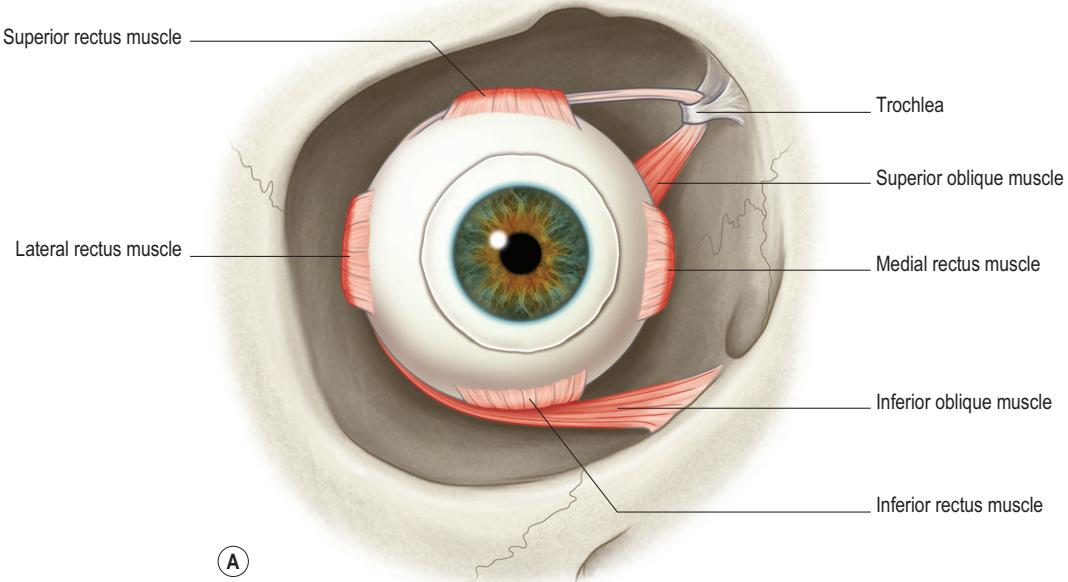

Figure 7.3 (A) Anterior view of the EOM in situ. Note that the origin for the inferior oblique is in the inferomedial aspect of the orbit and not the apex. (B) Superior view of the EOM in situ. Note the parallel arrangements of the horizontal muscles (medial and lateral rectus); the vertical muscles (superior and inferior rectus); and the insertional tendons of the superior and inferior obliques. (Modified from Clinical Orbital Anatomy, Marcos T. Doxanas and Richard L. Anderson eds, Baltimore, William and Wilkins, 1984.)

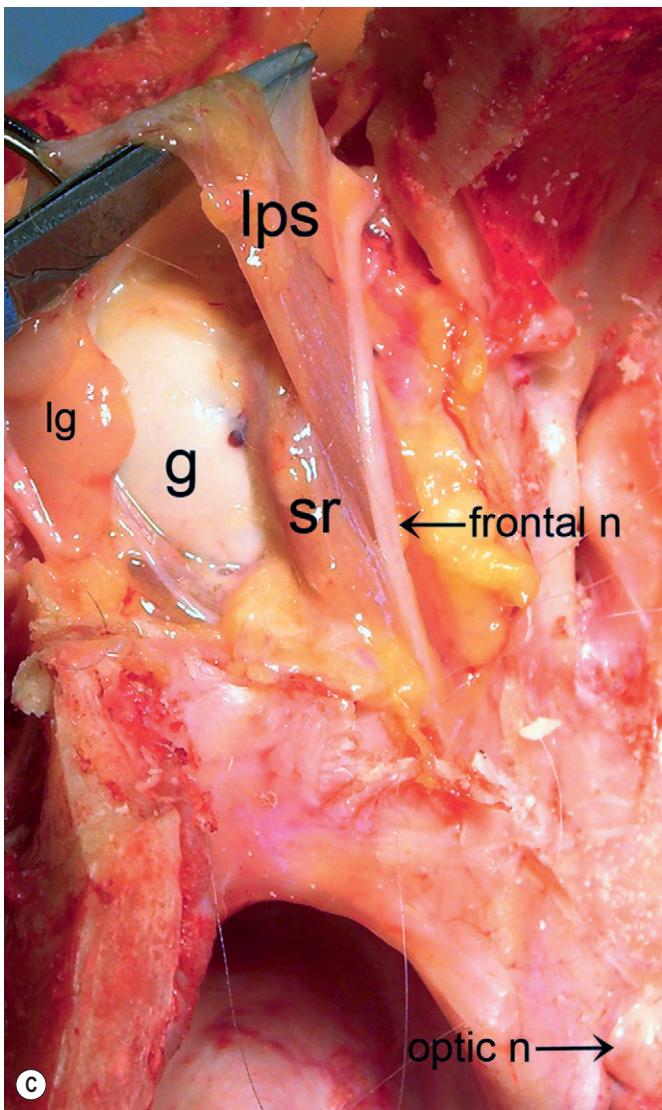

Figure 7.3, cont'd (C) Cadaveric dissection of the orbit from the superior approach. The levator palpebrae superioris (lps) is elevated. The superior rectus (sr) is directly inferior to it. The motor innervation cannot be seen from this view, as the oculomotor nerve (CNIII) runs within the muscle cone deep to the muscles. The frontal nerve is the most superior element and is a sensory branch of the ophthalmic nerve of CNV. The four rectus muscles insert into the anterior half of the globe, at approximately the level of the ora serrata. Insertions are found at increasing distances from the corneal limbus, medial rectus closest and superior rectus the furthest. The two oblique muscles insert into the posterior half of the globe. g, globe; l, lacrimal gland. Anterior is at the top of the photograph, and medial is to the right.

Horizontal movements are controlled by the medial and lateral rectus muscles, agonist–antagonist pairs with opposing primary functions; the medial rectus adducts the eye, while the lateral rectus abducts the eye. Vertical movements are more complex. The superior and inferior rectus muscles have a more complex effect on the direction of eye movements because the bony orbits are not parallel to each other (Fig. 7.2). In primary gaze, both the superior and inferior recti are angled laterally at approximately 22.5° from the sagittal plane. The primary action of the superior rectus

muscle is elevation, but it also adducts and intorts the eye (Table 7.1, Fig. 7.4). Intorsion is where the superior pole of the eye rotates medially. Thus, if the superior rectus muscle was acting alone, the direction of gaze would be superior and medial, that is, up and in towards the nose. The inferior rectus is parallel to the superior rectus, but inserts on the inferior surface of the globe. Thus, it primarily depresses the eye, but also adducts and extorts (Fig. 7.4); extorsion is rotation of the superior pole of the eye laterally.

Due to its insertion posterior to the equator of the globe, as well as the vector of force directed by the position of the trochlea in the superior and medial orbit, the superior oblique mainly intorts the eye (Table 7.1, Fig. 7.4). It also depresses and abducts. Thus, working unilaterally, gaze would be directed down and out. As the inferior oblique muscle parallels the superior oblique, but inserts on the inferior surface of the globe, its primary function is extorsion of the eye (Table 7.1, Fig. 7.4); it also elevates and abducts. In order for accurate positioning of the visual world on the fovea, activity of all the EOM must be tightly coordinated.

Cranial motor nerve innervation

The optic foramen is found within the lesser wing of the sphenoid bone at the orbital apex, through which runs the optic nerve (cranial nerve II, CNII) and ophthalmic artery. Between the greater and lesser wings of the sphenoid is the superior orbital fissure. The structures entering the orbit through this fissure are divided by the tendinous annulus (formerly the annulus of Zinn). Structures that enter the orbit superior to the annulus are the lacrimal and frontal nerves, both sensory branches of the ophthalmic division of the trigeminal nerve (CNV); the trochlear nerve (CNIV), motor nerve to the superior oblique muscle; and the superior ophthalmic veins (Fig. 7.5). Once through the annulus, structures enter what is referred to as the muscle cone, and are surrounded by the EOM and their connective tissue ensheathments. Within the annulus, the superior orbital fissure admits the superior and inferior divisions of the oculomotor nerve (CNIII) the motor nerve to the inferior rectus, inferior oblique, medial rectus, superior rectus and levator palpebrae superioris muscles; the nasociliary nerve which is a sensory branch of the ophthalmic division of the trigeminal nerve (CNV), and the abducens nerve (CNVI), the motor nerve to the lateral rectus muscle.³ On the floor of the orbit is the inferior orbital fissure, which admits the zygomatic nerve, a sensory nerve innervating the lateral mid-face; communications of the inferior ophthalmic vein with the pterygoïd plexus of veins inferiorly; and the lacrimal rami, carrying parasympathetic innervation from the facial nerve (CNVII) to the lacrimal gland.¹³

Once inside the bony orbit, the motor nerve branches of CNIII, CNIV and CNVI course anteriorly towards the muscles they innervate. The superior division of CNIII innervates the superior rectus muscle and continues superiorly to innervate the levator palpebrae superioris. The inferior division of CNIII innervates the medial and inferior rectus muscles, and the latter branch continues inferiorly to innervate the inferior oblique. All nerve branches enter the muscles on their deep surfaces within the muscle cone. CNVI also enters the lateral rectus muscle on its deep surface. Of the motor nerves, only the trochlear nerve, CNIV, enters the orbit outside the

Table 7.1 Extraocular Muscle Function: Primary and Secondary Actions

Muscle	Primary action	Secondary action	Motor innervation	Antagonists	Synergists
Lateral rectus	Abduction	None	Abducens n (CNVI)	Medial rectus	Superior and inferior oblique m
Medial rectus	Adduction	None	Oculomotor n (CNIII, inferior division)	Lateral rectus	Superior and inferior rectus m

Darrt. 2010. Copyright Elsevier 2010)

tendinous annulus innervating the superior oblique muscle on its superior or lateral surface (Fig. 7.5). All motor nerves that innervate the EOM enter the body of the muscles at their posterior third (Fig. 7.5).

Neuromuscular junctions (NMJ) are the specialized sites of communication between a nerve and the myofibers it innervates. In non-cranial skeletal muscle, NMJs usually form in the middle one-third of each myofiber. The NMJs formed by the cranial motor nerves with individual EOM myofibers display some distinct differences compared to those in non-cranial skeletal muscle. Similar to body muscles, the EOM have singly innervated myofibers with NMJs referred to as "en plaque" endings (Fig. 7.6). However, the "en plaque" NMJs in EOM are smaller and less complicated structurally than those in non-cranial skeletal muscles.¹⁴ In addition, the EOM have multiply innervated myofibers with neuromuscular junctions referred to as "en grappe" endings (Fig. 7.6). These are a linear array of small synaptic contacts often found towards the ends of individual myofibers, but can be continuous along the length of individual myofibers.¹⁵ The "en grappe" NMJ contacts are structurally simple.¹⁶ Thus, in EOM a single myofiber can have an "en plaque" NMJ somewhere along the middle one-third and also have multiple "en grappe" endings along the tapered ends (Fig. 7.6). Some myofibers in EOM that express the slow tonic myosin heavy chain isoform (MYH14) have "en grappe" endings along their entire myofiber length and do not have an "en plaque" ending.

The acetylcholine receptor found within NMJs is composed of 5 subunits, similar to skeletal muscle generally. In developing non-cranial muscle there are two alpha, 1 beta, 1 gamma, and 1 delta subunits ($\alpha_2\beta\gamma\delta$), and in the adult the γ subunit is replaced with the epsilon (ϵ) subunit.¹⁷ In contrast, in adult EOM the majority of the "en grappe" endings express the "immature" gamma subunit, rather than the epsilon subunit of mature endings.^{18,19} Both the "en plaque" and "en grappe" endings in the EOM can co-express both the epsilon and gamma subunits;²⁰ this appears to be unique to EOM. Due to the nature of EOM myofiber length, as discussed in a following section, NMJs can be seen throughout the origin-to-insertional length of EOM in most species where this has been examined.^{21,22} This is in contrast to most limb skeletal muscles, which have a motor endplate zone, an NMJ band that is fairly contained within a defined area in the midbelly region of the muscle.

It has generally been assumed that the multiply innervated myofibers are innervated by a single motor neuron, but polyneuronally innervated myofibers are also present.^{23,24} This means that more than one motor neuron can innervate a single myofiber. This has important implications for EOM physiology and will be discussed in that section.

Orbital connective tissue

A complex framework of connective tissue exists throughout the orbit, and this network has a clear structural organization

and constant pattern (Fig. 7.7).²⁵ These connective tissue septa contain nerves, vessels and smooth muscle, and are postulated to play a role in supporting eye movements. Recent studies have confirmed and extended these initial detailed analyses of orbital connective tissue septa to include thickenings around individual EOM called orbital pulleys (Fig. 7.7).²⁶ These connective and smooth muscle septa and bands constrain the paths of the EOM, changing the vector of force as the EOM contract and stabilize muscle position during movement.²⁷

Histological anatomy and physiologic implications

The EOM have a complex anatomy at the microscopic level. The overall cross-sectional areas of their myofibers are extremely small compared to non-cranial skeletal muscle. Each EOM is composed of two layers: an outer orbital layer composed of myofibers of extremely small cross-sectional area and an inner global layer with myofibers larger than in the orbital layer but still extremely small compared to non-cranial skeletal muscle (Fig. 7.8). Further descriptions will concentrate on human muscle, but the EOM of other mammals have the same general features despite some variations in detail.

In non-cranial skeletal muscles, two general fiber types are described, fast and slow, referring mainly to the myosin

heavy chain isoforms (MyHC) they express, which in turn determines their shortening velocity.²⁸ Whether a fiber is "fast" or "slow" is due, in part, to their complement of contractile proteins. Non-cranial skeletal muscles that are largely fast MyHC-positive, such as the extensor digitorum longus, have an oxidative metabolism, rapid shortening velocities, and rapid fatigue with activation. Slow MyHC-positive myofibers in non-cranial skeletal muscle have a glycolytic metabolism, slower shortening velocities, larger force generation, and are fatigue-resistant. The EOM also have the two basic myofiber types. About 85 percent of the myofibers in both layers in adult EOM are fast MyHC-positive (Fig. 7.8).^{29,30} The other 15 percent of the EOM myofibers immunostain for the slow MyHC. In contrast to non-cranial skeletal muscle, the EOM have extremely fast contractile characteristics yet are also extremely fatigue-resistant.³¹ Several factors support these apparently contradictory characteristics. While the vast majority of non-cranial skeletal muscles express one of four MyHCs, fast fiber types IIa, IIx, or IIb or slow type 1, EOM myofibers can contain up to nine MyHCs.³²⁻³⁵

The MyHC expressed in EOM include: fast types IIa (MYH2), IIx (MYH1), or IIb (MYH4); MyHCs associated with immaturity – embryonic (developmental) (MYH3) and neonatal or fetal (MYH8); slow or type 1 (which is the same as beta-cardiac myosin) (MYH7); alpha-cardiac (MYH6); EOM-specific (MYH13); and the slow tonic myosin (MYH14).

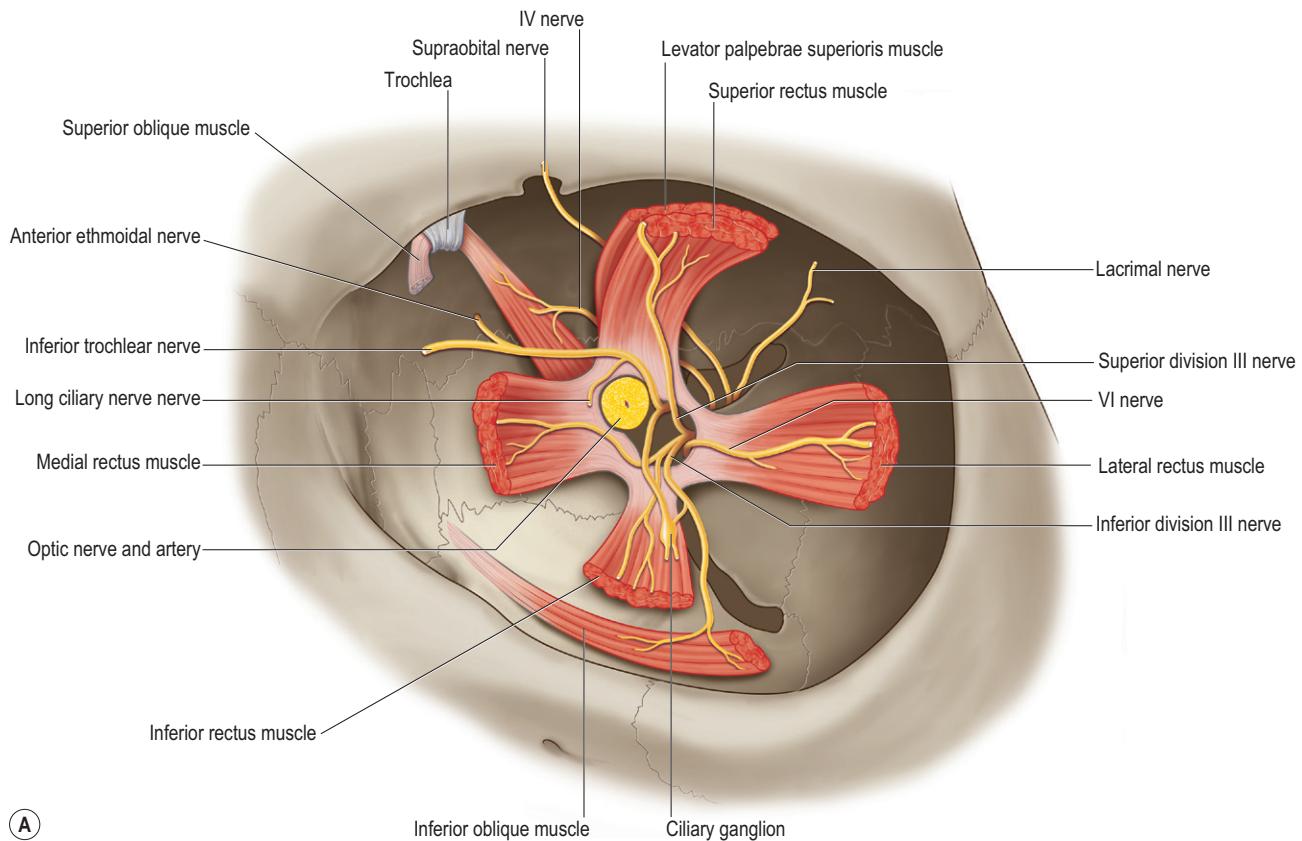

Figure 7.5 (A) Deep dissection of the orbit with the globe removed and the optic nerve sectioned, allowing visualization of the orbital nerves. All motor nerves except the trochlear nerve enter the muscles they innervate on their deep surfaces in the posterior third of their length. (Modified from Miller NR: Walsh and Hoyt's Clinical Neuro-Ophthalmology (ed 4), Vol. 1. Baltimore, Williams & Wilkins, 1982.)

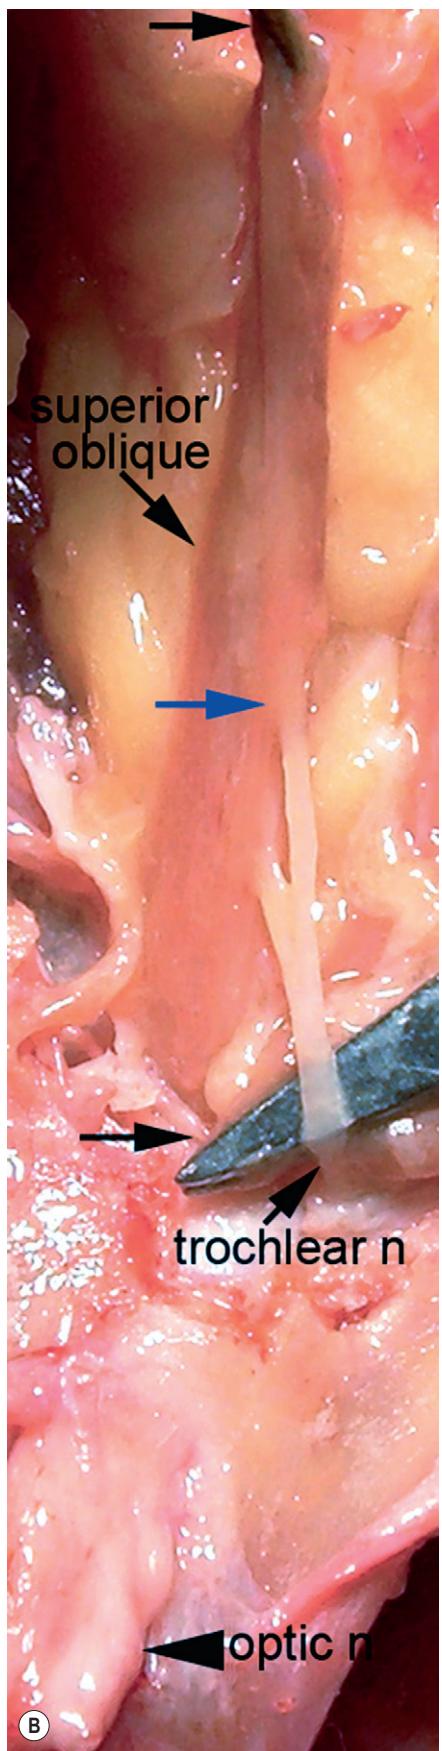

Figure 7.5, cont'd (B) The superior oblique muscle is innervated by CNIV on its superior surface in the posterior third of the muscle length. Anterior is at the top and medial is to the left.

This large array of expressed MyHC within the EOM helps explain why its dynamic physiologic properties are significantly different than those in limb muscles.³⁶ It should be noted that patterns of MyHC composition vary between each EOM, with lateral rectus being the most different.³⁷ Support for the idea that the MyHC composition may be critical for understanding control of force generation is the physiological demonstration that there are significant contractile differences between muscles. For example, in the medial and lateral rectus muscles, motor units in the medial rectus generate faster twitch contractions and those in lateral rectus generate greater tetanic tensions.³⁸ This concept is critical in understanding the CNS control of eye movements as well as eye movement disorders like strabismus.

The expression patterns of EOM myofibers for these MyHC differ significantly between the global and orbital layers (Fig. 7.8); for example, the vast majority of the orbital layer myofibers are positive for developmental myosin (MYH3), yet the global layer only has scattered fibers that immunostain for this isoform (Fig. 7.8). Distinct patterns of differential staining are seen for all other MyHC present in EOM. From a physiological perspective, this issue becomes even more complex. Approximately 25 percent of cat single lateral rectus motor units examined had myofibers in both the orbital and global layers.³⁹ These bilayer motor units are stronger and faster than motor units contained within single EOM layers, and tend to be fatigable. Approximately 54 percent of the global motor units examined were stronger and faster than orbital layer units, in part a reflection of the properties imbued upon the individual myofibers by their contractile proteins.

The expression of individual MyHC also varies along the origin-to-insertion length of each muscle.^{37,39,40} In part this is because many of the EOM myofibers do not run from origin to insertion in both the orbital and global layers;^{22,23,37,41–43} they can be arranged in parallel or in series, and many branched and/or split myofibers exist (Fig. 7.9).²² These short myofiber lengths have functional consequences. For example, in a series of studies examining summation of motor forces, individual cat and monkey motor units were stimulated, and the forces each unit produced in the lateral rectus muscle were determined. Then, using simultaneous stimulation, the evoked unit force of other motor units was added to the single motor unit force. In about 25 percent of the cases in cat and about 85 percent of the cases in monkey, the forces did not add linearly.^{44,45} Thus, force is “lost” as multiple myofibers are activated, partly due to force dissipation laterally through myomyous junctions and myoconnective tissue connections formed by short myofibers.

In addition, the serial or parallel arrangement of myofibers with different myofibrillar isoforms would significantly affect contractile behavior. This was elegantly demonstrated using sets of single myofibers *in vitro*, one fast and one slow, that were tied together in series or in parallel.⁴⁶ In any given combination of one fast and one slow myofiber, the paired fibers showed a range of forces with greater or lesser fast or slow characteristics. In a fast/slow combination, the fast fiber begins to contract prior to the slow fiber, which is then slack and therefore not at its optimal length to generate full force. Serial or parallel arrangements of myofibers with disparate MyHC isoform composition would be expected, based on these results, to result in a

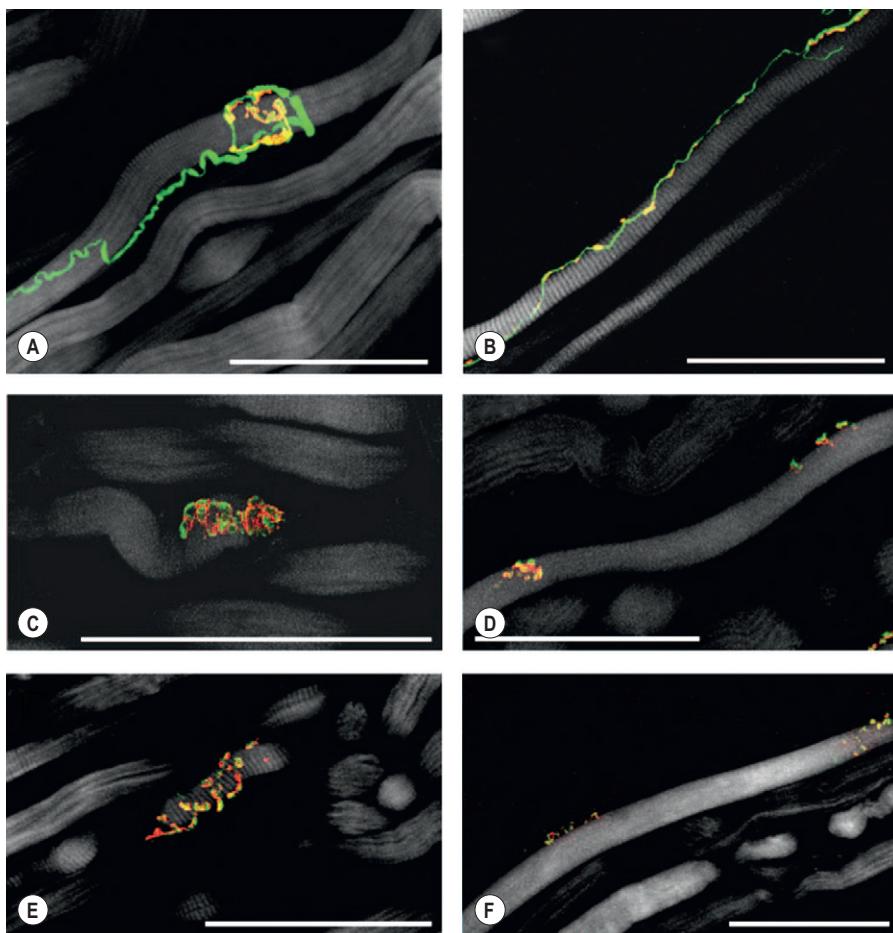

Figure 7.6 Confocal laser scanning microscopy images showing singly innervated myofibers with en plaque motor endplates and multiply innervated myofibers with en grappe motor terminals. Nerve fibers are labeled with anti-ChAT (green), motor terminals with α -bungarotoxin (red), and myofibers with phalloidin (white). **(A)** A ChAT-positive axon supplying an en plaque endplate that is positive for ChAT/ α -bungarotoxin. **(B)** ChAT-positive axon supplying en grappe endings positive for ChAT/ α -bungarotoxin. **(C)** En plaque endplate and **(D)** en grappe terminals showing ChAT/ α -bungarotoxin reactivity. **(E, F)** Motor terminals are labeled with anti-VACHT (green) and α -bungarotoxin (red), myofibers with phalloidin (white): **(E)** en plaque endplate and **(F)** en grappe terminals showing VACHT/ α -bungarotoxin-reactivity. range, or continuum, of forces produced by their co-activation. This suggests that a distributed model of motor unit recruitment at the CNS level is needed to address the non-linearity of the effector arm of the system, the EOM themselves.⁴⁷

Individual EOM myofibers are polymorphic and also can express more than one MyHC.^{31,40,41,48-50} This has been shown for a wide variety of species, including human muscle.³¹ For example, in both singly and multiply innervated myofibers in the orbital layer in rats, the fiber ends express the neonatal MyHC (MYH8), but this isoform is completely eliminated at the position of the NMJ, where the fibers immunostained for fast MyHC.⁴⁰ In the orbital layer, individual myofibers express the embryonic MyHC (MYH3) at their fiber ends and the EOM-specific MyHC (MYH13) in the NMJ region. Orbital multiply innervated myofibers were found that expressed slow MyHC (MYH7) along their entire length, but also expressed embryonic MyHC (MYH3) at the fiber ends.⁴¹ Single myofibers in the global layer were found that express EOM-specific MyHC (MYH13) at the NMJ region as well as fast myosins IIb and/or IIX.⁴⁹ In human EOM, orbital layer myofibers were found that expressed type 1 (MYH7), and of these (Fig. 7.10) some also expressed slow tonic (MYH14), alpha-cardiac (MYH6), and/or embryonic (MYH3) or EOM-specific (MYH13).^{31,50} Physiologic examination of individual multiply innervated myofibers from the orbital layer of rats showed that electrical activity varied

along the length of the fiber, with tonic characteristics at the fiber end and twitch characteristics in the central region near the endplate, the only location where fast MyHC was expressed.²⁴

Thus, physiologic properties of the EOM motor units, when activated singly or collectively, reflect these MyHC isoform complexities, as well as differences in individual myofiber length and branching patterns.⁴⁵ It should be noted that the EOM show significant activity at all times, even when the eye is directed in what would be considered the off-direction for muscle action.² In addition, all motor units participate in all types of eye movements, and there appear to be no motor units that specialize in rapid saccades or slow vergence movements, for example.⁵¹ Presumably, the MyHC composition is a reflection of demands placed on the EOM by the oculomotor control system, supported by the observation that altering the stimulation frequency of a muscle causes significant changes in MyHC expression.⁵² Functional denervation also affects MyHC composition.⁵³ It is reasonable to suggest that a complex “conversation” is constantly occurring between EOM myofibers and the neurons innervating them, helping them to adapt to ever-changing physiologic demands.

Because of these complex MyHC expression patterns and physiologic characteristics, past attempts to classify EOM myofibers into simple groups ultimately fail. Classically, myofibers in non-cranial skeletal muscles have been

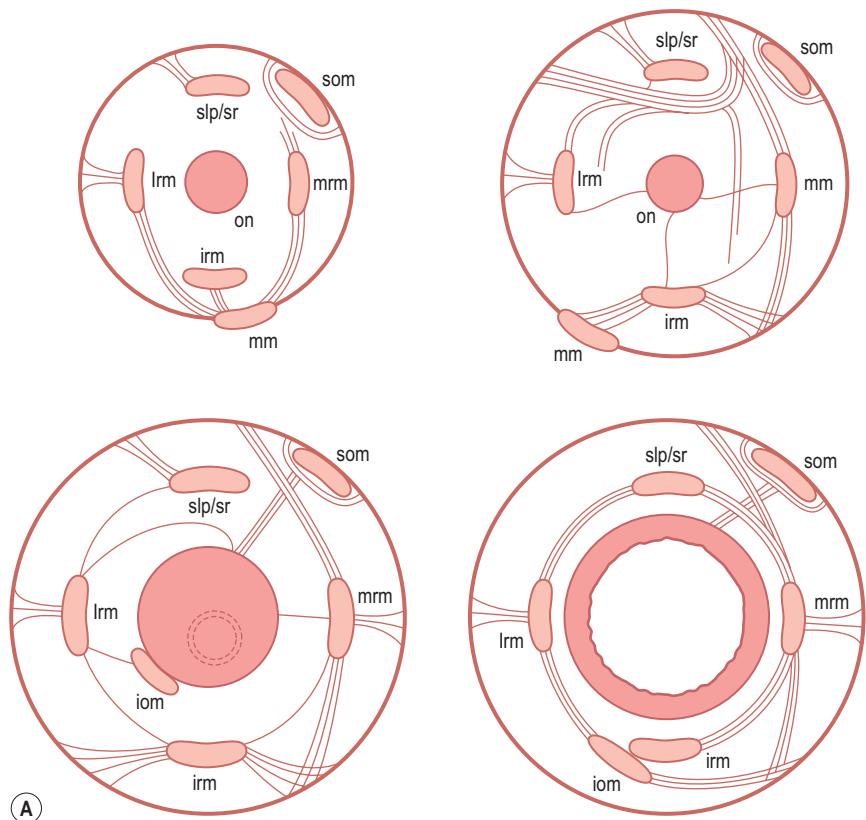

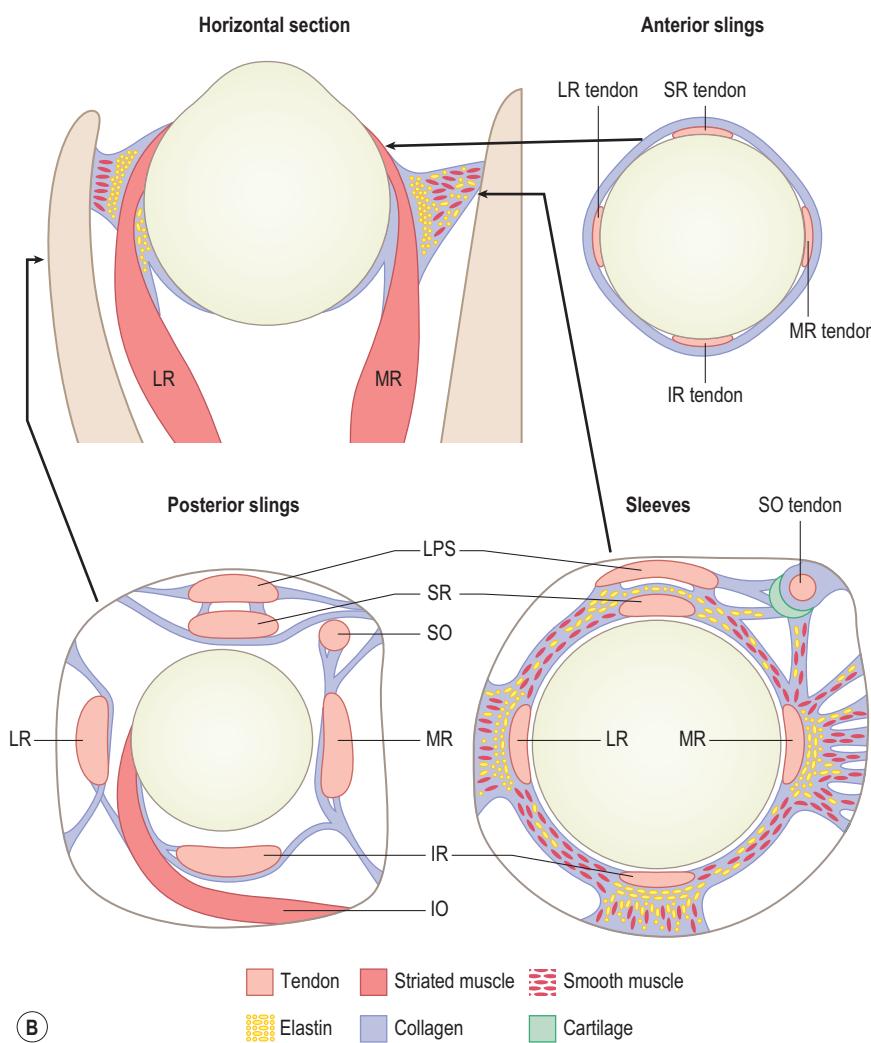

Figure 7.7 (A) Connective tissue septa at different levels in the orbit. Top left, near the orbital apex. Top right, halfway between apex and rear surface of globe. Arrows point to two myofibers, one positive for both fast and neonatal MyHC and one positive for fast but negative for neonatal MyHC. Bar is 100 μ m.

described by their MyHC expression profile (e.g. type IIa or type I). Even in non-cranial skeletal muscles, it is becoming increasingly clear that single myofiber MyHC polymorphism is more common than was previously believed.^{54,55} Another fiber type, called “mismatched”, has also been described in both non-cranial and cranial skeletal muscle.^{54,56} Mismatched myofibers include those with “mixed” fast and slow characteristics, and can include fibers with mixtures of fast and slow MyHC or fast or slow MyHC with various regulatory proteins such as troponin⁵⁷ or myosin-binding protein C⁵⁸ that are not of the same “type”. This complexity of protein expression and the heterogeneity of individual myofibers in EOM cannot be overstated. What these studies suggest is that rather than specific “types” of myofibers (Fig. 7.11), in EOM there is, in fact, a continuum of myofiber types. Each myosin heavy and light chain isoform results in a distinct shortening velocity,²⁹ which allows for an incredible plasticity in the control of muscle force generation. The modulation of the MyHC patterns with alterations in hormones or innervation changes also compound the heterogeneity of the EOM myofibers. These adaptive protein

changes are extremely rapid, and the control may be at the level of histone modifications⁵⁹ or at the translational level controlled by microRNA – known to be up-regulated in the EOM.⁶⁰ The EOM myofiber continuum hypothesis has been suggested previously for other skeletal muscles, including plantaris⁶¹ and masseter.⁶² This continuum of myofiber types in EOM combined with the non-linearity of eye muscle contractile properties⁴⁵ would allow CNS control of eye movement position and velocity to be finely tuned as the eyes are moved into an infinite number of positions.

Metabolism

The physiological properties of the EOM derive their dynamic and unusual characteristics from (1) their expression of specific contractile proteins including, but not limited to, isoforms of MyHC, myosin light chains, tropomyosin, and troponin, (2) the presence of myofibers shorter than the total origin-to-insertional length of each EOM, resulting in fibers connected in parallel or in series, (3) the presence of singly, multiply and polyneuronally innervated individual myofibers and (4) adaptations of their metabolic pathways.

The most studied metabolic property in EOM is calcium handling. Calcium plays a critical role in controlling the duration of muscle contraction. In part this is controlled by the sarcoplasmic reticulum Ca^{2+} ATPases (SERCA1 and SERCA2 in fast and slow myofibers respectively in non-cranial skeletal muscle). In the EOM, SERCA1 and 2 are co-expressed in the majority of individual myofibers.⁶³ The EOM contain an abundance of mitochondria, and EOM myofibers appear to use their mitochondria as fast calcium sinks to aid in regulation of calcium.⁶⁴ This effectively widens the dynamic range of EOM force production. Due to their efficient calcium handling, EOM myofibers are also resistant to pathological elevations of intracellular calcium levels.⁶⁵

EOM are resistant to injury and oxidative stress, and contain higher levels of superoxide dismutases and glutathione peroxidase activity than limb skeletal muscle.⁶⁶ This is concordant with the highly aerobic nature of the EOM. Only cardiac muscle has a higher blood flow rate.⁶⁷ Despite their highly oxidative metabolism, they are also extremely fatigue-resistant.⁶⁸ Unlike non-cranial muscles, EOM do not depend on creatine kinase activity for their fatigue resistance;⁶⁹ instead, EOM can utilize lactate as a metabolic substrate during times of increased contractile activity.⁷⁰ This further illustrates how the EOM can maintain a highly oxidative metabolism and fatigue resistance simultaneously. These two opposite metabolic demands are also met by the expression in individual EOM myofibers of both succinate dehydrogenase and alpha-glycerophosphate dehydrogenase, enzymes in the oxidative and glycolytic pathways, respectively. In contrast, these two enzymes are fiber type specific in limb skeletal muscle (Fig. 7.12).⁷¹ This supports the view that skeletal muscles consist of distinct allotypes,⁷² the EOM representing the extreme end relative to its anatomy, innervation, metabolism, and physiologic function.

Another distinctive aspect of EOM function is their ability to undergo myonuclear addition and subtraction throughout life^{73,74} while simultaneously maintaining their overall size, morphology and function. This is not seen in any of

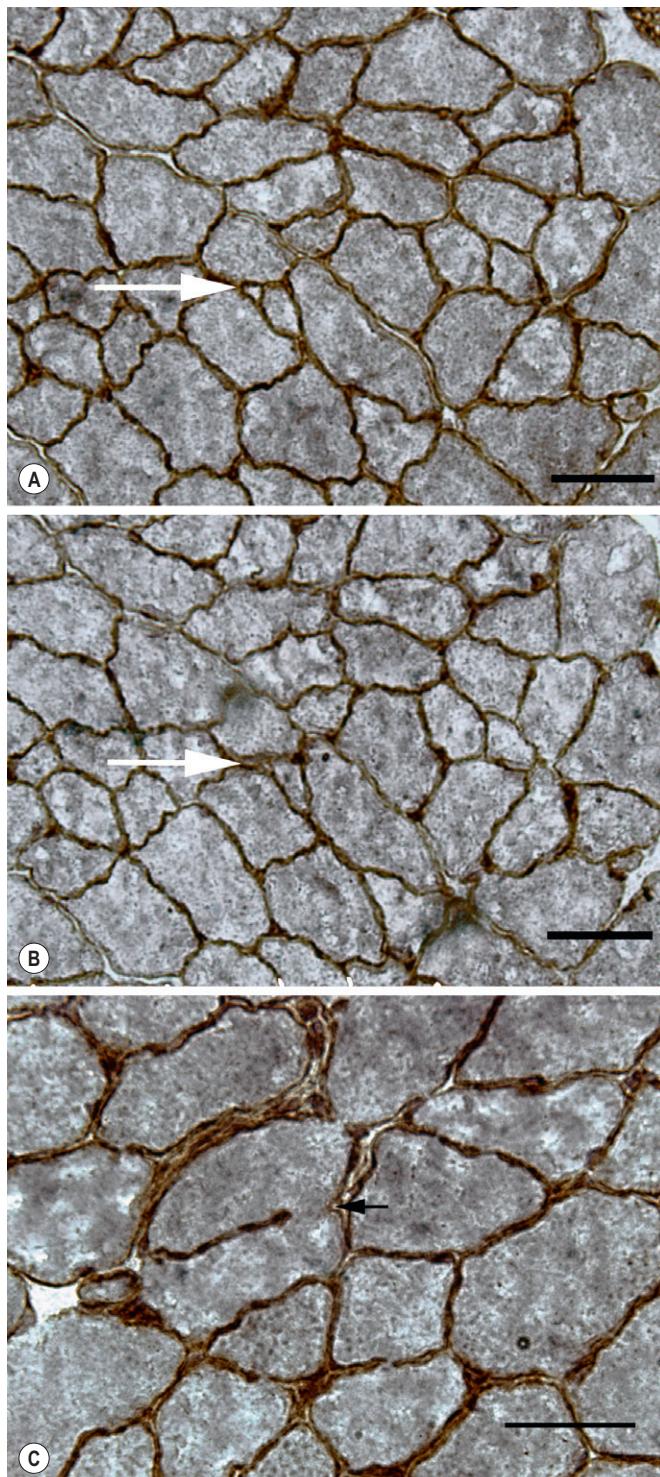

Figure 7.9 (A) and (B) Cross-sections through rabbit superior rectus muscle immunostained for dystrophin. Arrows indicate a myofiber present in one section that ended before the next section 24 μm distant. Bar is 20 μm . (C) Interconnected myofibers (arrow) in normal EOM immunostained for dystrophin. Bar is 20 μm . (D) Physiological demonstration of non-additive muscle forces in EOM using (a) twitch and (b) tetanic responses after stimulation. (a) Muscle responses to stimulation of one motor neuron (bottom trace, 45.9 mg), muscle responses to stimulation of several motor units (middle trace, 209.5 mg), and activation of a single motor unit plus nerve responses (upper trace, 257.5 mg). The twitch responses are additive; no force is “lost”. (b) Muscle responses of the same motor unit to tetanic stimulation. Muscle responses from tetanic stimulation of a single motor unit (bottom trace, 398.7 mg), several motor units (middle trace, 4066 mg) and the single motor unit plus nerve responses (upper trace, 4226 mg). This unit’s loses 40 percent of its force upon tetanic stimulation. Horizontal bar, 50 msec. Vertical bar, 917 mg. (From Goldberg et al., Muscle Nerve 20:1229–1235, 1997.)

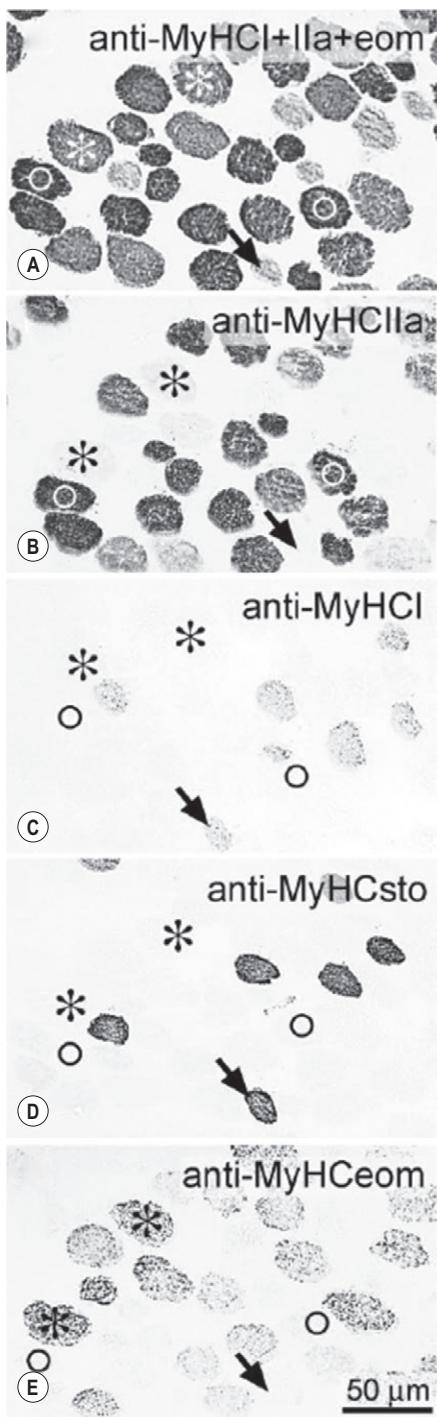

Figure 7.10 Photomicrographs of five serial sections from the global layer of an adult human superior oblique. Sections are immunostained with (A) anti-MyHCl+Ila+eom, (B) anti-MyHCIIa, (C) anti-MyHCl, (D) anti-MyHCslowtonic, and (E) anti-MyHCeom. O represents two myofibers immunostained with anti-MyHCIIa; arrow represents a fiber stained with anti-MyHCl; * represents two MyHCeom-positive and MyHCIIa-negative fibers. (Reproduced from Kjellgren et al., IOVS 44:1419–1425, 2003, with permission from the Association of Research in Vision and Ophthalmology.)

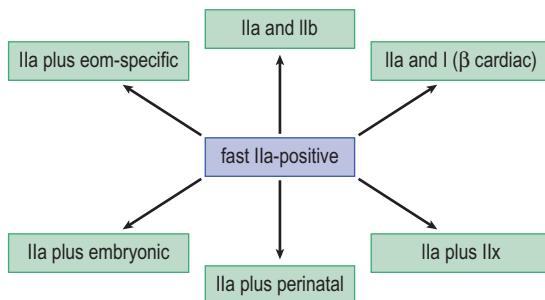

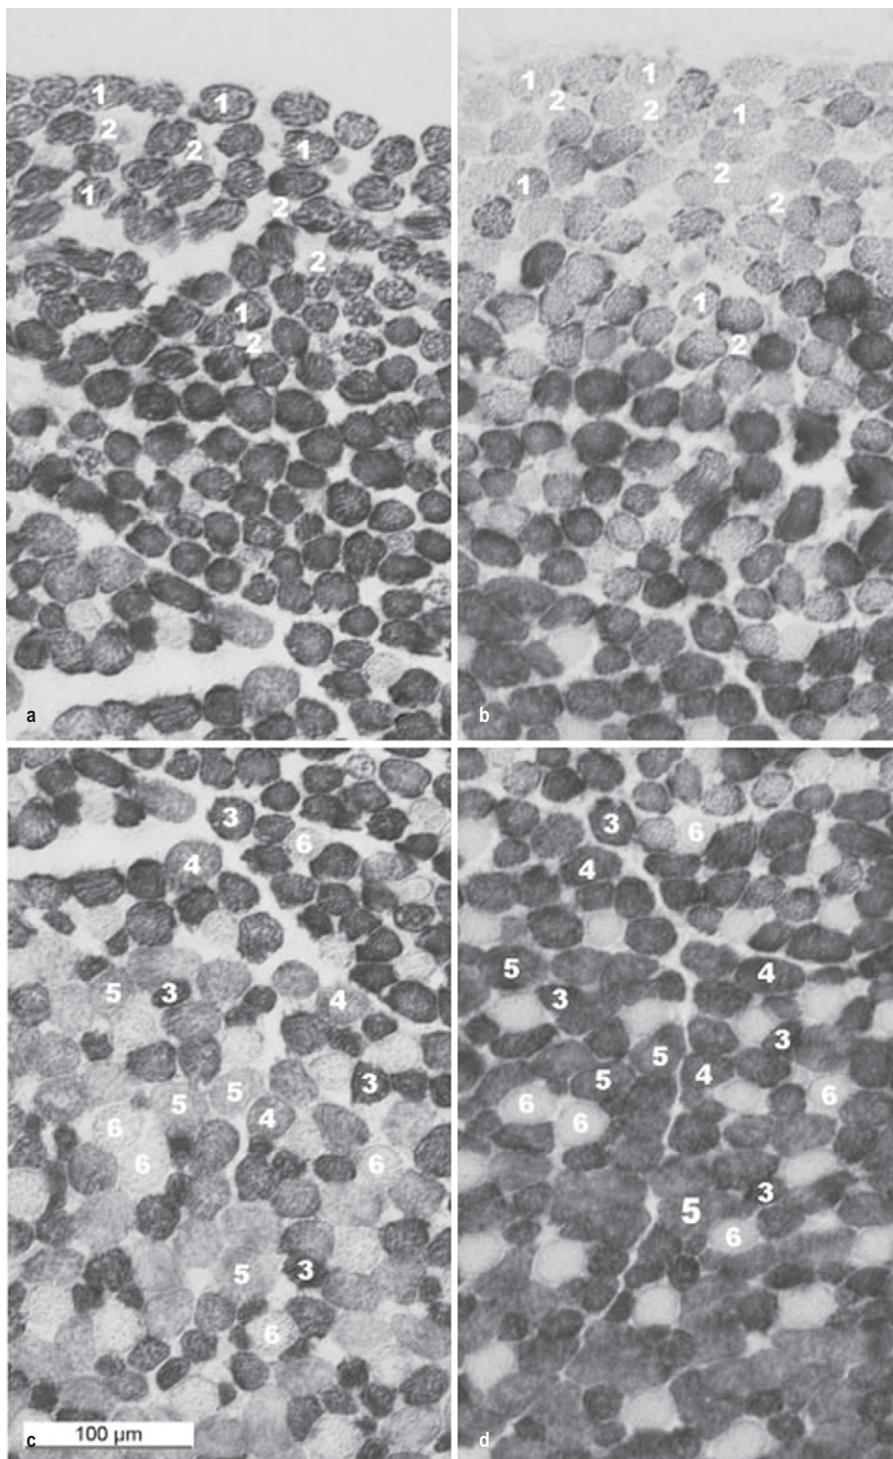

Figure 7.11 Schematic of human single myofiber co-expression of multiple MyHC isoforms. Myofiber can express MyHCIIa only, or it could co-express any one of the 6 MyHC isoforms shown, creating seven myofiber “types”. However, single myofibers can co-express three, four, or more MyHC isoforms, increasing the possible number of “types”, and this scheme only considers MyHC expression patterns. (Based on co-expression data found in Kjellgren et al, *Invest Ophthalmol Vis Sci* 44:1419–1425, 2003 and Stirn Kranjc et al, *Graefes Arch Clin Exp Ophthalmol* Epub July 17 2009.)

the non-cranial muscles examined thus far. Using labeling with the thymidine analog bromodeoxyuridine, activated satellite cells, the myogenic precursor cells of adult muscle, are seen; with sufficient post-labeling intervals, labeled myonuclei are present within existing myofibers in normal adult EOM of rabbits and mice. These new myonuclei are located peripherally, not centrally, indicating that this process of myonuclear addition is different than what occurs during muscle regeneration, when myotubes form followed by fibers with central nucleation (Fig. 7.13). The process of myofiber remodeling appears to continue throughout life, as the presence of activated satellite cells, identified by the myogenic lineage marker MyoD,⁷⁵ is seen in the EOM from elderly humans.⁷⁶ Ongoing myofiber remodeling occurs in other craniofacial muscles as well,⁷⁷ suggesting that the differences in genetic control of cranial muscle formation may play a role in retention of this dynamic process in adult EOM.⁷⁸ The control of this process in the adult EOM is unknown. In contrast to non-cranial skeletal muscles, EOM continue to express a number of myogenic growth factors and functional receptors for these growth promoting molecules (Fig. 7.13).^{79,80} Pitx2, a mitogen and repressor of differentiation,^{81,82} is a signaling factor expressed in adult EOM⁸¹ and may play a role in maintaining a proliferative state in adult EOM. A conditional knock-out of Pitx2 in adult EOM results in alteration of the adult EOM phenotype to more resemble that of limb skeletal muscle.²⁰¹ This is further evidence of EOM’s unique allotype.

EOM are also set apart from non-cranial skeletal muscles in their resiliency to injury and/or denervation. Botulinum toxin, a muscle paralytic agent used to treat strabismus and focal dystonias such as blepharospasm,⁸³ causes myofiber atrophy in limb skeletal muscle. However, botulinum toxin treatment in EOM actually causes some myofiber hypertrophy⁸⁴ (Fig. 7.14), short-term activation of satellite cell proliferation,⁵³ shifts in MyHC composition,⁵³ and few long-term effects except for loss of the EOM-specific MyHC isoform.⁸⁵ Recalcitrance to injury also is seen after injection of the local anesthetic bupivacaine. In limb skeletal muscles, bupivacaine is a potent myotoxin

(A)

Figure 7.12 (A) Serial cross-sections through the orbital (a, b) and global (c, d) layers of rat superior rectus muscle stained histochemically for (a, c) succinic dehydrogenase (SDH) and (b, d) α -glycerophosphate dehydrogenase (GPDH). Individual myofibers are indicated by numbers 1–6. Different proportions of both enzymes are present in many myofibers (Reproduced with permission from Asmussen et al., Invest Ophthalmol Vis Sci 49:4865–4871, 2008).

and causes massive myofiber degeneration, but in the EOM of primates minimal lesions were seen after retrobulbar injection.^{86,87} Surprisingly, denervation of adult EOM causes relatively little histological change,^{88–90} the multiply innervated myofibers actually hypertrophy in the denervated EOM.⁸⁸

Using a denervation/reinnervation animal model, previously denervated EOM actually has more myofibers than the non-operated control side.⁹¹ These data illustrate two very important features of the EOM: they are remarkably resistant to various forms of injury, and they are incredibly adaptable.

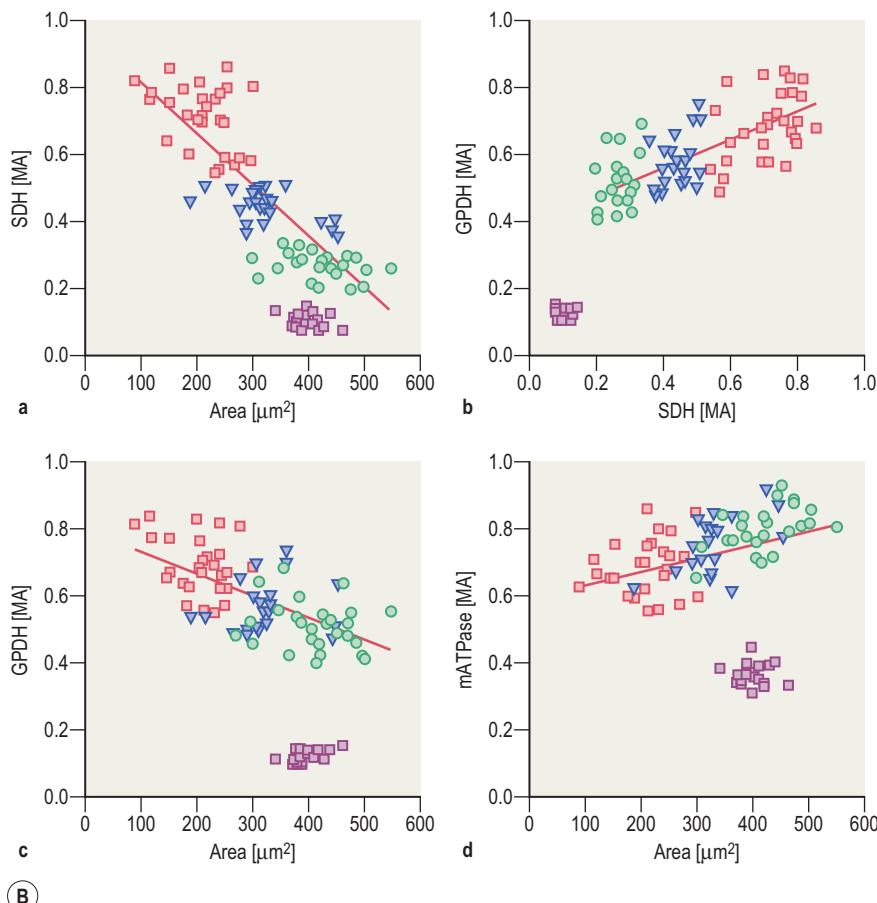

Figure 7.12, cont'd (B) Scatterplots of global layer data showing the relationship between cross-sectional area and SDH (a), GPDH (c) and mATPase (d) activities and between GPDH and SDH (b) expressed as the mean absorbance of the final reaction product in the cells of the fast twitch types 3 (■), 4 (▼), and 5 (◆) and the slow type 6 (□). The regression lines of the type 3 to 5 twitch fibers are indicated; they do not segregate into different "groups". (From Asmussen et al, *Invest Ophthalmol Vis Sci* 49:4865–4871, 2008, with permission from the Association of Research in Vision and Ophthalmology.)

Proprioception and proprioceptors

Proprioception in limb skeletal muscle is largely the job of muscle spindles, sensory receptors that detect changes in muscle length; this information is conveyed to the CNS which responds by regulating muscle tension to resist stretch. In the EOM, the role of proprioception is a matter of some controversy. Primate EOM does not appear to have a stretch reflex.⁹² Deafferentation of the EOM bilaterally does not result in eye position or eye movement changes.⁹³ However, when the EOM of a cat is stretched, neurons within the brain respond, despite the fact that cat EOM lack muscle spindles.⁹⁴ The brain has access to eye position, because even in total darkness humans perceive passive changes in eye position.⁹⁴ Visual cortex responses are modulated by changes in eye position also,⁹⁵ and primary somatosensory cortex contains proprioceptive representation of eye position.⁹⁶ What are the sensory organs, then, that receive and transmit this proprioceptive input?

The presence of muscle spindles has been histologically demonstrated only in the EOM of man, monkey and even-toed ungulates. Muscle spindles are composed of two types of specialized intrafusal myofibers within a connective tissue sheath (Fig. 7.15): nuclear chain and nuclear bag fibers. Only nuclear chain fibers are common in human EOM. Intrafusal fibers receive sensory innervation at their equatorial region and motor innervation at their spindle poles, and are surrounded by an acidic mucopolysaccharide-containing fluid (Fig. 7.15).⁹⁷ In human EOM, the number and

placement of muscle spindles varies quite significantly in the different muscles.⁹⁸ In general, they are higher in density in the more proximal and distal portions of the EOM and relatively devoid of spindles in the mid-belly region. The density varies between the individual EOM. Inferior rectus contains the most, with approximately 34 in the entire muscle. Superior oblique has two-fold more spindles than the other three rectus muscles. Inferior oblique has the fewest, averaging only four spindles which are located in the mid-belly region, rather than towards the origin and insertion.⁹⁸ Despite their well-described nature, the role muscle spindles play in the control of eye movements is unclear; one hypothesis suggests that they monitor static length and play no role in velocity monitoring, as no stretch reflex is seen in the EOM of monkey for example.⁹²

A second organ associated with proprioception is palisade endings (formerly called myotendinous cylinders), present in all mammalian EOM examined thus far, including man (Fig. 7.16).⁹⁹ These endings appear to be unique to the EOM.¹⁰⁰ They are found in the distal myotendinous region, where nerve fibers exit the muscle and then turn back to form synaptic contacts on the distal muscle tips of multiply innervated myofibers (Fig. 7.16).¹⁰¹ The synapses of palisade endings have been definitively shown to be motor (Fig. 7.16),^{102,103} supported by experiments lesioning the oculomotor nucleus which results in loss of both myofiber NMJs and those in the palisade endings.¹⁰⁴ Thus, palisade endings have an effector function and would not appear to be able to provide sensory feedback on eye position.^{102,103}

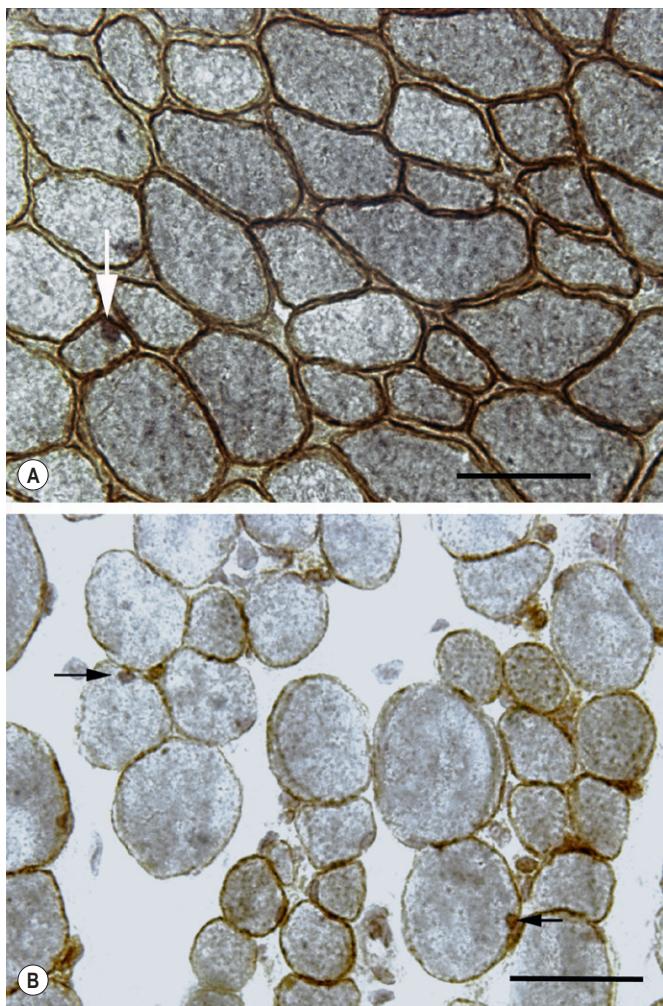

Figure 7.13 (A) Normal EOM incorporate the thymidine analog bromodeoxyuridine (brdU) into dividing satellite cells, and these are incorporated into apparently normal myofibers in adults. In this case, the rabbit was injected once daily with brdU for 7 days, followed by 14 days brdU-free. White arrow indicates brdU-positive nucleus. Myofibers are counterstained with an antibody to dystrophin for visualization of the sarcolemma. Bar is 20 μm . (B) Arrows indicate satellite cells positive for the insulin-like growth factor-1 receptor. The sections were counterstained for laminin for visualization of satellite cells. Bar is 20 μm .

Development

The distinct embryological origin of EOM may explain retention of its many unusual characteristics. While much more is understood about the early development of non-cranial skeletal muscles, recent studies have shed light on the genetic control of myogenesis in extraocular and other craniofacial muscles.^{105–107} The early control of craniofacial myogenesis uses a distinct set of genes and proteins compared to non-cranial muscles (Fig. 7.17A),^{108–110} and elucidating these differences will help lay the foundation for understanding clinical problems involving the EOM.

The EOM are derived from two sources of cranial mesoderm.¹¹¹ These early mesodermal precursor cells are not segmented, in contrast to the somites that give rise to non-cranial skeletal muscles. Additionally, cranial mesoderm does not separate into distinct dermamyotomes and sclerotomes.

Instead, EOM precursors arise from prechordal or paraxial mesoderm adjacent to the mes- and metencephalon, the future midbrain and hindbrain respectively, and migrate to their final locations.¹¹² When the transcription factor Pax3 is knocked out in mice, despite a complete absence of body and limb skeletal muscle, EOM develop normally.¹⁰⁸ Other myogenic regulatory factors such as Sonic Hedgehog (Shh), Wnt3a and bone morphogenetic protein 4 (BMP4), which turn on myogenesis in somitic mesoderm, have an inhibitory effect on myogenesis in cranial mesodermal cells both *in vitro* and *in vivo*.¹⁰⁵ These proteins are generated by the developing brain and surface ectoderm, delaying myogenesis onset. Soon after identifiable EOM anlagen form, neural crest-derived cells migrate into them,¹¹² and this migration depends on BMP signaling.¹¹³

Recent studies show that the homeodomain transcription factor Pitx2 is required for EOM development (Fig. 7.17A),^{114,115} and the absence of this gene in development causes ocular defects such as Rieger syndrome.¹¹⁶ EOM morphogenesis is tightly regulated by *Pitx2* gene dose, so if there is a small reduction in *Pitx2*, no superior and inferior oblique muscles form but the rectus muscles develop normally.¹¹⁷ If *Pitx2* levels are reduced further, the rectus muscles become smaller and more disorganized, and a total deletion of *Pitx2* results in the complete absence of all the EOM (Fig. 7.17B). *Pitx2* is a retinoic acid (RA) responsive gene, and RA controls neural crest movement.¹¹⁸ Neural crest infiltration into the EOM is required for their normal migration. In the absence of RA, the EOM form but do not successfully migrate.¹¹⁸ Other signaling factors such as *barx2* and *Lbx1* are differentially expressed in early developing EOM, but not universally¹¹⁰ (Fig. 7.17C), and their role in EOM formation is unclear.

After precursor migration, on a molecular level myogenesis proceeds similarly to that seen in non-cranial skeletal muscle, but it differs quite significantly on a temporal level.¹⁰⁹ Muscles derived from somites express *myf5* and *MyoD* transcripts, early markers of muscle-specific differentiation, earlier in development than in craniofacial muscle precursors.¹¹⁹ There is a prolonged period prior to expression of *MyHC* in craniofacial muscles compared to times between *MyoD* and *MyHC* expression in developing limb muscle. Neural crest cells express a number of signaling factors, including BMP, Wnt, and Shh, thought to be responsible for this early repression of myogenesis in developing craniofacial muscles,¹⁰⁵ whereas these same molecules promote muscle differentiation in somitic muscle precursors. The sequence and timing of *MyHC* expression also differs in cranial and non-cranial skeletal muscle.¹²⁰

In the EOM from human fetuses, only primary myotubes are present at early gestational ages, and co-express two developmental isoforms of slow myosin (type I). In addition they express the two “immature” isoforms, embryonic (MYH3) and fetal (MYH8). These developmental stages consistently lag behind limb skeletal muscle by 2–4 weeks.¹²⁰ When secondary myotube formation begins, the first type IIa (MYH2) is expressed.^{120,121} Even by 22 weeks of gestation in human fetuses, the alpha-cardiac (MYH6) and EOM-specific (MYH13) MyHC isoforms are not detected. This fiber type development and diversification in EOM occurs in the absence of morphologically mature endplates.¹²² Studies in mouse embryos show that EOM position is dependent on cues from the local environment, but early EOM myogenesis

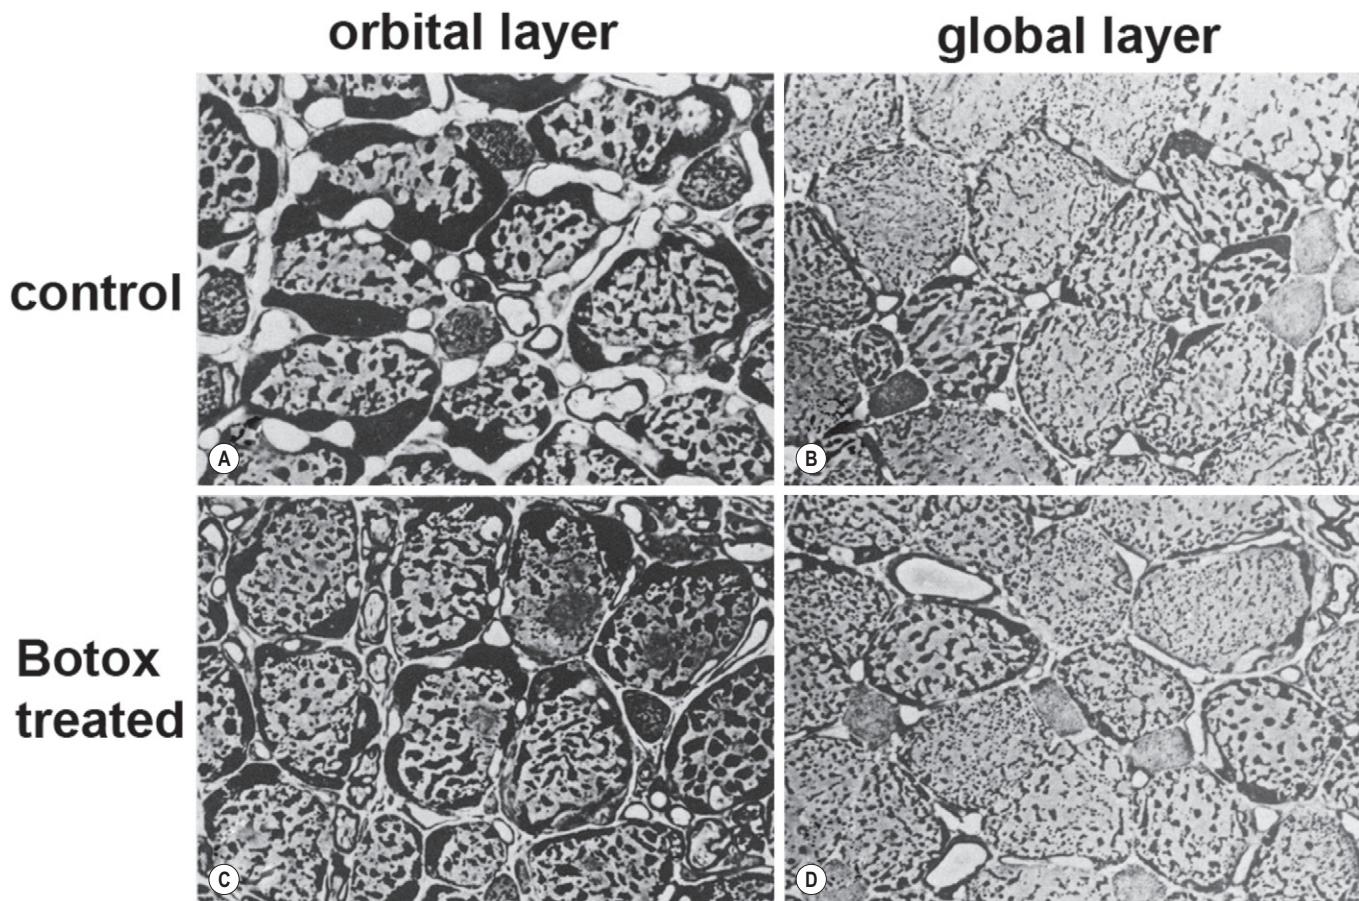

Figure 7.14 In (A, B) control or (C, D) botulinum toxin A (Botox)-treated (14 days post-injection) adult medial rectus muscle from primates, the orbital layer myofibers actually hypertrophy rather than atrophy. No change is seen in global layer fibers after Botox. Plastic sections stained with para-phenylenediamine. (From Spencer and McNeer Arch Ophthalmol 105:1703, 1987. Copyright 1987 American Medical Association. All rights reserved.)

is independent of neural crest cells, target tissues and nerves.¹²³ Modern molecular biological tools are helping to answer the question of how EOM becomes EOM and what controls its collective unusual properties at the molecular level, yet there is much still unknown. This becomes rapidly apparent when congenital conditions involving the EOM are examined.

Disease propensity

From a clinical perspective, the preferential involvement or sparing of the EOM in disease represent critical unsolved questions. Diseases that involve the EOM can be divided into three basic categories: (1) clinical disorders related to the specific motor functions of EOM, (2) diseases with preferential sparing of the EOM compared to limb skeletal muscle, and (3) diseases where the EOM are either primarily or preferentially involved compared to limb skeletal muscle. An exhaustive review of all these clinical entities is beyond the scope of this chapter; however, each of these general categories will be discussed.

Disorders of eye movements

Three examples of conditions that manifest with abnormal eye position and/or movements are discussed: strabismus,

nystagmus, and congenital cranial dysinnervation disorders (CCDD).

Strabismus

One of the most common motor disorders involving the EOM is strabismus, defined as misalignment of the eyes such that disparate images reach corresponding parts of each retina, disrupting binocular vision (see Chapter 36).

Many studies have examined the oculomotor control of eye position in strabismus, but much less is understood about the EOM themselves in these conditions. Studies measuring EOM forces during eye movements in strabismic patients yielded quite disparate results.^{2,128,129} In one study of adults with concomitant strabismus, whether convergent (esotropia) or divergent (exotropia), no differences in mechanical or contractile properties were seen.² All patients with superior oblique palsy showed reduced values for mean peak velocity in most directions of gaze compared with normal levels, whereas mean peak and steady state tension did not vary between normal EOM and patients with either congenital or acquired superior oblique palsy.¹²⁹

Studies of muscle structure in strabismic patients and animal models also yielded quite different results. Horizontal rectus muscle anatomy in naturally and artificially strabismic monkeys showed no differences in EOM size,

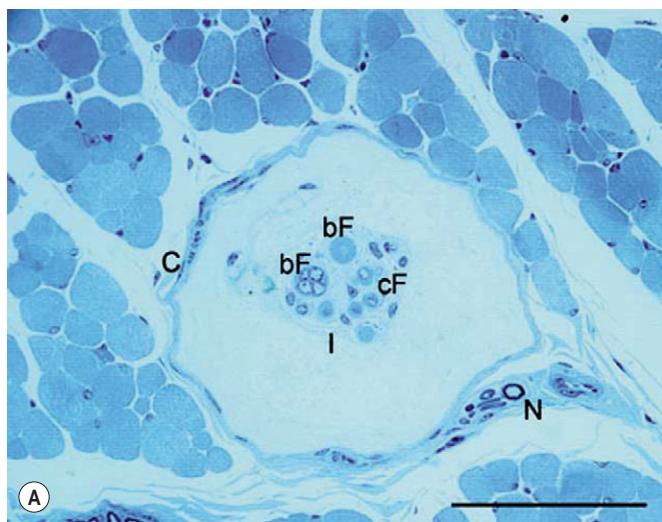

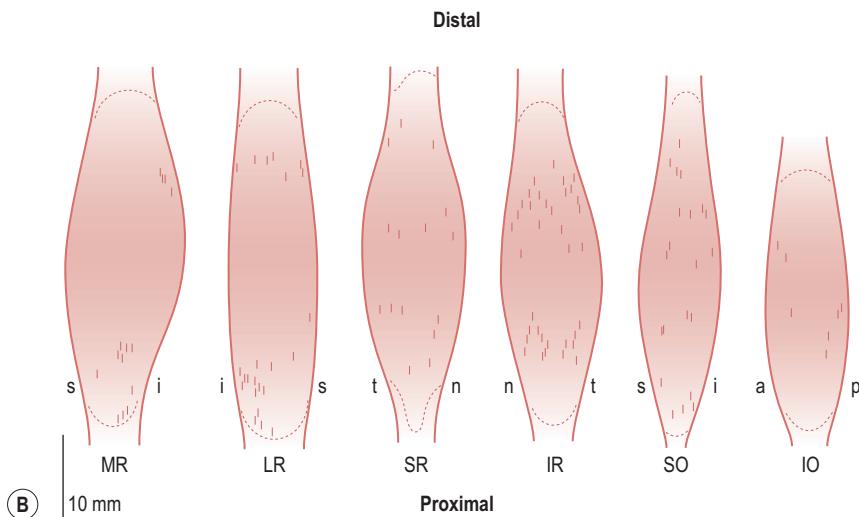

Figure 7.15 (A) Cross-section through the equatorial region of a cow muscle spindle. The muscle spindle contains two nuclear bag fibers (bF) and five nuclear chain fibers (cF). In one nuclear bag fiber the bag region containing several nuclei is visible. In some nuclear chain fibers their central nuclei are seen. Bag fibers have a larger diameter than chain fibers. An inner capsule (I) surrounds the intrafusal myofibers. Capsule (C), nerve (N). Scale bar: 100 mm. (From Blumer et al, *Exp Eye Res* 77:447–462, 2003. Copyright Elsevier 2003)

(B) Reconstructions from camera lucida drawings illustrating the exact positions and relative lengths of spindles projected into one plane for all six EOM of the same orbit (72-year-old woman). MR = medial rectus; LR = lateral rectus; SR = superior rectus; IR = inferior rectus; SO = superior oblique; IO = inferior oblique; n = nasal; t = temporal; s = superior; i = inferior; a = anterior; p = posterior. Scale = 1:2.5. (Modified from Lukas et al. *IOVS* 35:4317–4327, 1994, with permission from the Association of Research in Vision and Ophthalmology.)

structure, or innervation.¹³⁰ Interestingly, there was much less uniformity in cross-sectional area in the natural esotropes compared to those artificially induced. EOM obtained during strabismus surgery showed minimal changes at the light level, but an array of myofiber structural changes at the electron microscopic level, including fiber vacuolization and mitochondrial changes.^{131,132} Others described minimal changes in the myofibers and their motor innervation, but significant pathology in the proprioceptive innervation at the myotendinous junctions.¹³³ However, after examination of EOM from a number of different ocular motility disorders, some of the unusual features in the strabismic muscles appeared in the control muscles also.¹³⁴ Increased satellite cell numbers were present in the inferior oblique muscles from patients with inferior oblique overaction¹³⁵ suggesting up-regulated myofiber remodeling. Similarly, underacting medial rectus muscles from exotropes had two-fold higher levels of activated satellite cells, while overacting medial rectus muscles from esotropes had fewer activated satellite cells compared to control.¹³⁶ These studies suggest that adaptive changes occur in strabismic muscles. Current treatments for strabismus can include patching and surgery (see Box 7.2). Future approaches to strabismus treatment may be able to tap into these processes.

Box 7.2 Treatment of strabismus

Eye deviations are first treated by patching the “good” eye, the one aligned in primary gaze. If this is ineffective, incisional surgery is performed on the muscles. Recession surgery is thought to weaken an “overacting” muscle, performed by moving the muscle’s scleral insertion posteriorly. Resection surgery is thought to strengthen an “underacting” muscle, performed by removing a portion of the muscle and reattaching the muscle to its original site of insertion on the sclera.¹²⁷ If this misalignment is not corrected in early childhood, amblyopia may develop. Amblyopia is a condition of functional blindness in an otherwise normal eye.^{124–126}

Nystagmus

Nystagmus is defined as a bilateral, involuntary, and conjugate oscillation of the eyes, and is primarily a problem of oculomotor control within the brain. Patterns of eye movements in nystagmus patients are complex, and many different forms exist including both congenital and acquired.^{137,138} Nystagmus can be inherited genetically, and may have a

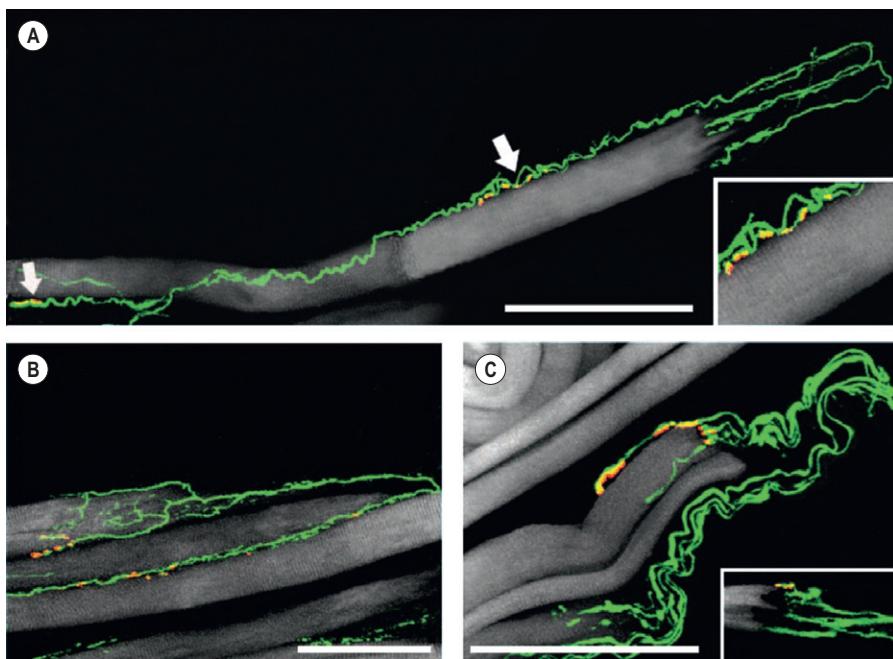

Figure 7.16 Confocal laser scanning microscopy images of palisade endings. Nerve fibers are labeled with anti-ChAT (green), nicotinic acetylcholine receptors with α -bungarotoxin (red), and myofibers with phalloidin (white). The tendon not labeled continues from the myofiber to the right. Neuromuscular contacts which exhibit ChAT/ α -bungarotoxin reactivity appear yellow in the overlay. (A) ChAT-positive nerve fiber running alongside the myofiber forms palisade ending at the myofiber tip. The same nerve fiber established multiple, ChAT/ α -bungarotoxin positive neuromuscular contacts (arrows) on the same myofiber. (Details of the neuromuscular contacts are shown in the insets.) Preterminal axons and nerve terminals of the palisade ending are also ChAT-positive. Palisade nerve terminals exhibit no α -bungarotoxin-binding, thus no neuromuscular contacts are present. (B) ChAT-positive nerve fiber forming a palisade ending at a myofiber tip and establishing ChAT/ α -bungarotoxin-positive neuromuscular contacts on a neighboring myofiber outside the palisade complex. The palisade ending establishes neuromuscular contacts that are ChAT/ α -bungarotoxin-positive. (C) Palisade endings with neuromuscular contacts exhibiting ChAT/ α -bungarotoxin-reactivity. A detail of another palisade ending with a single ChAT/ α -bungarotoxin-positive neuromuscular contact is shown in the inset. Scale bars, 100 μ m. (Reproduced from Blumer et al. IOVS 50:1176–1186, 2009, with permission from the Association of Research in Vision and Ophthalmology.)

Box 7.3 Surgery for congenital nystagmus

It has been suggested that tenotomy in congenital nystagmus patients, removal of the muscle from its scleral insertion and reattachment, results in reduced amplitude and intensity.¹⁴⁴ Other investigators found tenotomy increased the velocity and intensity of the nystagmus in a monkey model.¹⁴⁵ Further studies are needed to clarify this issue; however, it is important to note that the myotendinous junctions thought to be disrupted by this procedure are motor, not sensory as originally proposed.¹⁰²

of one or more of the EOM resulting in a static eye position or directional impairment. The genetic bases for several of the congenital cranial dysinnervation disorders (CCDD), as they are now called, have been instructive in understanding EOM and cranial motor neuron development (Box 7.4).¹⁴⁶ Each identified genetic mutation causes distinct developmental defects of the oculomotor (CNIII), trochlear (CNIV) and/or abducens (CNVI) nerves.¹⁴⁷ While patients with these CCDDs are rare, they demonstrate the incredible complexity in the genetic control of the EOM and their innervation.

Diseases where EOM are preferentially spared

sensory or motor origin.^{139,140} The complex waveforms of the oscillatory eye movements have been extensively studied, but little is known about adaptive changes at the EOM level. Ultrastructural studies on human EOM from patients with congenital nystagmus show that myofibrillar orientation as well as mitochondrial structure are altered.^{141,142} While a variety of pharmacologic treatments have been suggested, controlled clinical trials are needed.¹⁴³ Surgery also is a common treatment option for these patients (Box 7.3).

Congenital cranial dysinnervation disorders (CCDD)

Several rare, non-progressive inherited strabismic disorders have been described and characterized by congenital fibrosis

There are many skeletal muscle diseases that spare the EOM (Table 7.2). Duchenne muscular dystrophy (DMD) is a devastating X-linked genetic disorder characterized by the absence of dystrophin, repeated cycles of degeneration and regeneration, progressive muscle weakness, and ultimately death. The EOM are spared, both morphologically¹⁵³ and functionally.¹⁵⁴ The mechanism that allows for this sparing is unknown. None of the potential structural or metabolic characteristics examined thus far has proven to be mechanistic for this sparing including, but not limited to: calcium handling, antioxidative enzymes, nitric oxide location, cation handling, and utrophin up-regulation.^{65,81,156–159}

The *constitutive* nature of EOM sparing is supported by the EOM being spared in other dystrophic diseases,¹⁵⁹ including Becker muscular dystrophy,¹⁵⁴ laminin alpha2-deficiency,¹⁶⁰ merosin-deficient muscular dystrophy,¹⁶¹ sarcoglycan deficiency,¹⁶² and congenital muscular dystrophy, where, despite some ultrastructural changes,¹⁶¹ the EOM display full ocular motility.¹⁶³ EOM sparing has even been documented for inflammatory autoimmune diseases of skeletal muscle such as dermatomyositis.¹⁶⁴ This wide array of skeletal muscular dystrophies and degenerative disorders that spare the EOM suggests that the sparing mechanism must be intrinsic to EOM muscle. Two interesting hypotheses currently being tested as potential mechanisms for EOM sparing in dystrophies suggest that either the EOM are inherently able to resist the necrosis caused by the “hostile” tissue milieu within dystrophic muscle, or they have the capacity for increased regenerative potential, an idea supported by their ability to remodel and repair throughout life.¹⁶⁵ Their inherent ability to survive denervation supports the first hypothesis.^{84,85,90} The ability of the EOM to remodel even in aging muscle⁷⁵ and the relative absence in the EOM of the sarcopenia and other defects seen in aging non-cranial skeletal muscle¹⁶⁶ suggest that the intrinsic regenerative capacity in adult EOM is sufficient to provide functional EOM throughout the lifetime of these patients. An understanding of the mechanism of sparing may lead to new treatments for these fatal dystrophic diseases.

The EOM, and the motor neurons which innervate them, have long been considered spared in amyotrophic lateral sclerosis (ALS), with histopathologic examination of nerve roots as supporting evidence.¹⁶⁷ However, many studies cast doubt on this hypothesis, suggesting instead that the overall time course of the disease plays a role in whether eye movement disorders are apparent. Analysis of ocular movements and muscle pathology is made difficult by the heterogeneity of the patient populations relative to onset and speed of decline. In a longitudinal study of eight patients, all but one showed changes in electro-oculography of the EOM; some were subclinical but most were progressive over time.¹⁶⁸ Differential vulnerability of cranial motor neurons innervating the EOM occurs in several mouse models of ALS, with differential loss or sparing of motor neurons in transgenic mice expressing the human mutation in the superoxide dismutase gene-1 compared to two spontaneous mouse models of ALS.¹⁶⁹ Direct examination of the EOM post-mortem from two subsets of ALS patients, those with either a short- or long-time course of neuron loss, showed there were degenerative changes in the cranial motor nerves within the EOM from these patients, and differential sparing of myofibers in the two groups.¹⁷⁰ The preferential sparing of the ocular motor neurons and the EOM in ALS patients may just be temporal; if an individual lives sufficiently long, the ocular motor neurons and associated EOM would show degenerative changes. Alternatively eye movements may not be

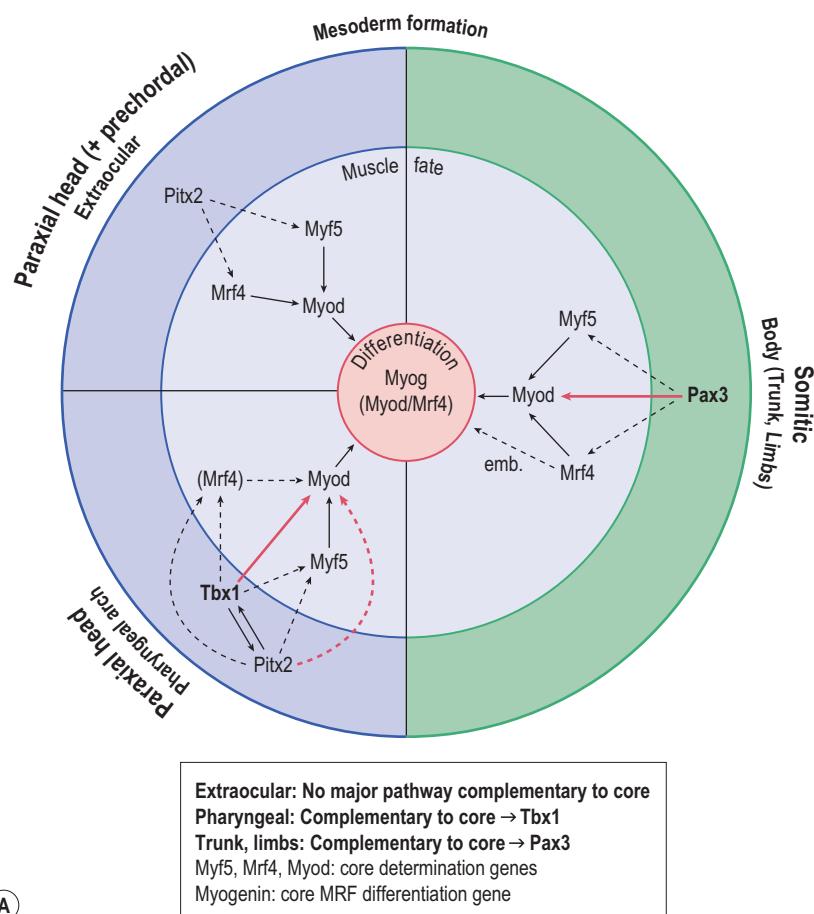

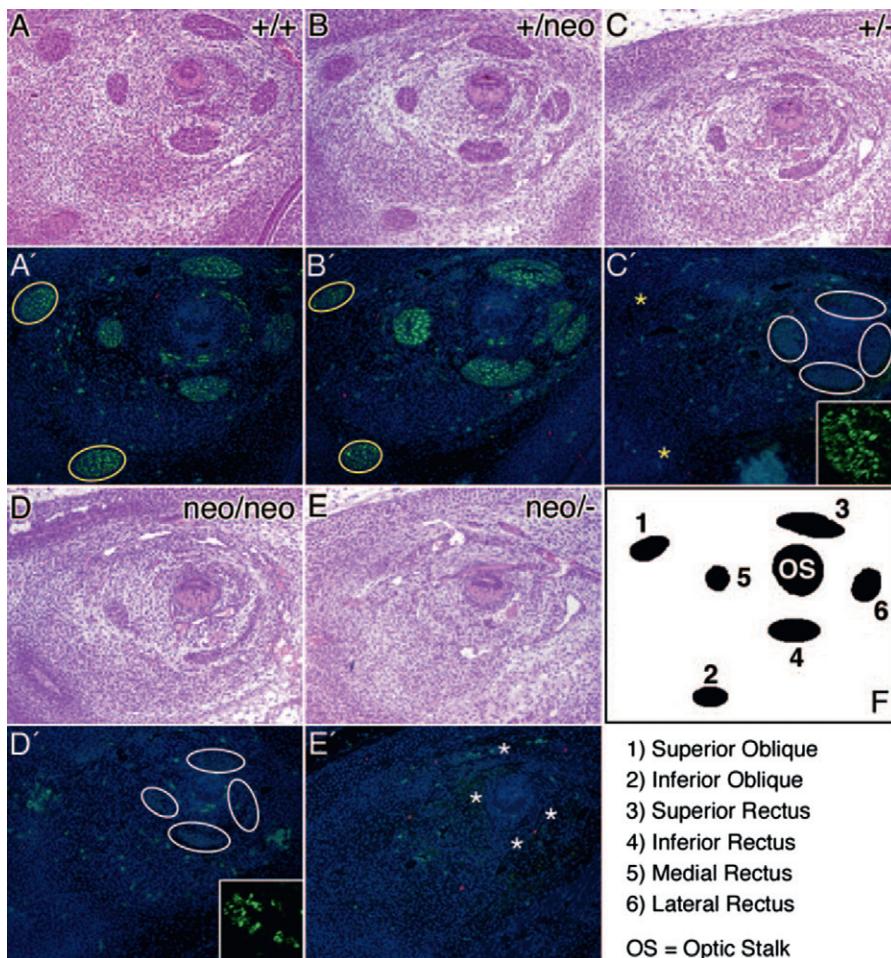

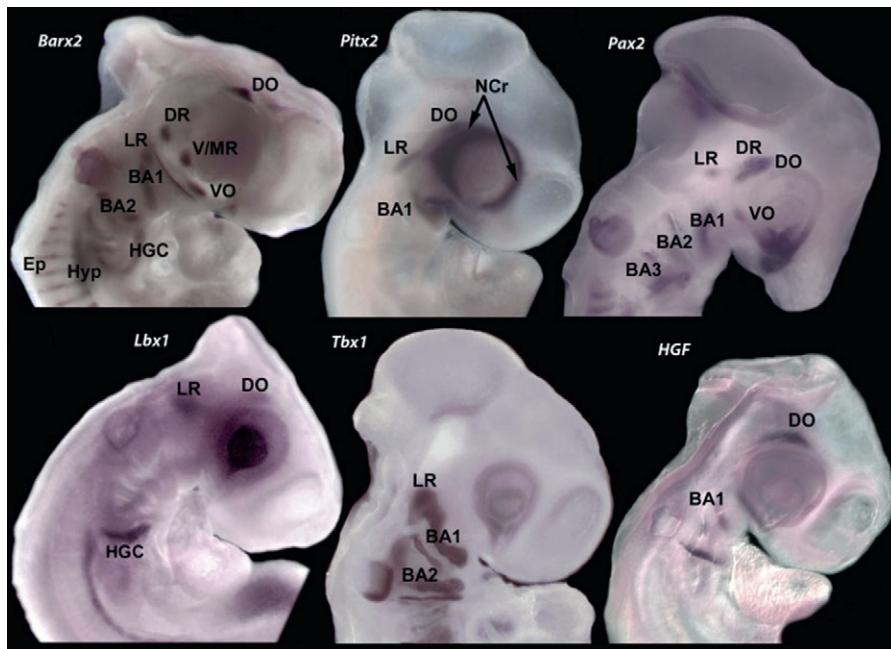

Figure 7.17 (A) EOMs do not have complementary regulatory pathways. MyoD expression is not rescued in the absence of Myf5 and Mrf4, and EOMs do not form. In pharyngeal (PA) muscles, Tbx1 cooperates with Myf5. In their combined absence, MyoD is not activated, and PA muscles are missing. In the body and EOMs, Mrf4 determines embryonic but not fetal MPC fate. Pitx2 may cooperate with Tbx1 at this regulatory step in the PA. Pax3 acts as the complementary pathway for body myogenesis to rescue MyoD expression. (Modified from Sambasivan et al, Dev Cell 16:810–821, 2009. Copyright Elsevier 2009.)

(B)

(C)

Figure 7.17, cont'd (B) EOM morphogenesis correlates strongly with *Pitx2* gene dose. Sagittal sections immediately medial to the optic cup taken from E14.5 mice embryos of the indicated genotypes. Sections were stained by hematoxylin and eosin (A-E) or developmental myosin heavy-chain (dMyh) immunofluorescence (A-E). Insets: medial rectus muscles. Superior and inferior oblique muscles (yellow ovals in A and B) are more sensitive to *Pitx2* gene dose than rectus muscles (white ovals in C and D). All EOM, including rectus muscles (E, *), are absent in *Pitx2neo/-* embryos. (F) Schematic key for EOM position. Only rectus and oblique muscles are shown; the retractor bulbi muscle has been omitted. Magnification, $\times 20$; insets, $\times 40$.

(Reproduced from Diehl et al., Invest Ophthalmol Vis Sci 47:1785-1793, 2006, with permission from the Association of Research in Vision and Ophthalmology.)

(C) Genes expressed in all (*barx2*, *pax2*) or subsets of chick head muscles. *Lbx1* is, like *paraxis*, expressed in glossal and laryngeal myoblasts derived from occipital somites, and in the lateral rectus (and *lbx1* in the dorsal oblique). *Tbx1* is in all branchial myoblasts and also the lateral rectus, and is expressed in other epithelial and mesenchymal cells of the head. *Pitx2* is present in the 1st branchial arch muscle plate and also in several EOMs plus periocular neural crest cells. *HGF* is produced in the mandibular and dorsal oblique muscles, and serves as a neurotrophic factor for the mandibular and trochlear nerves. (From Noden and Francis-West. Dev Dyn 235:1194-1218, 2006.)

Box 7.4 Congenital fibrosis of the extraocular muscles

Patients with congenital fibrosis of the EOM type 1 (CFEOM1) have a defect in the development of the superior division of the CNIII resulting in atrophic superior rectus and levator palpebrae superioris muscles.¹⁴⁶ The mutation is in the KIF21A gene, a developmentally expressed kinesin which presumably delivers a molecule critical for early neurite survival.¹⁴⁸ CFEOM2 has a recessive inheritance, and all EOM are missing except the lateral rectus, which is innervated by CNVI (Fig. 7.18). This disorder is due to mutations in the PHOX2A gene,¹⁴⁹ a transcription factor restricted to several classes of differentiating neurons. Its role in development is unclear; however, in PHOX2A null mice, no

oculomotor or trochlear neurons develop along with other brain abnormalities.¹⁵⁰ Duane's retraction syndrome is a congenital EOM disorder characterized by the lack of CNVI, and aberrant innervation of the lateral rectus from CNIII is often seen (Fig. 7.18).¹⁵¹ The genetic mutation in this disorder is the CHN1 gene which encodes alpha1-chimaerin, a Rac guanosine triphosphatase-activating protein signaling protein. This results in a gain-of-function mutation causing increased $\alpha 2$ -chimaerin on cell membranes¹⁵², and its over-expression in transgenic mice leads to pathfinding errors.

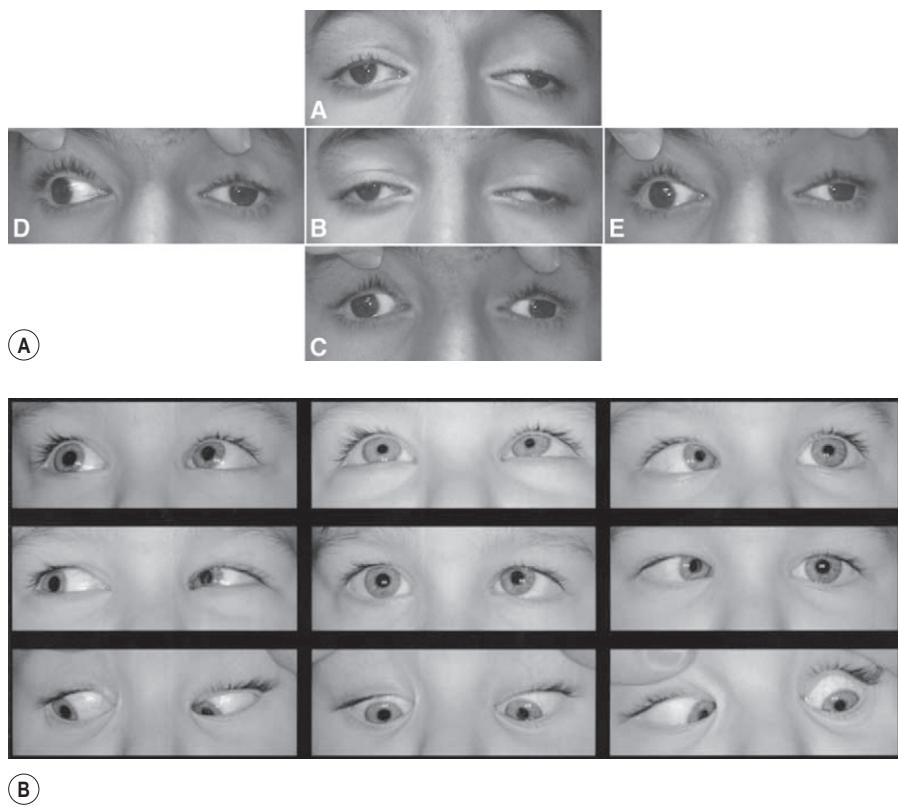

Figure 7.18 (A) Patient with congenital fibrosis of the EOM type 2 (CFEOM2). In primary position, note eyelid ptosis and lack of fixation in either eye (center panel). Up-gaze (A) and down-gaze (C) show complete absence of vertical movement. Right gaze (D) and left gaze (E) show complete lack of adduction of the left eye with almost full abduction of the right eye but moderately reduced abduction of the left eye. (Reproduced with permission from Bosley et al., Brain 129:2363–2374, 2006.) (B) Child with Duane's retraction syndrome, the congenital absence of CNVI resulting in a paralytic lateral rectus muscle. In primary position (center panel), the child is esotropic. Note limited abduction (middle row, far right). (From Morad et al., J AAPOS 5:158–163, 2001. Copyright Elsevier 2001.)

abnormal in these patients because even in the absence of 25 percent of cranial motor neurons, eye movements are completely unchanged.¹⁷¹ In addition, polyneuronal innervation, where more than one neuron can control the same myofiber, may protect the eye movement system against disease; if one motor neuron is lost, there are others that can take over functionally.²⁴

Diseases where EOM are preferentially involved

There are many diseases where the EOM are exclusively or preferentially involved. One disorder with primary EOM involvement is thyroid eye disease (TED) or Graves' ophthalmopathy, an autoimmune disease with significant inflammatory cell invasion of the EOM (Fig. 7.19).¹⁷² Despite many studies, the autoantigen responsible for this disease is still a

Box 7.5 Optic neuropathy of thyroid orbitopathy

Optic nerve compression in thyroid eye disease is a vision-threatening condition, and if the severity of the inflammation does not abate on its own and cannot be reduced medically with oral or intravenous pulse corticosteroids¹⁷³, surgical decompression of the orbit by surgically produced transpalpebral orbital floor removal or endoscopic decompression is required to prevent permanent vision loss.¹⁷⁴

matter of debate.^{175–180} Eye findings include exophthalmos, lid retraction, periorbital edema, pain, and diplopia.^{181,182} Significant enlargement of the EOM can occur, and in severe cases causes compression of the optic nerve posteriorly, resulting in permanent vision loss (see Box 7.5). This is caused by the inability of the bony orbit to accommodate enlargement of soft tissues, resulting in compression injury.

Table 7.2 Extraocular Muscles Have Different Disease Profiles Compared to Limb Skeletal Muscle

Diseases where EOM are spared	Etiology	Limb muscle pathology
Duchenne muscular dystrophy	X-linked genetic mutation of dystrophin gene	Progressive. Muscle wasting and weakness
Becker muscular dystrophy	X-linked genetic mutation of dystrophin gene, less severe phenotype than Duchenne	Progressive. Muscle wasting and weakness
α , γ and δ -sarcoglycan deficiency (limb girdle muscular dystrophy)	Mutation of the sarcoglycan gene	Progressive. Muscle wasting and weakness
Laminin α 2-congenital muscular dystrophy	Mutation of the laminin α 2 gene	Progressive. Muscle wasting and weakness
Amyotrophic lateral sclerosis	Mutations of the superoxide dismutase gene; mitochondriopathy	Progressive. Muscle wasting and paralysis
Diseases where EOM are primarily or preferentially involved	Etiology	EOM pathology and/or symptoms
Graves' ophthalmopathy	Autoimmune disease of the EOM, resulting in enlargement; presumably due to one or more shared antigens with the thyroid gland	Inflammatory orbitopathy, myopathy
CPEO (chronic progressive external ophthalmoplegia)	Mitochondrial DNA deletion, mutation of DNA polymerase-gamma gene	Accumulation of mutant mitochondria leads to muscle paralysis
Kearns–Sayre syndrome	Longer mitochondrial DNA deletions than CPEO	Accumulation of mutant mitochondria leads to muscle paralysis
Ocular myasthenia gravis	Autoimmune disease to either the acetylcholine receptor or MuSK	EOM and levator palpebrae superioris muscle weakness
Myotonic dystrophy type 1	Expansion of a CTG repeat within the DMPK gene	Saccadic slowing, optokinetic nystagmus
Myotonic dystrophy type 2	Expansion of a CCTG repeat expansion of the CNBP gene	Rebound nystagmus
Childhood strabismus	Unknown. Complex genetic cause?	Under- or overactive EOM with loss of binocularity and eye alignment in primary gaze
Congenital nystagmus	Missense mutation in FRMD7 gene; function unknown. Clinically heterogeneous; multiple genes involved	Conjugate, horizontal eye oscillations, in primary or eccentric gaze
Miller-Fisher syndrome	Autoimmune disease against ganglioside GQ1b/GT1a	EOM paralysis
Congenital cranial dysinnervation disorders	Specific gene mutation for each type	EOM weakness or absence

Primary EOM involvement occurs with some mitochondrial myopathies, such as chronic progressive external ophthalmoplegia (CPEO). CPEO is not one specific disorder but a clinical set of symptoms associated with mitochondrial DNA deletions or mutations and primarily defined by paralysis or weakness of one or more of the EOM,^{183,184} with no current treatments (see Box 7.6). CPEO is one of many diseases associated with clonal expansions of mitochondrial DNA mutations within myofiber segments.¹⁸⁴ Some mitochondrial myopathies affect both the EOM and other organs, including Kearns–Sayre syndrome (KSS) and Myoclonic Epilepsy associated with Ragged Red Fibers (MERRF).¹⁸⁵ In KSS, patients have a more severe phenotype than seen with CPEO; in addition to ophthalmoplegia, patients have retinopathy, proximal muscle weakness, cardiac arrhythmia, and ataxia. In MERRF, chronic neurodegenerative changes also occur. While it is still unclear why mitochondria with deletions would preferentially increase in the EOM and/or EOM and brain, both tissues are highly oxidative, with rates of

Box 7.6 Chronic progressive external ophthalmoplegia

Unfortunately there are no proven effective therapies for CPEO, KSS, and related mitochondrial cytopathies. In CPEO, for example, symptoms of strabismus, dry eye and ptosis can only be managed, as is true for those patients with concomitant cardiac defects.¹⁹²

mitochondrial function three to four times greater than limb skeletal muscles.¹⁸⁶ Mitochondrial mutations reduce energy production, a problem for the oxidative EOM.¹⁸⁷

Aging has been associated with the clonal expansion of defective mitochondria in this disorder,¹⁸⁸ as mutated mitochondria can completely replace normal ones over time.^{189,190} Interestingly, magnetic resonance imaging (MRI) of the EOM in CPEO patients demonstrates that the EOM are

Figure 7.19 (A) Axial MRI of a patient with TED. Increased thicknesses of medial rectus muscles bilaterally (arrow) is prominent. (B) Coronal MRI of a patient with TED. Note all muscles are enlarged except the lateral rectus (arrowhead). (Courtesy of Dr. Michael Lee, University of Minnesota.)

significantly smaller than in controls.¹⁹¹ This can aid in the differential diagnosis of this condition.

Myasthenia gravis is an example of a condition that preferentially involves the EOM, but can also involve multiple non-cranial skeletal muscles. Myasthenia gravis is an autoimmune disease of the NMJ resulting in skeletal muscle weakness and fatigability caused by functional NMJ dropout. While EOM weakness occurs in 90 percent of patients with myasthenia gravis, approximately 15 percent have only ocular myasthenia without other muscle involvement.¹⁹³ Interestingly, in generalized myasthenia patients, 90 percent have serum antibodies to the nicotinic acetylcholine receptor, while only 65 percent of the ocular myasthenics are positive for this autoantigen.¹⁹⁴ Other possible autoantigens that have been discussed include muscle-specific kinase (MuSK),¹⁹⁵ the ryanodine receptor,¹⁹⁶ and a number of eye muscle-specific proteins.¹⁹⁷ The frequent involvement of the levator palpebrae superioris and the EOM in myasthenia gravis may be due to the distinct NMJ characteristics of EOM compared to non-cranial skeletal muscles.¹⁹³ Early in the disease, slight weakness of the EOM results in lack of

Box 7.7 Treating ocular myasthenia

There are a number of drug treatments available for ocular myasthenia gravis. For example, prednisone can reduce symptoms in ocular myasthenic patients as well as significantly reduce the frequency of developing generalized myasthenia gravis both acutely and over the course of four or more years.²⁰⁰

alignment of the visual world on the retina causing diplopia, blur, vertigo, and other ocular symptoms (see Box 7.7).

The brain oculomotor control system cannot quickly adapt to the asymmetric or variable EOM weakness.¹⁹⁸ Therefore, EOM weakness is quickly discerned by patients. However, when patients with ocular myasthenia are examined, many have measurable, albeit subclinical, weakness in other muscle groups as well. Another hypothesis for EOM preferential involvement is the differences between their NMJ endplates compared to those in limb skeletal muscle.²⁰ Differences in both classical and alternative complement-mediated immune response pathways in EOM may also increase their susceptibility to ocular myasthenic symptoms.¹⁹⁹

Conclusion

The EOM are a specialized collection of craniofacial muscles with many distinct characteristics compared to non-cranial skeletal muscle. These muscles have a complex anatomy and physiology, which should be carefully considered when determining treatment of the motor disorders that affect them. The EOM are also highly adaptable, altering their protein expression and physiological characteristics in response to hormones, denervation, and toxins. This adaptability should lend itself to pharmacologic manipulation of these muscles for the treatment of EOM motor disorders. Furthermore, understanding the mechanisms that result in EOM sparing or preferential involvement in diseases of skeletal muscle will hopefully suggest new treatments for EOM diseases and for skeletal muscle diseases in general.

Three-Dimensional Rotations of the Eye

Christian Quaia & Lance M. Optican

Eye motility

In principle the eyeball, like any rigid object, has six degrees of freedom: three for rotation, and three for translation. The adult human eyeball is about 24–25mm in diameter, and can rotate about $\pm 50^\circ$ horizontally, 42° up and 48° down, and about $\pm 30^\circ$ torsionally. In contrast, the amount of translation possible for the eye is very limited: over the whole horizontal range the eyeball translates no more than 2 mm along the antero-posterior axis and 0.7 mm in the frontal plane.¹ Given the limited translational excursion, the globe can be treated as a spherical joint capable of rotating around its fixed center, and its motion has thus only three degrees of freedom.

Eye movements are easy to measure, in both the laboratory and the clinic. Technology for eye movement recording has been evolving for over 100 years, and although none are without their disadvantages, it is easy to find a commercial product to suit most needs (Box 8.1). Binocular recordings are especially important, because when both eyes fail to point in the same direction double vision (diplopia) results. Pathological conditions thus give rise to strabismus, the misalignment of the two gaze axes. This is commonly measured in the clinic with a Hess chart (Box 8.2), which gives a static measure of the misalignment. Binocular recordings can give both static and dynamic accounts of the misalignment as gaze angle changes.

Quantifying eye rotations

Describing translations is simple and intuitive. Once three orthogonal axes (e.g. Cartesian coordinates) are defined, a translation of a rigid object can be specified by simply providing the amount of translation of any one point of the object along each of the three axes. Importantly, the final position reached is independent of the order in which the three axes are considered (e.g., x -axis followed by y -axis movement yields the same position as y followed by x , i.e. translations are *commutative*). This happens because the familiar Euclidean space of translations is flat.

In contrast, rotations and their resulting orientations can not be described by any simple (i.e. intuitive) set of three

coordinates. One of the fundamental reasons for this complexity is that the space of all rotations is curved. This can be easily noted by considering that if one keeps rotating an object around the same axis it will eventually (after 360°) get back to its initial orientation. One of the implications of this feature is that the final orientation, or attitude, reached after a sequence of rotations around different axes depends on their order. In the two panels of Figure 8.1 a camera, starting from the same initial orientation (left column), is rotated around the same pair of axes (arrows in the figure), but in different order. Clearly, the final orientation (right column) is different for the two sequences of rotations; unlike translations, rotations are *non-commutative*.

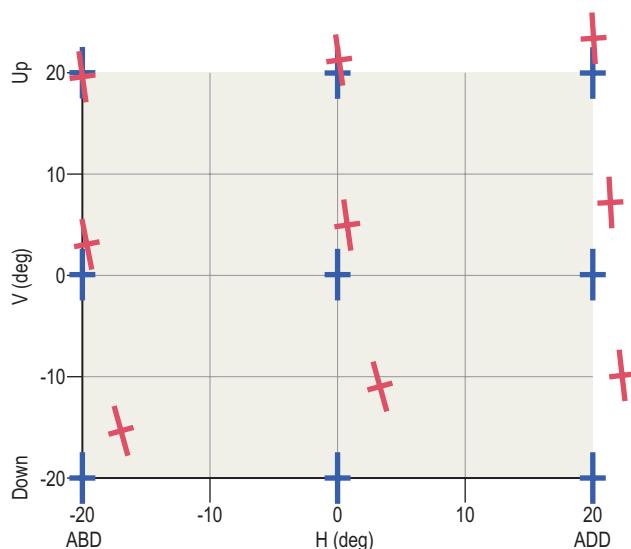

To address the inherent complexity of rotations, many mathematical tools have been developed over the last 150 years, such as quaternions, sequences of rotations, rotation matrices, rotation vectors, spinors, rotors, motors, etc. Although all these methods must be equivalent (they all describe the same rotations), each method has both advantages and disadvantages in different applications.^{2–4} Accordingly, we can choose the mathematical formalism that best facilitates our thinking about eye rotations.

The first issue that must be addressed when describing rotations or orientations of the eye is the selection of three orthogonal axes. Obviously, they must pass through the center of the eye, but other than that there are few constraints. Of course, keeping the axes fixed in space, so that they point in the same spatial direction regardless of the movements of the eye or the head, would not be very useful, as the six extraocular muscles rotate the eye relative to the head. One reasonable arrangement is to fix them to the eye, so that their spatial orientation changes whenever either the eye or the head move. Alternatively, they could be fixed to the head, so that their orientation in space would change only when the head moves. These two possibilities might sound radically different, but they are tightly connected if the head is fixed: starting from an initial orientation, a sequence of two eye rotations within one system leads to the same eye orientation as the reversed sequence of rotations in the other system. A final possibility is represented by the use of nested axes, in which one axis is fixed to the head, the second one rotates with it, and the third one is fixed to the eye and thus rotates with the other two. Unfortunately, these nested systems are often inappropriately called eye-fixed.

Box 8.1 Clinical eye movement recording methods

Axes	Range	Bandwidth	Resolution	Advantages	Disadvantages
Electro-oculography (EOG)					
H, V	~ $\pm 25^\circ$ H ~ $\pm 15^\circ$ V Not good for small movements ($< 5^\circ$)	~ 30 Hz	~ 0.5°	Easy to use, low cost	1, 2, 3, 4. EMG from scalp or jaw muscles can interfere
Infrared Reflection Device (IRD)					
H, V	~ $\pm 30^\circ$ H ~ $\pm 20^\circ$ V	~ 100 Hz	~ 0.02°	Easy to set up, moderate cost. Available for MRI, but limited range	1, 2, 5. Risk of ocular drying from IR source
Video-oculography (VOG)					
H, V, T	~ $\pm 30^\circ$ H, +30° up, -45 down, less for T	~ 25 Hz – 1 kHz H, V, but less for T	~ 0.05° H, V, ~ 0.1° T	Good for clinical use, good for children and infants, available for MEG & MRI	1, 2, 5, 6. Limited range, high cost
Magnetic Field Scleral Coil					
H, V, T	> $\pm 45^\circ$ in monkeys, but ~ $\pm 30^\circ$ in people because of eye coil limitations	>1 kHz	~ 0.01°	Coil can be permanently implanted in animals	6, 7. Contact lens causes discomfort, so inappropriate for children. High cost

1. Eye closure or eye lid artifacts.
2. Blink artifacts.
3. Poor linear range.
4. Signal drifts over time.
5. Sensitive to translation of head relative to device.
6. Torsion bandwidth and/or range reduced.
7. Limited recording time (~30 min) for people.

Box 8.2 3-D Effects of Muscle Weakness

3-D Hess chart of ocular alignment following unilateral trochlear (IVth) nerve damage. The denervated superior oblique muscle can only develop a passive force. The graph shows the effects of a superior oblique palsy (SOP) in a monkey. These measurements were made with 3-D eye coils in each eye. The normal eye views the target, but the palsied eye is covered. The monkey follows a light as it jumps to each of the nine target positions. The blue cross shows the attitude of the normal eye. The red cross shows the attitude of the palsied eye. Note that as the animal looks down in adduction (the main effect of the SO muscle), the deficit worsens. When the deviation between the two eyes is not constant with gaze angle, it is called an *incomitant strabismus*.

Note that the error is not only a displacement of the cross (up and out), but also includes a CCW twist. Similar recordings can be made in human patients with eye coils on a contact lens. In a lower technology method subjects wear (red or blue) colored filters over each eye. A blue cross is projected onto the screen, and is seen only by the normal eye. A red cross is also projected, which can only be seen by the affected eye. The subject moves and twists the red cross until it is aligned, perceptually, with the blue cross.

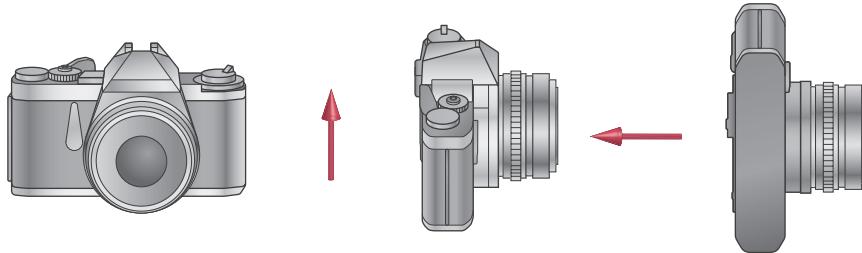

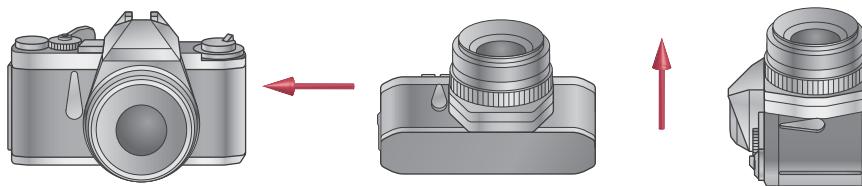

Figure 8.1 Non-commutativity of rotations. The image on the right of each arrow is obtained by rotating the image on its left around an axis collinear with the arrow. **(A)** The camera first rotates 90° around a vertical axis, and then 90° around a horizontal axis. **(B)** The order of rotations is reversed. The final orientation of the camera is clearly different in the two cases. (Redrawn from Quaia C, Optican LM. Commutative saccadic generator is sufficient to control a 3-D ocular plant with pulleys. *J Neurophysiol* 1998 Jun; 79(6):3197–3215. Used with permission.)

In oculomotor research only head-fixed and nested-axes systems have been extensively used. The decision of which one to use is affected by personal preference, and by the specific oculomotor task under study.

Nested-axes coordinates

Nested-axes coordinate systems are inspired by the classical mechanical method for mounting a rotating object, such as a camera. The simplest way to mount a camera is to have one axis for panning the camera left or right (yaw or Z-axis), one for tilting it up or down (pitch or Y-axis), and one for twisting it clockwise or counter-clockwise about the lens's optical axis (roll or X-axis). These axes are nested, one within the other, in a system of gimbals (since there are three rotation axes, there are six possible nesting sequences). As noted above, final orientation depends crucially on the order of rotations. However, in a gimbal system the mathematical order of the rotations is determined by the nesting order of the gimbals, and not by the order in which the mounted object is moved within the gimbals. Note that this mechanical coupling of the axes does not render rotations commutative; the space of rotations is still curved.

Two such nested-axes systems have been extensively used in the field of oculomotor research.⁵ The Fick system starts with a *horizontal* rotation around the vertical axis, followed by a *vertical* rotation around the new horizontal axis, and finally a *torsional* rotation about the new line of sight. The Helmholtz system starts with a *vertical* rotation around the horizontal axis, followed by a *horizontal* rotation around the new vertical axis, and finally a *torsional* rotation about the new line of sight. The leftmost column of Figure 8.2 shows a Fick gimbal system, and the rightmost column shows a Helmholtz gimbal system (torsional axes not shown). Initially (top row) the eye looks straight ahead, in *primary* position. When the eye rotates from primary position around the head-fixed horizontal or vertical axis, it is said to move into a *secondary* position (note: all secondary positions lie along the horizontal or vertical meridian of the globe; cf. Fig. 8.5 below). This is shown in

the middle row for Fick and Helmholtz gimbals: the first Fick rotation turns the eye to the left, whereas the first Helmholtz rotation turns the eye upward. The bottom row shows the eye rotated away from the horizontal or vertical meridian, into what is called a *tertiary* position. Note that, in spite of the magnitude of the two rotations being the same, the final orientation of the eye is different in the two cases.

Head-fixed coordinates

Over the years several different mathematical formalisms have been used to quantify eye rotations using head-fixed coordinate systems. The formalism that we prefer (because we consider it the most intuitive), and the only one that we describe here, is the so-called axis-angle form (Fig. 8.2, middle column), which follows from Euler's theorem. This theorem states that *any orientation of a rigid body with one point fixed can be achieved, starting from a reference orientation, by a single rotation around an axis (through the fixed point) along a unit-length vector \hat{n} by an angle Φ .*⁶ Euler's theorem highlights an aspect common to all the methods that can be used to represent rotary motion: the need to define a *reference*, or *primary*, orientation. Although its choice is totally arbitrary, the one most commonly adopted in eye movement research is the orientation with the head upright and the eye looking straight ahead. (Note: when eye orientations are discussed in the context of Listing's law, a somewhat different reference orientation is chosen for convenience; this will be discussed below.) The three main axes of rotation then point straight ahead (X-axis, roll or torsional rotations), straight to the left (Y-axis, pitch or vertical rotations) and straight up (Z-axis, yaw or horizontal rotations). The X-, Y-, and Z-axes define a right-handed system of head-fixed coordinates (x , y , z), that describe, for each eye orientation, Euler's axis of rotation. In a right-handed coordinate system, positive rotations are in the direction that the fingers of the right hand curl when the thumb points along the axis \hat{n} .

With this convention, for example, after a 45° rotation to the left, the orientation is described by $\{(0, 0, 1), 45\}$, as that orientation is achieved, starting from the reference

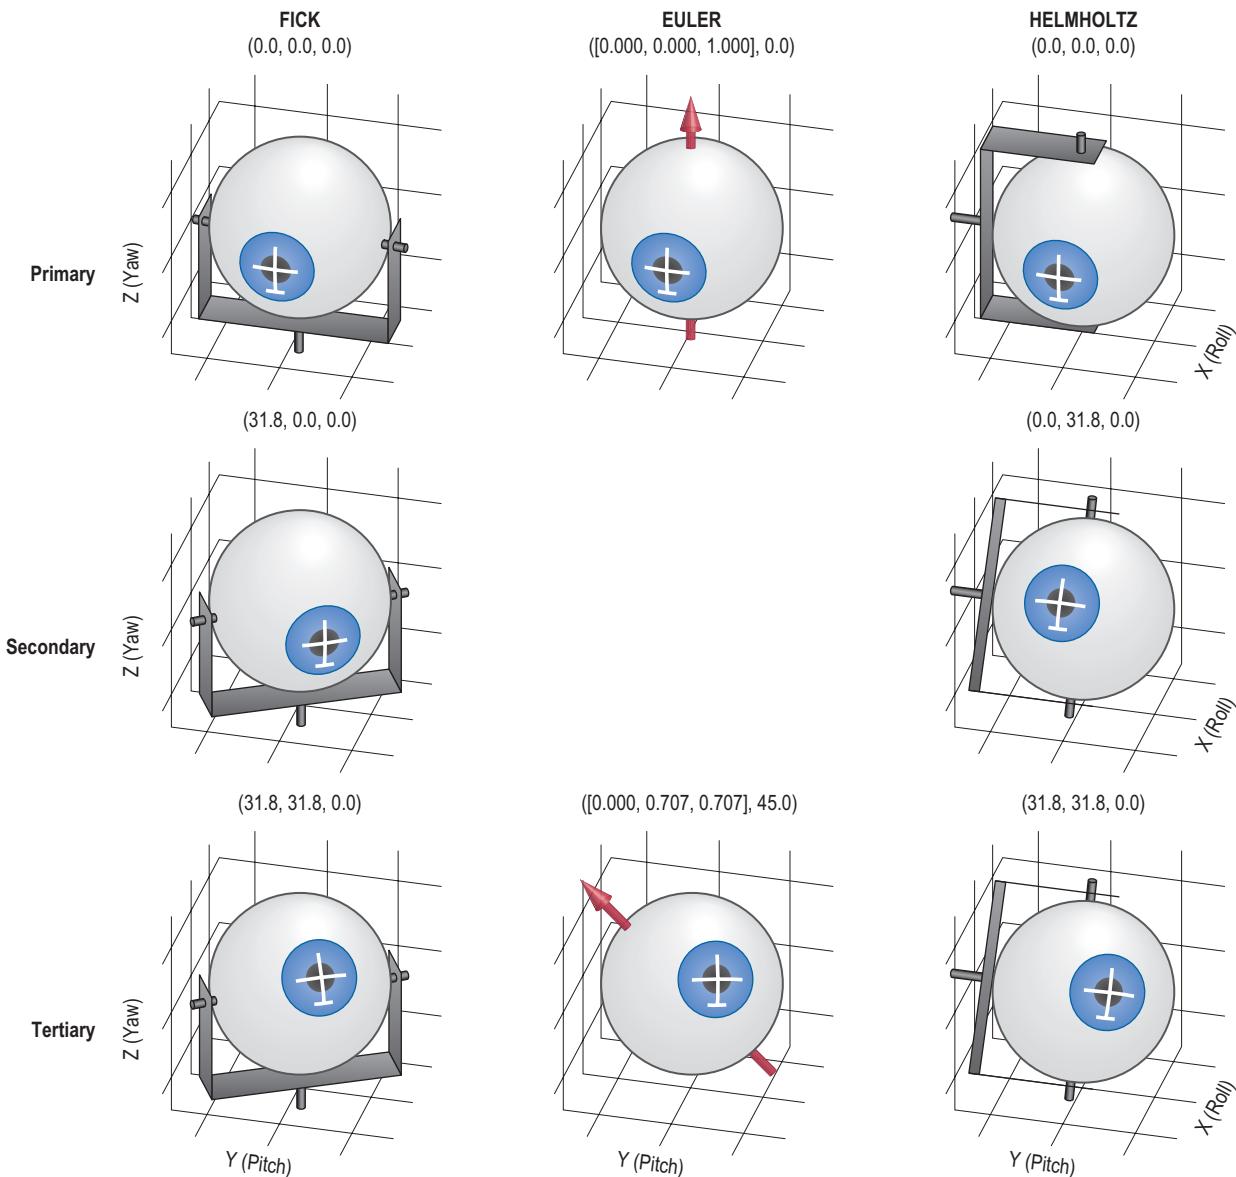

Figure 8.2 Head-fixed and nested-axes coordinate systems. In the left column Fick's nested-axes coordinate system is illustrated (torsion axis not shown). The axes can be represented by a gimbal system. The nesting order is: vertical axis, horizontal axis, torsional axis. In the middle column rotations are described in a head-fixed coordinate system, and Euler's axis is shown. Any orientation is represented by a single axis, tilted appropriately. In the right column another nested-axes system is shown (Helmholtz). In the Helmholtz system, the nesting order is: horizontal axis, vertical axis, torsional axis. Orientations are referred to as primary (looking straight ahead, top row), secondary (on the horizontal or vertical meridian, middle row), or tertiary (off both the horizontal and vertical meridians, bottom row). In all three cases we applied a rotation of 31.8° around the vertical and horizontal axes. In Fick coordinates, that corresponds to (31.8, 31.8, 0), in Helmholtz coordinates to (31.8, 31.8, 0), and in head-fixed coordinates to {[0, 0.707, 0.707], 45}. NB: even when the coordinates in two systems are the same numerically, the final orientations are different because rotations do not commute. In Euler coordinates, these Fick and Helmholtz rotations would be {(-0.198, 0.693, 0.693), 44.7} and {(0.198, 0.693, 0.693), 44.7}, respectively (note the opposite sign for the torsional component).

orientation, by rotating 45° around the vertical axis (0,0,1) (Fig. 8.3A; note that we are looking at the camera from in front, so the X, Y, and Z axes point out of the page, to the right, and up, respectively). Similarly, after a rotation 45° up and to the left, the orientation is {(0, 0.707, 0.707), 45} (Fig. 8.3B, and Fig. 8.2 middle column, bottom row).

Listing's law

The purpose of voluntary eye movements is to point the region of highest visual acuity (the fovea) at the object of

interest. Because the eye can rotate about the line of sight without changing the direction of gaze, the latter has only two degrees of freedom, whereas eye orientation has three. This situation, called *kinematic redundancy*,⁷ implies that an infinite number of different eye orientations correspond to each direction of gaze. Despite this redundancy, observation of voluntary eye movements reveals that the brain constrains the torsion to be a function of the horizontal and vertical gaze direction. This reduces the number of degrees of freedom of eye orientation from three to two, so that each gaze direction (achieved with saccadic or smooth pursuit movements) corresponds to a unique eye orientation,

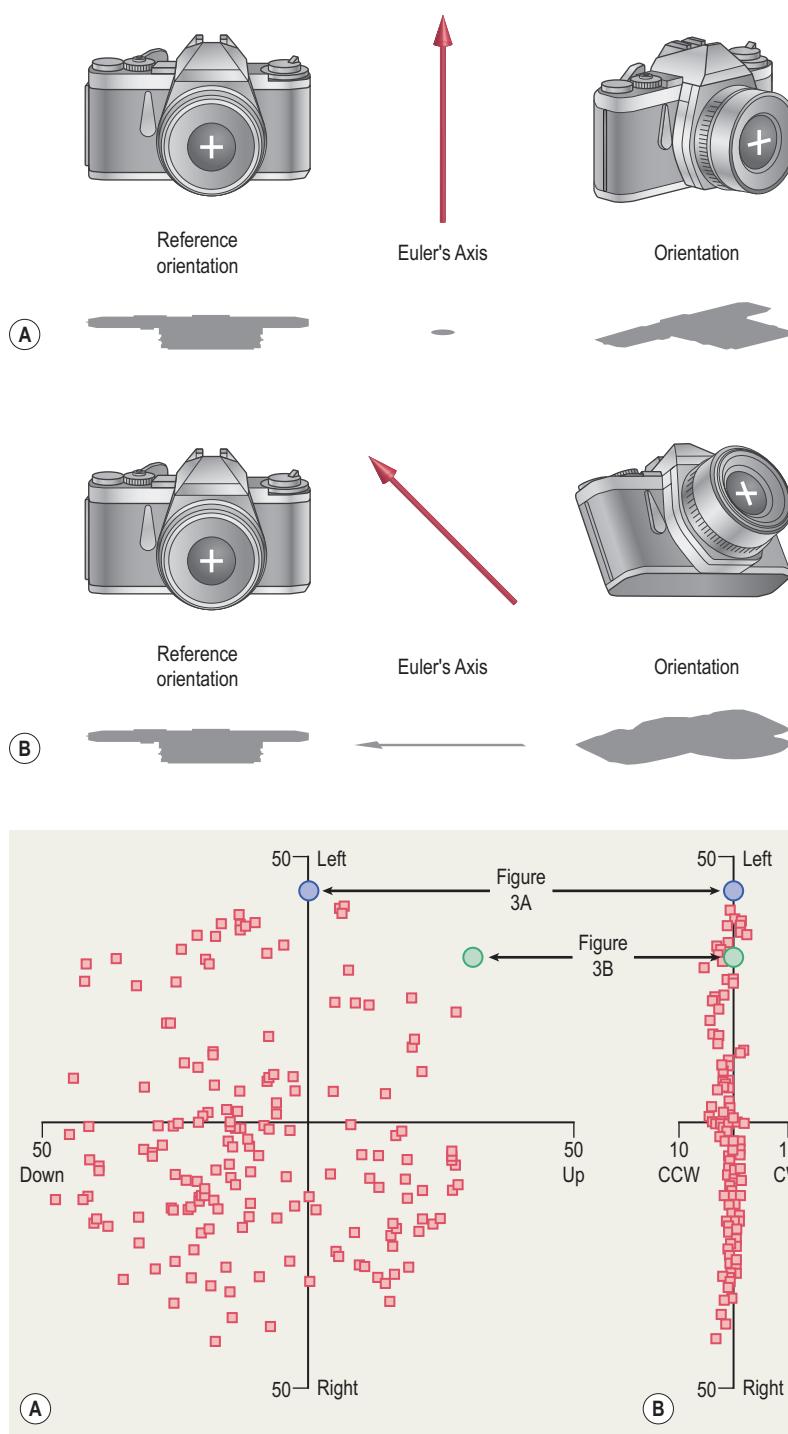

Figure 8.3 Representing orientation using the axis-angle form. For each panel, the reference orientation is shown on the left. (A) The camera is rotated 45° to the left, and the corresponding Euler's axis points straight up, (0, 0, 1) in the XYZ coordinate system (see text). (B) The camera is rotated 45° around the tilted axis (0, 0.707, 0.707). Note that the central cross on the camera's lens appears twisted with respect to the vertical axis, even though the Euler axis has no torsional component. (Redrawn from Quaia C, Optican LM. Commutative saccadic generator is sufficient to control a 3-D ocular plant with pulleys. *J Neurophysiol* 1998 Jun;79(6):3197–3215. Used with permission.)

regardless of previous movements and orientations. This observation is known as *Donder's law*.⁸

Donder's law states that the torsional component of the eye's attitude is a function of the horizontal and vertical components, but does not specify the relationship. Listing extended Donder's law, by specifying the torsional angle for any line of sight.⁸ *Listing's law* states that if the Euler vectors describing the eye orientations attained by a subject looking around with his head fixed in space are plotted, they lie in or near a plane (the so-called *Listing's plane*). In Figure 8.4 orientations measured in a human subject are shown; each

point indicates the orientation of the eye during a period of fixation. Figure 8.4A shows the vertical and horizontal components of the Euler axis (from the subject's point of view), whereas Figure 8.4B shows the vertical and torsional components (the components of the unit-length axis are multiplied by the eccentricity). As an example, on top of the human data we have added two symbols indicating where the Euler axes for the camera orientations shown in Figure 8.3A (blue disks) and Figure 8.3B (green disks) would be in this graph (note that the horizontal component is reversed, as in Figure 8.3 we were looking at the vectors from the front,

and not from the camera's point of view). Obviously the points in Figure 8.4 form a thin cloud; Listing's plane is defined as the plane that best fits this cloud.

With the head upright, Listing's plane is normally tilted backwards (about 20°), i.e. it is not aligned with the vertical plane. However, the data are usually transformed to a new coordinate system so that the torsional axis is perpendicular to Listing's plane (Tweed et al.⁹ show how to compute a unique reference position, called *primary position*, which is tilted away from straight ahead, and is perpendicular to Listing's plane). This was done, for example, in Figure 8.4. The major advantage of using this transformation is that Listing's law then simply states that *only eye orientations with zero torsion are allowed*.

It must be stressed that Listing's law is enforced only when the head is fixed; it breaks down when the head is moving. When the head turns, the vestibulo-ocular reflex (VOR) counter-rotates the eye, so that the visual world is kept (approximately) stable on the retina (cf. Chapter 9). When this involves head motions with the eyes in an elevated or depressed position, accumulated VOR slow phases can carry the eye out of Listing's plane by as much as 30°; this deviation is usually pre-compensated by adding a predictive torsional component to the innervation of the preceding VOR quick phase.¹⁰ Furthermore, when binocular orientations (cf. Chapter 9) are considered, Listing's plane varies as a function of the distance to the target, so that Listing's plane for each eye rotates outward as the eyes converge.¹¹ This implies that Listing's law cannot arise from a mechanical property of the peripheral oculomotor complex (e.g. by gimbals), but must be enforced by generating an appropriate set of innervation signals. (Note: Obviously the lack of a torsional component for movements in Listing's plane does not imply that when the eye orientation is in Listing's plane the brain sends no innervation to the oblique muscles; Table 8.1).

Table 8.1 Classic description of muscle actions with the eye in primary position

Muscle	Primary	Secondary	Tertiary
Lateral rectus	Abduction	None	None
Medial rectus	Adduction	None	None
Superior rectus	Elevation	Intorsion	Adduction
Inferior oblique	Extorsion	Elevation	Abduction
Inferior rectus	Depression	Extorsion	Adduction
Superior oblique	Intorsion	Depression	Abduction

The axis of action is perpendicular to the plane formed by the center of the eye and the (functional) origin and insertion of the muscle. Each axis has some orientation, which can be described in head-fixed coordinates. The head-fixed axis where most of the force is generated by the muscle gives rise to its primary action. The axis with the next most force gives rise to the secondary action, and the axis with the least force projection gives rise to the tertiary action. Note that muscles work in pairs. From primary position, the lateral and medial recti move the eye horizontally, the superior rectus and the inferior oblique elevate the eye, the inferior rectus and the superior oblique depress the eye, and the superior oblique and the inferior oblique twist the eye. This classification is difficult to maintain once the eye moves away from primary position.

False torsion

Listing's law clearly puts a constraint on the normal orientation of the eyes, but the quantification of this constraint is closely intertwined with the coordinate system used. For example, with the head-fixed system we can simply say (with the above-mentioned caveats) that the Euler's axis describing orientation should have no torsional component. However, it would be incorrect to say that in the Fick or Helmholtz systems Listing's law means no rotation around the torsional axis. To demonstrate this fact, in Figure 8.5 we show a set of eye orientations. In this figure the orientation of the eye is indicated by a short line. Think of this line as a small piece of tape glued to the eye. With the eye in primary position this piece of tape, centered on the pupil, lies along the horizontal meridian. In red we show orientations described by an Euler axis with zero torsional component. In green we show orientations that are reached through rotations about the horizontal and/or vertical, but not torsional, axes in the Fick system. The orientations shown in blue are reached through rotations about the horizontal and/or

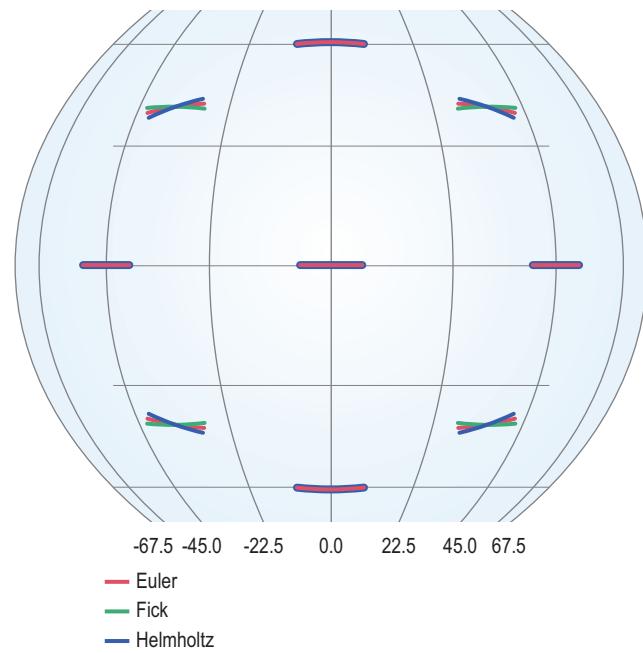

Figure 8.5 False torsion demonstrated by rotations in nested-axes and head-fixed axes coordinates (orthographic projection). Gray lines show the longitude and latitude lines of the globe (every 22.5°). A colored line (Euler: red, Fick: green, Helmholtz: blue) is drawn on an invisible eyeball to show its orientation. The eye is then rotated in the three coordinate systems so that the same gaze directions are achieved. If Listing's plane were orthogonal to straight ahead, the eye would assume the orientation given by the Euler rotation (red line). In primary position ($\theta = 0^\circ$ and $\varphi = 0^\circ$) and in secondary positions (along the horizontal and vertical meridians, $\varphi = 0^\circ$ or $\theta = 0^\circ$) all three orientations are aligned. In tertiary positions (rotated $\pm 45^\circ$ around an axis tipped $\pm 45^\circ$) the Fick lines (green) remain horizontal, but the others are twisted. This twist is called false torsion. Fick lines have always zero false torsion (unless a rotation around the torsional axis is imposed); for the eccentricity tested here Euler lines have $\approx 9.7^\circ$ and Helmholtz lines have $\approx 19.4^\circ$ of false torsion. Rotations are not commutative, so the Euler axis-angle rotation $\{0, 0.707, 0.707\}, 45$ corresponds to Fick and Helmholtz rotations of about $(35.3, 30, 0)$ and $(30.0, 35.3, 0)$, respectively.

vertical, but not torsional, axes in the Helmholtz system. The rotations applied are such that the direction of the line of gaze is the same regardless of the coordinate system used.

Obviously, the lines are identical in primary and secondary orientations, but they differ in tertiary orientations. More precisely, in tertiary positions the line is horizontal in the Fick coordinate system, but in the other two it is twisted. This last observation has led to a lot of confusion in the study of eye rotations. Remember that only the red lines represent orientations that obey Listing's law. Saying that orientations in Listing's plane have zero torsion is jargon for saying that the Euler vector describing an orientation in Listing's plane has a torsional component equal to zero. But that obviously does not mean that the horizontal meridian is not twisted relative to the gravitational vertical. To distinguish these two measures of torsion, the twist shown in [Figure 8.5](#) is called *false torsion*. Three simple rules apply to false torsion. First, tertiary gaze directions reached using the two outermost gimbals in the Fick system always have zero false torsion. Second, gaze directions reached using the two outermost gimbals in Helmholtz systems always have values of false torsion larger (in magnitude) than if those same gaze directions were reached obeying Listing's law. Third, orientations in Listing's law are *not* characterized by zero false torsion. In [Figure 8.5](#), the false torsion for the Euler lines (red) is about 9.7° , and for the Helmholtz lines (blue) it is about 19.4° .

Neural control of ocular orientation

The study of eye rotations is fundamental to identifying the patterns of innervation to the extraocular muscles that the brain must generate to accurately control the orientation of the eyes, suppress ocular drift, and (when necessary) enforce Listing's law. Using as an approximation to plant mechanics the biomechanical model of the eye plant developed by Robinson^{12,13} it is possible to show that, because of the viscoelastic properties of the orbital tissues, the *torque* applied to the eyeball to generate an eye movement can be interpreted as the sum of three components: a *Step* (i.e. a signal proportional to the current eye eccentricity), a *Slide* (i.e. a low-pass filtered version of the velocity profile), and a *Pulse* (i.e. a signal proportional to the velocity of the eyes). This decomposition of the torque always holds, as it simply mirrors (a simplified representation of) the mechanical make-up of the orbital tissues.

The brain does not have direct control over this torque; instead, it indirectly controls it by generating the innervation signals that are delivered to the extraocular muscles. Unfortunately, the muscles are not very good actuators, especially at high speeds of shortening or lengthening, and the brain must take their properties into account when generating the innervation signals. More precisely, an analysis of Robinson's linear model of the eye plant reveals that, in the process of transferring force to its tendon, each muscle absorbs both a *Step* and a *Pulse* of force. The former is a function of the length of the muscle, while the latter is proportional to its speed of shortening. The muscles behave so poorly that approximately 90 percent of the energy

consumed during a saccadic eye movement is dissipated by the muscles, and only the remaining 10 percent is actually used to rotate the eyeball ([Fig. 8.6C&D](#), Pulse). Even during periods of fixation only 20 percent of the energy is transferred to the tendons, while the remaining 80 percent is used to maintain the length of the muscles ([Fig. 8.6C&D](#), Step). In other words, to deliver the appropriate torque to the eyeball ([Fig. 8.6D](#), note ten-fold gain increase for this graph), an extra, and much larger, innervation ([Fig. 8.6B](#)) must be supplied to account for the loss in the extraocular muscles ([Fig. 8.6C](#)).

The decomposition of the innervation signal into the force absorbed by the muscles and the force delivered to the tendons, as well as the decomposition of these forces into their basic components, follows from the properties of the eye plant, and thus holds for any movement, regardless of its dynamics or of the innervation pattern. However, it cannot be stressed enough that the only signal that must exist in the brain is the overall innervation command, which is carried by the motoneurons ([Fig. 8.6B](#), bottom row). The various force/torque components described above (Pulse, Slide, and Step for the orbital tissues, and Pulse and Step for the muscles) are the result of an objective, but artificial, decomposition; these components do not need to have a corresponding neural signal in the brain. Nevertheless, each of these components is associated with different tissue properties, and thus their adaptation requirements are quite different. Accordingly, it would make sense to generate the innervation signals by computing separate neural signals for each of the physical signals described above, and then sum them together, with adaptable weights, at the level of the motoneurons ([Fig. 8.6B](#), top row). The neural signals would thus have to be *matched* to the physical components. This does not however imply that these signals would have to be computed independently from each other. In fact, because they would be associated with physical signals that are related to each other (e.g. eye velocity and orientation are related, as the latter is a function of the history of the former), these neural signals would also have to be related to each other.

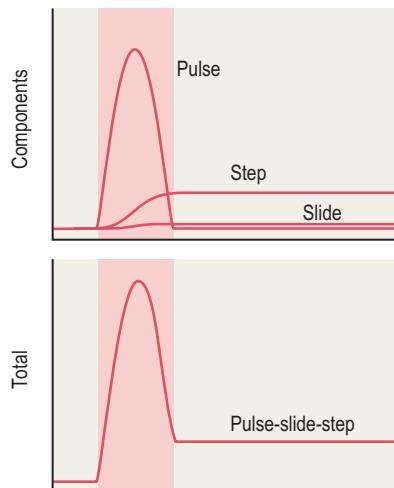

Robinson¹⁴ recognized these issues and proposed an elegant solution for the one-dimensional case, i.e. for rotations around a single axis. In this simplified case, there is a direct proportionality between muscle length and eye orientation, and between eye velocity and rate of change of muscle length. Robinson noted that the Step of innervation could then be computed by simply integrating (in the mathematical sense) the Pulse. Similarly, the Slide can be computed by low-pass filtering the Pulse (i.e. passing it through a leaky integrator). This works well because, for rotations around one axis, the orientation (associated, when matching is perfect, with the Step component) is equal to the integral of angular velocity (associated, also under matching conditions, with the Pulse component).

If the three components are appropriately matched, the movement is fast and the eyes stop abruptly ([Fig. 8.7A](#)). However, if the neural Pulse, Slide and Step are not matched to the corresponding force/torque components, a fast movement is still generated, but a slow post-saccadic ocular drift follows ([Fig. 8.7B](#)). Since the purpose of eye movements is to serve vision, and any drift after a movement degrades vision,¹⁵ perfect matching is very important.

(A) Eye Position

(B) Innervation or innervation force

(C) Force dissipated by the muscle

(D) Force at the tendon x10

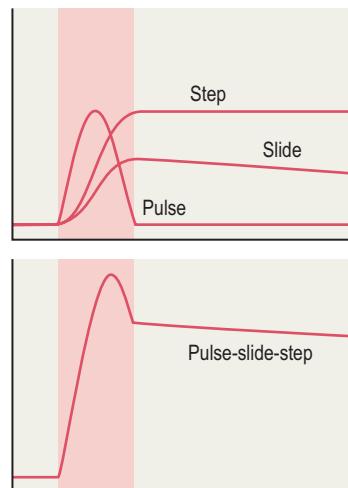

Figure 8.6 Distribution of forces between extraocular muscles and orbital tissues. (A) Schematic saccadic eye movement. (B) The saccadic innervation consists of a Pulse, Slide, and Step, which generate corresponding forces in the muscles. (C) Most of the Pulse and the Step are used to change muscle length. Thus the muscle itself “eats up” most of the force. (D) The remaining force delivered to the tendon consists of a small piece of the Pulse, the Slide, and part of the Step (Note: the forces in D are magnified about 10 times). The ratio of the Pulse dissipated by the muscle and the Pulse delivered to the tendon is about 20. The ratio of the Step dissipated to that delivered is about 3.3 (Second row shows components of innervation and force; third row shows total innervation and force; the gray area indicates saccade duration).

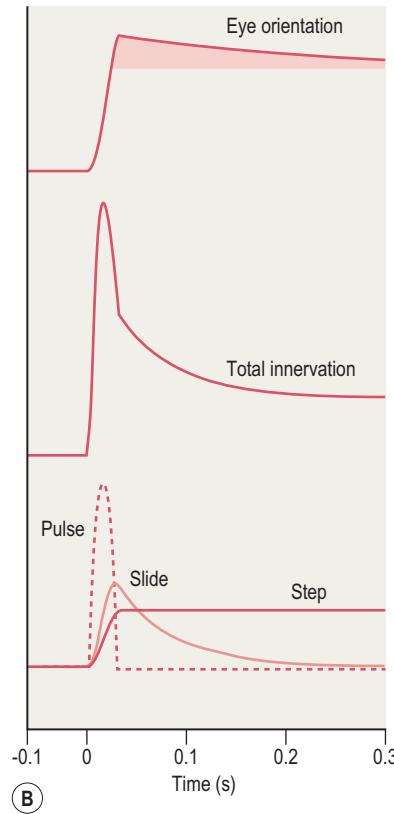

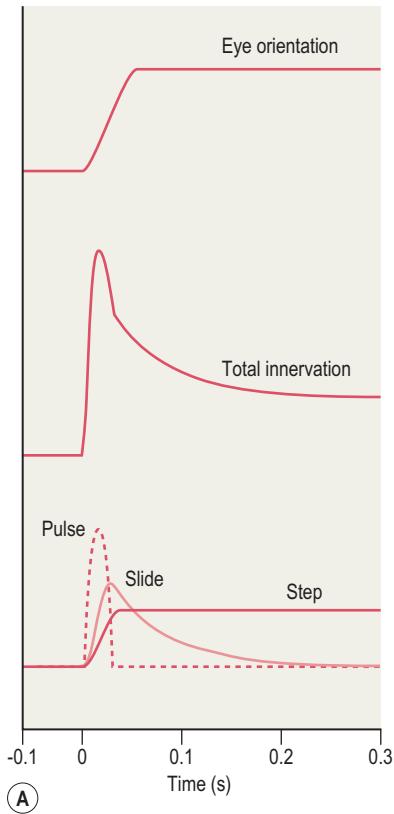

Figure 8.7 Components of the innervation signal. The innervation signal is the sum of three components: a Pulse, a Slide and a Step. (A) When the three signals are appropriately matched, the eyes move quickly to the target and stop abruptly. In this case the eye orientation follows the Step of innervation. (B) If the components are mismatched (in this case the Pulse is too large), the eyes drift back toward the target. The Step is no longer a faithful representation of eye orientation.

Extending this line of reasoning to three dimensions, when rotations around arbitrary axes must be considered, is not trivial, because in general *the derivative of eye orientation is not equal to eye angular velocity*.⁶ This inequality, which is true for any rigid body rotating around a point fixed in space, is due to the non-commutativity of rotations (cf. Fig. 8.1). Thus, if the neural Pulse were proportional to the angular velocity, its integral would not be proportional to the orientation; if the neural Step were computed by integrating the neural Pulse, a post-saccadic drift would ensue. It turns out that, if the initial and final orientations are in Listing's plane, this drift would be confined mostly, but not exclusively, to the torsional axis. It is important to realize that this drift has nothing to do with the matching issue described for one-dimensional movements, as it is not due to an inappropriate weighting of the Pulse and the Step. To avoid such a drift the brain would need to perform a different, more complex, computation to produce the neural Step: the mathematical integral would not suffice.

To understand how the brain deals with this problem we must see whether such torsional drifts (usually referred to as blips) occur. As we noted above, Listing's law specifies only the final orientation of the eye (the Euler axis for the orientation must lie in Listing's plane), but it does not say anything about what happens during or around the movement. However, it was found that, for rotations in which the initial and/or final orientation is tertiary, the orientation of the eye remains in Listing's plane throughout saccadic and pursuit movements, i.e. torsional blips are very small.^{16,17} For this to occur, the angular velocity vector about which the eye rotates must tilt *out* of Listing's plane.¹⁸ This tilt of the angular velocity axis is given by the so-called half-angle rule,¹⁶ i.e. if the eyes are elevated 45° up, and you want to rotate the eyes from, say, left 10° to right 10°, the axis of angular velocity must be tipped back from the vertical by 22.5° for the orientation to stay in Listing's plane (Fig. 8.8B, dashed line). In other words, to ensure that the orientation vector has no torsional component throughout the movement, the angular velocity vector must have a torsional component whose amplitude is a function of the orientation of the eyes.

How does all this influence the task of generating the innervation command appropriate to rotate the eyes in 3-D? Obviously whenever a rotation to/from a tertiary orientation is required, if the Pulse of innervation determines the angular velocity of the eyes, it will need to have a torsional component, or the eye orientation will not be confined to Listing's plane. Furthermore, the neural Step would have to be computed by passing the neural Pulse through a rotational operator: simply integrating it would not produce the correct signal. There is one caveat, though. Nothing of what we have said so far about the plant or the controller implies that the angular velocity of the eye is proportional to the neural Pulse. The innervation signal delivered to a muscle determines only the length and speed of length change of that muscle, not the orientation or angular velocity of the eye. It is the geometrical arrangement of the muscles that determines how the former set of signals is converted into the latter. Without a deeper understanding of the mechanics of the eye orbit it is not possible to make further inferences about the neural processing required to control eye rotations.

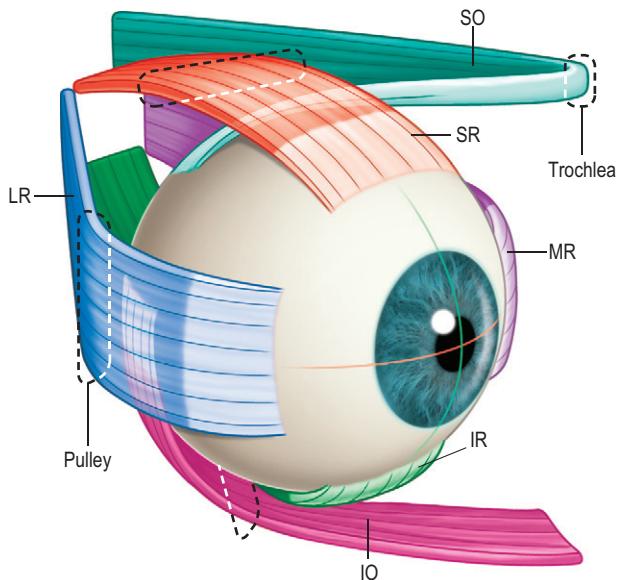

Orbital mechanics can simplify neural control: extraocular pulleys

Clinically, muscle actions are described in terms of how much they rotate the eye around each of the head-fixed axes, when the eye is in primary position (cf. Table 8.1). A more accurate analysis considers that each muscle tends to turn the eye around a specific axis, called the *axis of action* of the muscle. By definition, the axis of action is the unit length vector that is perpendicular to the plane determined by the following three points: center of the eye, origin of the muscle, and insertion of the muscle.

If the axes of action of the muscles were fixed in the orbit (i.e. the axes did not change when the eye moved), there would be a one-to-one correspondence between shortening velocity of the muscle and angular velocity of the eye. However, it has been demonstrated that the axes of action of the extraocular muscle are not fixed in the orbit.¹⁹ Instead, they vary as a function of the orientation of the eye. The reason for this dependency is that the muscle's path, which determines its axis of action, is constrained so that the belly of the muscle moves very little during eye rotations.^{19–21} Anatomical studies^{22–24} have shed light on the underlying constraint mechanism, showing that each rectus muscle passes through a ring or sleeve just posterior to the equator of the globe (Box 8.3). The ring is made of collagen²⁵ and is linked to Tenon's fascia, adjacent muscles, and the wall of the orbit by bands consisting of collagen, elastin and smooth muscle. This anatomical structure thus forms a functional pulley.^{26,27}

How does the presence of these pulleys affect oculomotor control? The mechanical effect of the pulleys is to make the axes of action of the extraocular muscles vary dramatically as a function of the orientation of the eye. Before the discovery of the pulleys it was assumed that the axis of action of each rectus muscle was perpendicular to the plane formed by its origin on the annulus of Zinn, its insertion, and the center of the globe. Under these conditions (Fig. 8.8A), changing the orientation of the eye (e.g. from straight ahead to 45° up) would only minimally affect the axis of action of the muscles (horizontal recti shown). However, with orbital pulleys (Fig. 8.8B), the axis of action of each muscle is now perpendicular to the plane formed by the location of its pulley, its insertion on the globe, and the center of the globe. In other words, the pulley acts as the functional point of origin of the muscle. If we now consider what happens when the eye is elevated, we see that the axes of action of the muscles change considerably (Fig. 8.8B). As a consequence, heterotopy of the pulleys (being in the wrong location; Box 8.4) can cause misalignment of the eyes.²⁸

Quantitatively it can be shown²⁹ that, if the orbital pulleys are properly located, the velocity of shortening of the muscles (which, as we pointed out previously, is associated with the viscous force that must be compensated by the Pulse of innervation) closely approximates the *derivative of eye orientation*, and not eye angular velocity. The derivative of the eye orientation signal, unlike angular velocity, is confined to Listing's plane whenever the orientation is. Accordingly, it becomes much easier to implement Listing's law: all that is needed to keep the orientation of the eye in Listing's plane is to generate the Pulse of innervation in that plane. If the Step is then computed by integrating the Pulse, the resulting

Box 8.3 Scale Model of Orbital Geometry

Scale model of the human orbit (globe radius = 12.5 mm). The eye moves as if its center is (approximately) stationary in the orbit. The orientation of each eye is controlled by six muscles: lateral rectus (LR, blue), medial rectus (MR, purple), superior rectus (SR, orange), inferior rectus (IR, green), superior oblique (SO, greenish blue), inferior oblique (IO, magenta). The muscles act in push-pull, i.e. as agonist/antagonist pairs (LR/MR, SR/IR, SO/IO). The force generated by a muscle is a function of both its length and its innervation. For a given length, the higher the innervation the stronger the force. For a given innervation, the longer the muscle the stronger the force. Each muscle (dark color) is made up of two layers. The *global layer* is continuous with the tendon (light color), which inserts on the globe. The *orbital layer* inserts on fibromuscular connective tissue pulleys, which constrain the path of the muscle. These are analogous to the cartilaginous trochlea of the SO. Great circles drawn on the eye show the horizontal (red) and vertical (green) meridians of the eye. Primary position is where they cross. All secondary positions have the gaze axis on one of those meridians; all tertiary positions are not on them. NB: Pulleys are drawn as compact objects at the point of maximum muscle deflection, but they are actually more distributed in front and behind that point.

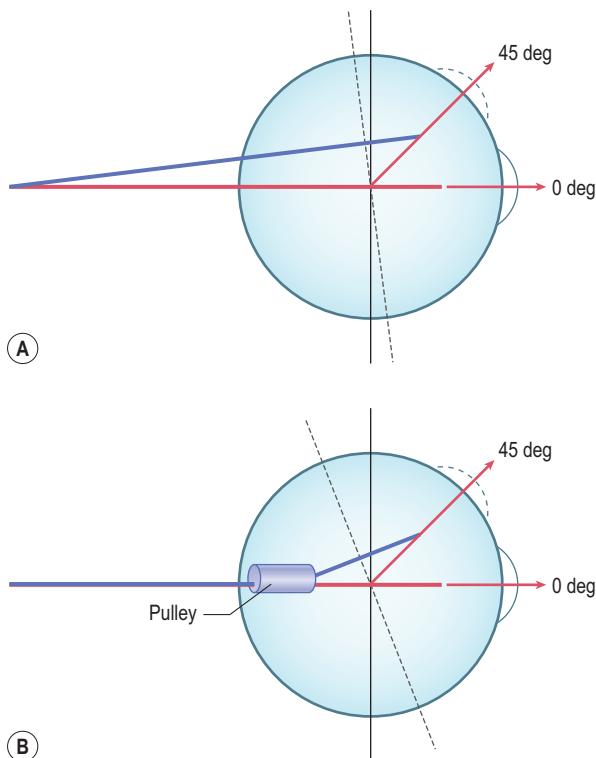

Figure 8.8 Axis of action of the horizontal recti for two different models of orbital mechanics. The schematics are a scaled version of an actual human orbit.¹² (A) If the muscles can move freely in the orbit, the muscular path does not change much whether the eye is in primary position (red solid line) or elevated by 45° (blue solid line). Correspondingly, the axis of action (black solid and dashed lines) is approximately fixed in the orbit. (B) If the path of the muscles through the orbit is constrained by pulleys, the muscular path from the origin to the pulleys is essentially constant in the orbit, regardless of the orientation of the eye. However, the axis of action of the muscles changes dramatically with orientation; the magnitude of this change is clearly a function of the position of the pulleys. (Note: the axis of action is collinear with the angular velocity vector about which the eye would spin if moved by that pair of muscles.) (Redrawn from Quiaia C, Optican LM. Commutative saccadic generator is sufficient to control a 3-D ocular plant with pulleys. J Neurophysiol 1998 Jun;79(6):3197–3215. Used with permission.²⁹)

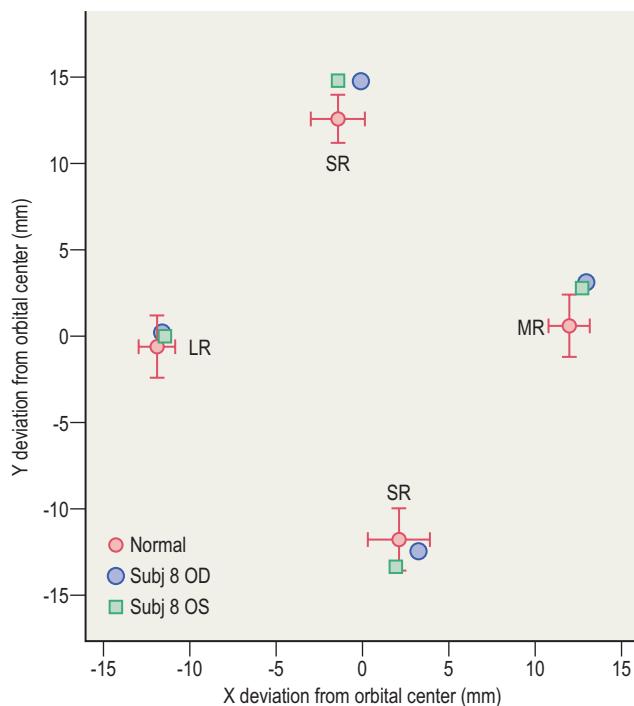

movement will have very small post-saccadic drifts, certainly small enough not to impede vision.³⁰

This simplification *must not be confused with a mechanical implementation of Listing's law*. If the brain generates a Pulse of innervation that has a non-zero torsional component, the eye will rotate out of Listing's plane. Indeed, during head-free gaze shifts, the vestibulo-ocular reflex (VOR) rotates the eyes opposite to the head's rotation. If the head rotates out of Listing's plane, the VOR will be constantly violating Listing's law, and the saccade generator will need to compute torsional components to compensate for this.¹⁰ Thus, Listing's law must be enforced by the brain, although the pulleys make the required computations much simpler than they would be if the muscle axes were fixed in the orbit.

It is important to realize that the mechanical configuration in the orbit only simplifies the neural machinery because the orbital tissues are viscoelastic. If the orbital tissues had no viscous components (i.e. if they were purely elastic), pulleys would be unnecessary. Without viscosity there would be no Pulse of torque, and the eye orientation would instantly track the torque generated by the muscles; because torques are vectors (i.e. they are commutative) the non-commutativity of rotations would become irrelevant.

Any confusion regarding the difference between a neural and a mechanical implementation of Listing's law can be avoided by analyzing the sequence of events that lead to a refixation movement (Fig. 8.9). First, a sensory-to-motor transformation combines 2-D retinal information with ocular orientation to determine what 3-D rotation is required to foveate the target.³¹ Second, the brain generates the corresponding 3-D Pulse of innervation, which it integrates to get the Step. Third, the geometrical arrangement of muscles and pulleys converts the torque generated by the muscles into an angular velocity vector that will not induce post-movement drift. It is in the second step that Listing's law is enforced, whereas the third step takes care of the non-commutativity of rotations. So, for example, the control law for the Pulse could be changed, e.g. so that the eye uses Fick's coordinates. The pulleys would still guarantee that there

Box 8.4 3-D Effects of Mislocated Pulleys

Clinical photographs show the eyes of a patient with a "V" pattern of esotropia in nine diagnostic positions. Note under-elevation bilaterally when the eye is adducted (top row, eye towards the nose), but normal depression in adduction (bottom row). Graph shows average positions of the eye muscle paths in the coronal plane. Red spots show the average muscle positions of normal subjects (error bars show 95 percent confidence intervals). SR, LR, MR, and IR are superior, lateral, medial, and inferior rectus muscles.

Blue spots show the muscle position for the right eye, and green squares show the muscle position for the subject's left eye. This indicates that the pulley positions in this patient are deviated by from 0 to 2.5 mm. A "V" pattern of esotropia with under-elevation in adduction could be caused by an under action of the inferior oblique muscle. However, in this patient the misplaced pulleys caused the direction of action of the muscles to shift, giving rise to the strabismus. (Adapted, with permission, from Clark et al.²⁸)

would be no post-saccadic drift, even though Listing's law would clearly not hold.

Needless to say, the pulleys can play this simplifying role only if they are appropriately placed. More precisely, they have to be located between the equator and the posterior pole of the globe, in the position that causes the angular velocity vector to tilt half as much as the change in elevation, i.e., to enforce the half-angle rule. For this action to remain unaltered as the eye moves around, the pulleys would also have to move,³² but simulations show that this would not be particularly critical, as ensuing drifts would be within the physiological

range. However, if the pulleys were static, for large rotations the agonist muscles' insertions would move behind the pulleys, and the muscle would stop being effective. Indeed, just 30° of adduction would cause the medial rectus muscle to lose tangency; it would then translate, rather than rotate, the eye.³⁰ To avoid this situation, as a muscle contracts its pulley must be moved backwards. This behavior was indeed observed in high-resolution MRI studies of the human orbit.³³

The mechanism proposed to achieve such a dynamic relocation of the pulleys turns out to be quite simple, albeit surprising. It has been known for a long time that the fibers

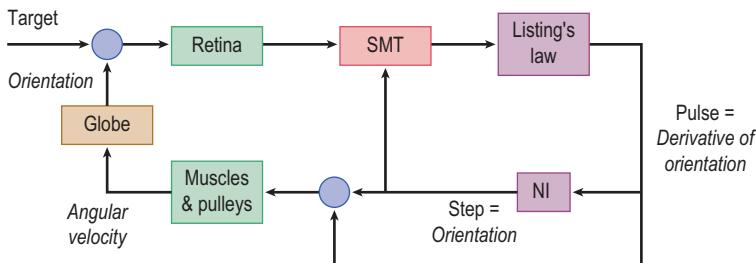

Figure 8.9 Cartoon of transformations in visually guided 3-D eye movements. Retinal target information is combined with eye orientation to obtain the desired eye displacement (a sensory-to-motor transformation, or SMT). A control law is imposed to reduce the motor system's degrees of freedom from three to two by generating the Pulse in Listing's plane. The Pulse, which is the derivative of orientation, is integrated (neural integrator, NI) to obtain the Step, which is the orientation. The total innervation (Pulse + Step) specifies the forces applied by the muscles. The geometry of the muscles and pulleys mechanically shift the axes of action of the muscles according to ocular orientation (i.e., by the half-angle rule), which tilts this force so that the globe has the correct angular velocity vector.

that make up each extraocular muscle can be histologically differentiated into two groups: the global fibers and the orbital fibers.⁸ Whereas the global fibers of the rectus muscles go through the pulley and insert anterior to the globe's equator, the orbital fibers insert directly on the pulley.³³ Thus, when the whole muscle contracts, part of its tension will be delivered to the globe, and part will be delivered to the pulley itself, moving it as required.

Summary

Our vision is poor when our eyes move relative to a subject of interest; consequently, movements of the eyes must be as fast as possible, and prolonged drifts must be avoided. Once a target of interest has been chosen, the innervation signal to the extraocular muscles required to point the foveae toward the target must be produced. Unfortunately, the viscoelastic nature of the orbital contents, and some basic properties of rotations, makes generating this signal a far from trivial proposition.

The first challenge that the brain faces is that gaze direction has only two degrees of freedom whereas the eye can move around three axes. The reduction in dimensionality is achieved by generating innervation signals that keep the eyes in Listing's plane. There are many possible alternatives for reducing this kinematic redundancy, but Listing's law is the evolutionary choice.

The non-commutativity of rotations, coupled with the viscoelasticity of the orbital tissues, adds further complexity to the process of producing drift-free movements, regardless of whether Listing's law is obeyed or not. Fortunately, the brain does not need to take into account such complexity in its computations, because that problem is solved by the orbital pulley rig. It appears to be simpler, and perhaps more reliable, to control the location of the pulleys rather than to implement neural circuitry to perform non-commutative operations. This probably reduces the overall complexity of the system.

Neural Control of Eye Movements

Clifton M. Schor

Introduction

Three fundamental visual sensory-motor tasks

The neural control of eye movements is organized to optimize performance of three general perceptual tasks. One task is to resolve the visual field while we move either by translation or rotation through space (self motion). Our body motion causes the image of the visual field to flow across the retina and reflexive eye movements reduce or stabilize this image motion to improve visual performance. The second task is to resolve objects whose position or motion is independent of the background field (object motion). Eye movements improve visual resolution of individual objects by maintaining alignment of the two foveas with both stationary and moving targets over a broad range of directions and distances of gaze. The third task is to explore space and shift attention from one target location to another. Rapid eye movements place corresponding images on the two foveas as we shift gaze between targets lying in different directions and distances of gaze.

Three components of eye rotation

All three perceptual tasks require three-dimensional control of eye position. These dimensions are controlled by separate neural systems. As described Chapter 8, three pairs of extraocular muscles provide control of horizontal, vertical, and torsional position of each eye. Eye movements are described as rotations about three principal axes as illustrated in Figure 9.1. Horizontal rotation occurs about the vertical Z-axis, vertical rotation about the horizontal X-axis, and torsion about the line of sight or Y-axis. As described in Chapter 8, the amount of rotation about each of the three principal axes that is needed to describe a certain direction of gaze and torsional orientation of the eye depends upon the order of sequential rotations (e.g. horizontal, followed by vertical and then torsional).¹ Some oculomotor tasks, such as retinal image stabilization, utilize all three degrees of freedom whereas other tasks, such as voluntary gaze shifts, only require two degrees of freedom, i.e. gaze direction and eccentricity from primary position. As described by Donder's law, torsional orientation of the eye is determined by horizontal and vertical components of eye position. Ocular torsion is independent of the path taken by the eye to reach

a given eye position and is constrained by the gaze direction. Listing's law quantifies the amount of ocular torsion at any given eye position, relative to the torsion of the eye in primary position of gaze.

Binocular constraints on eye position control

Binocular alignment of retinal images with corresponding retinal points places additional constraints on the oculomotor system. Because the two eyes view the world from slightly different vantage points, the retinal image locations of points subtended by near objects differ slightly in the two eyes. This disparity can be described with three degrees of freedom (horizontal, vertical, and torsional components) that are analogous to the angular rotations of the eye shown in Figure 9.1. The main task of binocular eye alignment is to minimize horizontal, vertical, and cyclodisparities subtended by near targets on the two foveas. This requires a conjugate system that rotates the two eyes in the same direction and amount, and a disconjugate system that rotates the visual axes in opposite directions. As described by Hering,² a common gaze direction for the two eyes is achieved by a combination of conjugate and disconjugate movements that are controlled by separate systems. The *version* system controls conjugate movements and the *vergence* system controls disconjugate movements.

Pure version and vergence movements are described respectively by the isovergence and isoversion contours shown in Figure 9.2. The isovergence circle describes the locus of points that stimulate the same vergence angle in all directions of gaze.³ A different isovergence circle exists at each viewing distance. The isoversion lines describe the locus of points that stimulate the same version angle over a range of viewing distances in a common direction of gaze relative to the head. Pure vergence movements occur along any of the isoversion lines and not just along the central or midsagittal plane. Fixation changes along any other contour result from a combination of version and vergence movements. Both version and vergence movements are described as combinations of horizontal, vertical, and torsional rotations. For example there can be horizontal and vertical version and vergence movements. Torsional rotations are usually referred to as cyclorotations (e.g. cycloversion or cyclovergence). Hering's law implies that there is equal innervation of yoked muscle pairs: "one and the same

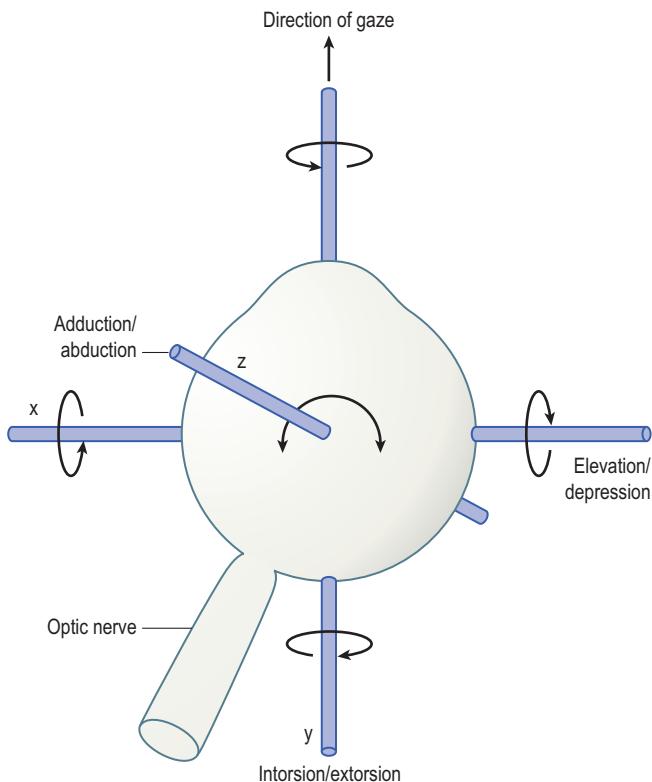

Figure 9.1 The three principal axes of eye rotation. Horizontal rotation occurs about the vertical axis (Z), vertical rotation about the transverse axis (X), and torsion about the anterior-posterior axis (Y). (From Goldberg ME, Eggers HM, Gouras D: The ocular motor system. In: Kandel ER, Schwartz JH, Jessell TM (eds): Principles of Neural Science, 3rd ed, Appleton and Lange 1991.)

impulse of will directs both eyes simultaneously as one can direct a pair of horses with single reins." The law should not be taken literally, because common gaze commands from higher levels are eventually parceled into separate innervation sources in the brainstem that control individual muscles in the two eyes.

Feedback and feedforward control systems

The oculomotor system requires feedback to optimize sensory stimuli for vision with a sufficiently high degree of precision. Feedback provides information about motor response errors based upon their sensory consequences, such as unwanted retinal image motion or displacement. This visual error information usually arrives too late to affect the current movement, because the time delays in the visual system are about 50–100 msec. Instead, it is used to adaptively adjust motor responses to minimize subsequent errors. Oculomotor systems use sensory information to guide eye movements in two different ways. Motor responses can be guided in a closed-loop mode with an ongoing feedback signal that indicates the difference between the desired and actual motor response, or they can operate without concurrent feedback in an open-loop mode. The closed-loop feedback mode is used to reduce internal system errors or external perturbations. A physical example of a closed-loop system is the thermostatic regulation of room temperature, e.g. if the outside temperature drops, the furnace will turn on so that the room temperature stays constant. Motor responses can also be controlled in an open-loop mode, without a concurrent feedback signal. A physical example of an open-loop system is a water faucet, e.g. if the pressure drops, the flow of water will also drop, because the valve does not compensate for the pressure drop.

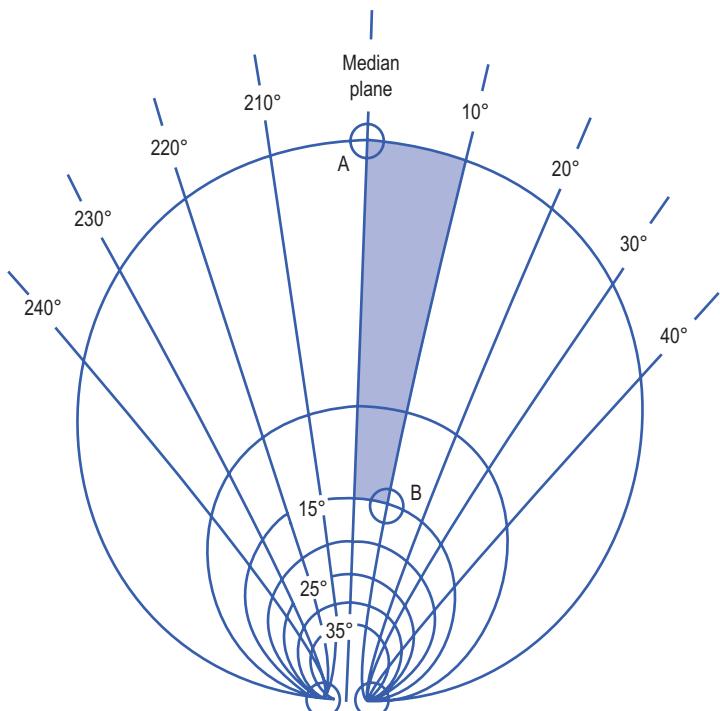

Figure 9.2 Geometric representation of the two components of eye movements by locations of the intersections of the two visual axes. The value in degrees marked along each isovergence circle denotes the convergence angle and the value in degrees marked on the hyperbola isoversion lines denotes the visual direction when a line is not very close to the eyes.

The mode of the response depends on the latency of the response, its duration and velocity. In most examples, visual feedback in a closed-loop system is used to maintain or regulate a fixed position or slow movements of the eyes when there is adequate time to process the error signal. Errors in eye posture or movement are sensed from displacement of the object of regard from the fovea or slippage of the retinal image and negative feedback control mechanisms attempt to reduce the errors to zero during the response.

Feed-forward control systems do not utilize concurrent visual feedback and are described as open-loop. These systems can respond to non-visual (extra-retinal) stimuli, or they respond to advanced visual information with short latencies and brief durations. For example, brief rapid head movements stimulate vestibular signals that evoke compensatory eye movements to stabilize the retinal image. These head movements can produce retinal image velocities of 300–400 deg/sec, yet the eyes respond with a counter rotation within 14 msec of the movement.⁴ The oculomotor response to head motion must rely on vestibular signals since retinal image velocities produced by head rotation exceed the upper velocity limit for sensing motion by the human eye. Retinal image velocities that exceed this upper limit appear as blurred streaks rather than as moving images. Visual feedback is not available when the response to head rotation begins because the latency is too short to utilize concurrent visual feedback. A minimum of 50 msec is needed to activate cortical areas that initiate ocular following,⁵ such that any motor response with a shorter latency must occur without concurrent visual feedback. Some open-loop systems, such as brief rapid gaze shifts (saccades), respond to visual information sensed prior to the movement rather than during the movement. Their response is too brief to be guided by negative visual feedback. Accuracy of a feed-forward system is evaluated after the response is completed. Visually sensed post-task errors are used by feedforward systems to improve the accuracy of subsequent open-loop responses in an adaptive process that calibrates motor responses. Calibration minimizes motor errors in systems that do not use visual feedback during their response. All feed-forward oculomotor systems are calibrated by adaptation and this plasticity persists throughout life.

Hierarchy of oculomotor control

The following sections present a functional classification of eye position and movement control systems used to facilitate three general perceptual tasks and a hierarchical description of their neuro-anatomical organization (Box 9.1). A hierarchy of neural control exists within each of the functional categories of eye movements that plans, coordinates,

and executes motor activity. Three pairs of extraocular muscles that rotate each eye about its center of rotation are at the bottom of this hierarchy. The forces applied by these muscle pairs to the eye are controlled at the level above by the motor nuclei of cranial nerves III, IV, and VI. Motor neurons in these nuclei make up the final common pathway for all classes of eye movements. Axon projections from these neurons convey information to the extraocular muscles for executing both slow and fast eye movements. Above this level, premotor nuclei in the brainstem coordinate the combined actions of several muscles to execute horizontal, vertical, and torsional eye rotations. These gaze centers orchestrate the direction, amplitude, velocity, and duration of eye movements. Interneurons from the premotor nuclei all converge on motor nuclei in the final common pathway. Premotor neurons receive instructions from supranuclear regions including the superior colliculus, the substantia nigra, the cerebellum, frontal cortical regions including the frontal eye fields (FEF) and supplementary eye fields (SEF), and extrastriate regions including the medial temporal visual area (MT), the medial superior temporal visual area (MST), the lateral intraparietal area (LIP), and the posterior parietal area (PP). These higher centers plan the desired direction and distance of binocular gaze in 3-D space. Cortical-spatial maps of visual stimuli are transformed into temporal codes for motor commands between cerebral cortex and ocular motoneurons, to which the superior colliculus and cerebellum contribute.⁶ They determine when and how fast to move the eyes to fixate selected targets in a natural complex scene or to return them to a remembered gaze location. The following sections will discuss the hierarchical control for each of three functional classes of eye movements. The next section describes the final common pathway that conveys innervation for all classes of eye movements.

Final common pathway

Cranial nerves: III, IV, & VI and motor nuclei

Cranial nerves III, IV, and VI represent the final common pathway as defined by Sherrington,⁷ for all classes of eye movements. All axon projections from these cranial nuclei carry information for voluntary and reflex fast and slow categories of eye movements.⁸ The oculomotor (III), trochlear (IV), and abducens (VI) nuclei innervate the six extraocular muscles, iris and ciliary body. The abducens nucleus innervates the ipsilateral lateral rectus. Premotor interneurons also project from VI to the contralateral oculomotor nucleus for control of the contralateral medial rectus, to produce yoked movements on lateral gaze that are consistent with Hering's law. The trochlear nucleus innervates the contralateral superior oblique. The oculomotor nucleus innervates the ipsilateral medial rectus, inferior rectus, and inferior oblique, and the contralateral superior rectus. The anterior portion of the oculomotor nucleus also contains motor neurons that control pupil size and accommodation in a specialized region called the Edinger-Westphal nucleus.⁹ Afferents from this nucleus synapse in the ciliary ganglion prior to innervating their target muscles.¹⁰ The regions of the oculomotor nucleus that control various eye muscles are illustrated in Figure 9.3.

Box 9.1 Hierarchy of motor control

Subcortical oculomotor disorders are classified by lesion sites in the hierarchy of motor control:

- Peripheral (cranial nerves and muscles)
- Nuclear (cranial motor nuclei making up the final common pathway)
- Premotor (coordinates combined actions of several muscles)
- Internuclear (connections between nuclear and premotor sites)
- Supranuclear (motor planning stage)

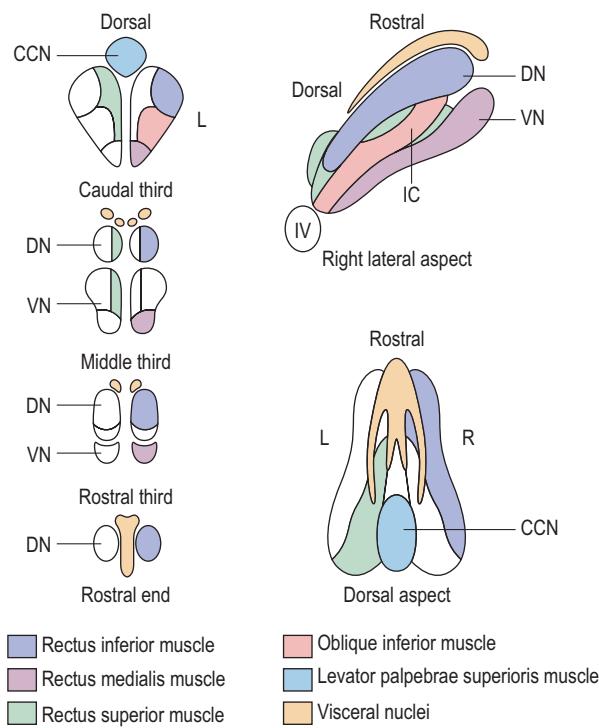

Figure 9.3 Representation of motor neurons for right extraocular muscles in the oculomotor nucleus of monkey. Transverse sections at levels as indicated in the complex. DN, dorsal nucleus; VN ventral nucleus, CCN caudal central nucleus; IC, intermediate column; IV, trochlear nucleus. Lateral and dorsal views are shown to the right. (Modified from Warwick R. Representation of the extra-ocular muscles in the oculomotor nuclei of the monkey: J Comp Neurol 1953; 98: 449.)

Motor neuron response

The motor neurons control both the position and velocity of the eye. They receive inputs from burst and tonic cells in premotor nuclei. The tonic inputs are responsible for holding the eyes steady, and the more phasic or burst-like inputs are responsible for initiating all eye movements to overcome orbital viscosity and for controlling eye movements. All motor neurons have the following characteristics as illustrated in Figure 9.4.¹¹

1. They have on-off directions (they increase their firing rate in the direction of agonist activity).
2. All cells participate in all classes of eye movements including steady fixation.
3. Each cell (especially tonic) has an eye position threshold at which it begins to fire. Motor neurons have thresholds that range from low to high. Cells with low thresholds begin firing when the eye is in the off field of the muscle that it innervates. Cells with higher thresholds can begin to fire after the eye has moved past the primary position by as much as 10 degrees into the on field of the muscle. The graded thresholds of motor neurons are responsible for the recruitment of active cells as the eyes move into the field of action for the muscle.
4. Increasing the frequency of spike potentials for a given neuron increases contractile force. Once their threshold is exceeded all cells increase their firing rate as the eye moves further along in the on direction of the muscle until they saturate. Cells increase their firing rate linearly as the eye moves into their on field.

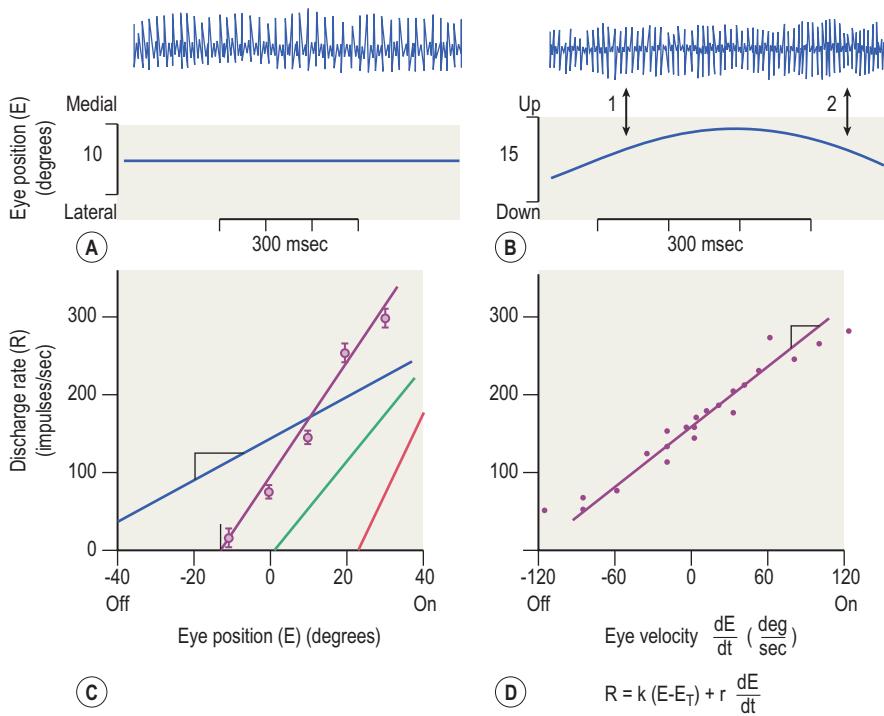

Figure 9.4 Discharge rate of oculomotor neurons in relation to eye movement. On the left, the steady firing rate is shown when the eye is stationary; and below, the rate-position curve illustrates an increase of firing rate with eye position for four neurons. On the right, the firing rate is shown during a slow voluntary eye movement. The arrows indicate points where the eye passes through the same position with velocity of opposite signs, and the associated firing rate is different. Below, firing rate is plotted for a single unit and a particular deviation of the eye as a function of eye velocity.¹¹ (From Robinson DA, Keller EL: Bibl Ophthalmol 82:7, 1972.)

Functional classification into three general categories

I. Stabilization of gaze relative to the external world

Movements of the head during locomotion tasks such as walking are described by a combination of angular rotations and linear translations. The oculomotor system keeps gaze fixed in space during these head movements by using extra-retinal and retinal velocity information about head motion. The primary extra-retinal signal comes from accelerometers in the vestibular apparatus.

A. Extra-retinal signals

The vestibular system contains two types of organs that transduce angular and linear acceleration of the head into velocity signals (Fig. 9.5).^{12,13} Three semicircular canals lie

on each side of the head in three orthogonal planes that are approximately parallel to a mirror image set of planes on the contralateral side of the head. These canals are stimulated by brief angular rotations of the head and the resulting reflexive ocular rotation is referred to as the vestibulo-ocular reflex (angular VOR). In addition, two otoliths (the utricle and sacculus) transduce linear acceleration caused by head translation as well as head pitch (tilt about the interaural axis) and roll (tilt about the nasal–occipital axis) into translation velocity and head orientation signals (linear VOR). Angular acceleration signals stimulate the semicircular canals and result in eye rotations that are approximately equal and opposite to the motion of the head. This stabilization reflex has a short 7–15-msec latency because it is mediated by only three synapses⁴ and is accurate for head turns at velocities in excess of 300 deg/s.¹⁴ Hair cells in the canals can be stimulated by irrigation of one ear with cold water. This produces a caloric-vestibular nystagmus that causes the eyes to rotate slowly to the side of the irrigated ear.¹⁵ These slow-phase

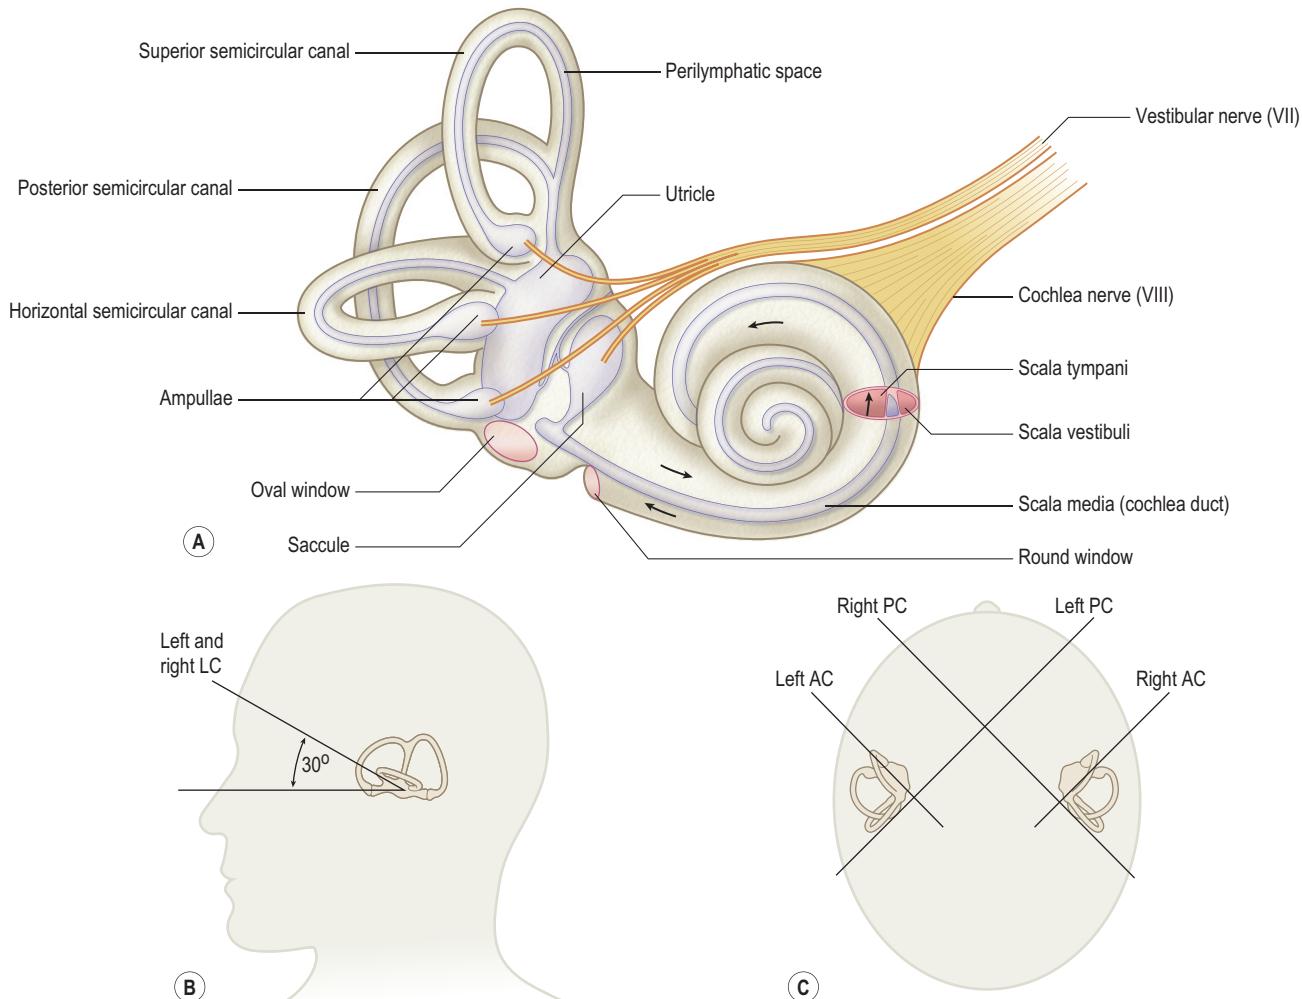

Figure 9.5 Vestibular end-organs in the human temporal bone. Three canals transduce angular head acceleration and two otoliths, the sacculus and utricle, transduce linear acceleration and head orientation. Right labyrinth and cochlea are viewed from horizontal aspect. (Drawings by Ernest W. Beck; courtesy Belton Electronics Corp., Chicago, Ill.) The canals are in three orthogonal planes that are approximately parallel to a mirror image set of planes on the contralateral side of the head that lie roughly in the pulling direction of the three muscle planes. **A**, Lateral canals. **B,C** Anterior and posterior vertical canals. LC, lateral canal; AC anterior vertical canal; PC, posterior vertical canal. (Modified from Barber HO, Stickwell CW: Manual of electronystagmography, St Louis, CV Mosby, 1976).

Figure 9.6 OKN and VOR are composed of a slow phase (beta) that rotates the eye in a direction that stabilizes the retinal image and a fast phase (alpha) that resets the eye's position. The figure illustrates the vestibulo-ocular response to sustained rotation. The slow phase is in the direction opposite to head rotation. Horizontal position is plotted against time. The reflex gradually habituates and has disappeared by about 30 seconds. (Redrawn with permission from Miller, NR (ed) Walsh and Hoyt's Clinical Neuro-Ophthalmology 4th Edition. 1982. Page 611, Figure 30.02. Williams & Wilkins, Baltimore.)

movements are interrupted by fast saccadic eye movements that reset eye position in the reverse direction (fast phase). A sequence of slow and fast phases is referred to as jerk nystagmus (Fig. 9.6). Head rotations about horizontal, vertical, and nasal–occipital axes produce VOR responses with horizontal, vertical, and torsional counter-rotations of the slow phase of the nystagmus.¹⁶

To be effective, these reflex eye rotations must stabilize the retinal image. If the axis of angular head rotation coincided with the center of eye rotation, perfect compensation would occur if angular eye velocity equaled angular head velocity. However, the axis of head rotation is the neck and not the center of eye rotation such that when the head rotates, the eyes both rotate and translate with respect to the visual field. This is exacerbated during near viewing conditions. To stabilize the retinal image motion of a nearby target caused by angular head movements, the eye must rotate more than the head. Indeed, the gain of the VOR increases with convergence.¹⁷ Mismatches between eye and head velocity also occur with prescription spectacles that magnify or minify retinal image motion. Because the VOR responds directly to vestibular and not visual stimuli, its response is classified as open loop. The VOR compensates for visual errors by adapting its gain in response to retinal image slip to produce a stabilized retinal image.¹² Perfect compensation would occur if angular eye velocity were equal and opposite to angular head velocity while viewing a distant scene. However empirical measures show that at high oscillation frequencies (2 Hz) compensation by the VOR is far from perfect and yet the world appears stable and single during rapid head shaking without any perceptual instability or oscillopsis.¹⁸ Thus, to perceive a stable world, the visual system must be aware of both the amount of head rotation and the inaccuracy of compensatory eye movements so that it can anticipate any residual retinal image motion during the head rotation.

Linear acceleration signals and gravity stimulate the otoliths and result in ocular rotations that are approximately 10

percent of the static head tilt caused by pitch and roll from vertical. Head pitch causes vertical eye rotations and head roll causes ocular torsion in the direction opposite to the head roll, "the ocular counterrolling reflex".^{19,20} Head roll can also elicit skew movements. When the otolith membranes are displaced on their maculae by inertial forces during rapid linear acceleration, such as during takeoff of an aircraft, a false sense of body pitch called the somatogravitational illusion can occur. This illusion results from perceiving vertical as the non-vertical combination of gravitational and acceleration-inertial force vectors. The non-vertical gravitoinertial force causes pilots to perceive the aircraft as pitched upward during takeoff, and if the pilot corrects the false climb this can cause the aircraft nose to pitch downward with dangerous consequences.²¹

Disorders of the vestibular system can produce imbalanced otolith inputs that can result in large amounts of vertical divergence of the eyes (skew deviation) by as much as 7 degrees, bilateral conjugate ocular torsion by as much as 25 degrees, and paradoxical head tilt known as the ocular tilt response (OTR).²² For example, if the head is tilted to the left, there is paradoxical torsion of both eyes in the direction of head roll and the left eye is rotated downward with respect to the right eye.²³ Manifestations of the OTR will be discussed in the section on nystagmus.

B. Retinal signals

Head motion also produces whole-field retinal image motion of the visual field (optic flow).²⁴ These retinal signals stimulate reflexive compensatory eye rotations that stabilize the retinal image during slow or long-lasting head movements. The eyes follow the moving field with a slow phase that is interrupted by resetting saccades (fast phase) 1 to 3 times per second.²⁵ This jerk nystagmus is referred to as optokinetic nystagmus (OKN) and it complements the VOR by responding to low-velocity sustained head movements such as those that occur during walking and posture instability. Like the VOR, OKN also responds with horizontal, vertical and cyclo-

eye rotations to optic flow about vertical, horizontal, and nasal–occipital axes.²⁶

The optokinetic response to large fields has two components, including an early and delayed segment (OKNe and OKNd). OKNe is a short-latency ocular following response (<50 msec) that constitutes the rapid component of OKN,⁵ and OKNd builds up slowly after 7 seconds of stimulation.²⁷ OKNe is likely to be mediated by the pursuit pathway.²⁸ The delayed component is revealed by the continuation of OKNd in darkness (optokinetic after nystagmus, OKAN). OKNd results from a velocity memory or storage mechanism.^{27,29} The time constant of the development of the OKAN matches the time constant of decay of the cupula in the semicircular canals.³⁰ Thus OKAN builds up so that vision can compensate for loss of the vestibular inputs during prolonged angular rotation that might occur in a circular flight path. OKN can be used clinically to evaluate visual acuity objectively by measuring the smallest texture size and separation in a moving field that elicits the reflex.

C. Neuro-control of stabilization reflexes

1. Vestibulo-ocular reflex

The transducer that converts head rotation into a neural code for driving the VOR consists of a set of three semicircular canals paired on each side of the head.¹² The horizontal

canals are paired and the anterior canal on one side is paired with the posterior canal on the contralateral side (Fig. 9.5). These are opponent pairs so that when one canal is stimulated by a given head rotation its paired member on the contralateral side is inhibited. For example, downward and forward head motion to the left causes increased firing of the vestibular nerve for the left anterior canal and decreased firing of the vestibular nerve projections from the right posterior canal. The three canals lie roughly in the pulling directions of the three muscle planes.¹² Thus the left anterior canal and right posterior canal are parallel to the muscle planes of the left eye vertical recti and the right eye obliques. Pathways for the horizontal VOR are illustrated in Figure 9.7 for a leftward head rotation.⁸ Excitatory innervation projects from the left medial vestibular nucleus to the right abducens nucleus to activate the right lateral rectus, and an interneuron from the right abducens nucleus projects to the left oculomotor nucleus to activate the left medial rectus. The abducens serves as a premotor nucleus to coordinate conjugate horizontal movements to the ipsilateral side in accordance with Hering's law.

The cerebellar flocculus is essential for adaptation of the VOR to optical distortions such as magnification. The flocculus receives excitatory inputs from retinal image motion (retinal slip) and head velocity information (canal signals) and inhibitory inputs from neural correlates of eye

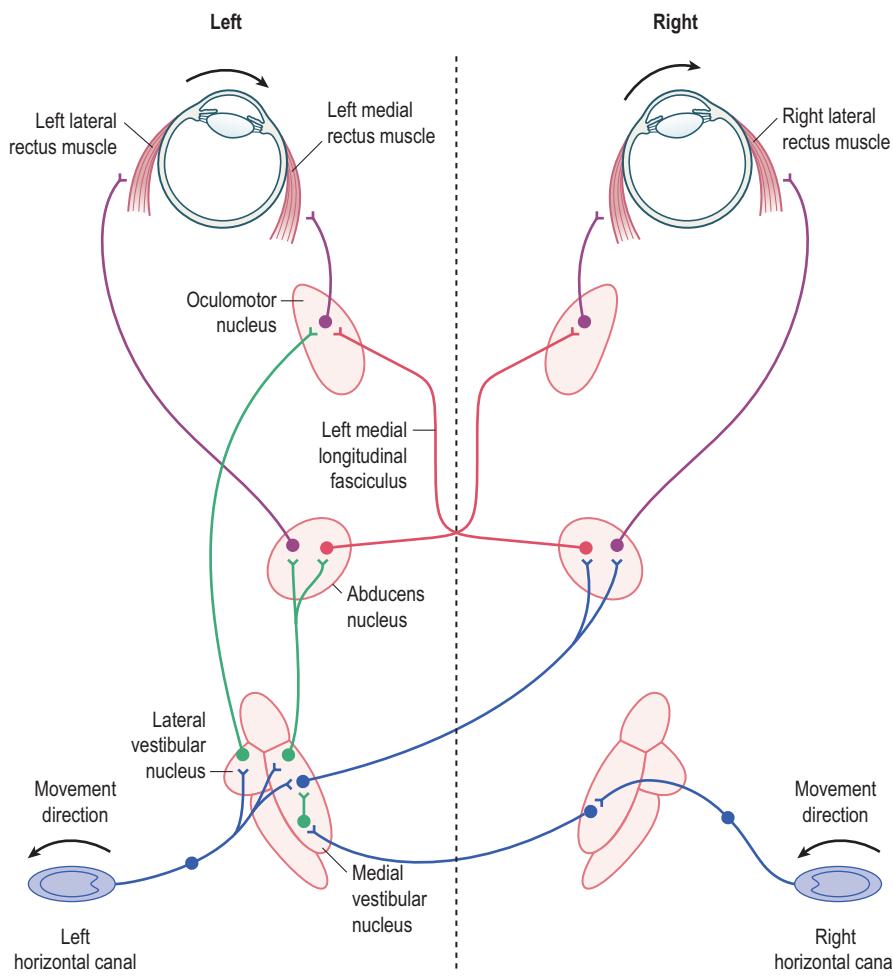

Figure 9.7 Pathways of the horizontal VOR in the brain stem for leftward head rotation. Inhibitory connections are shown as filled neurons, excitatory connections as unfilled neurons. Leftward head rotation stimulates the left horizontal canal and inhibits the right horizontal canal. This results in an increased discharge rate in the right lateral and left medial rectus and decreased discharge rate in the left lateral and right medial rectus.³¹ (From Goldberg ME, Eggers HM, Gouras D: The ocular motor system. In: Kandel ER, Schwartz JH, Jessell TM (eds): Principles of Neural Science, 3rd ed, Appleton and Lange 1991.)

movements that provide a negative feedback signal.³² Adaptation only occurs if retinal image motion and head turns occur together.³³ The gain of the VOR will be adapted to decrease whenever retinal slip and head turns are in the same direction, and to increase whenever they are in opposite directions. Following adaptation, an error correction signal is projected from the flocculus by Purkinje cells to floccular target neurons (FTN) in the vestibular nucleus to make appropriate changes in VOR gain.³²

2. Optokinetic nystagmus

The visual stimulus for OKN is derived from optic flow of the retinal image.³⁴⁻³⁶ The retina contains ganglion cells that respond exclusively to motion in certain directions or orientations. This information passes along the optic nerve, decussates at the chiasm and projects to the cortex via the geniculate body (LGN) or to the midbrain via the accessory optic tract (Fig. 9.8).³⁷ This tract has several nuclei in the pretectal area.³⁸ One pair of these nuclei, the nucleus of the optic tract (NOT), is tuned to horizontal target motion to the ipsilateral side (i.e. nasal to temporal motion). The lateral and medial terminal nuclei (LTN and MTN) are tuned for vertical target motion.³⁹ Neurons in these nuclei only receive subcortical inputs from the contralateral eye. They have large receptive fields and respond to large textured stimuli moving in specific directions. Stimulation of the right NOT with rightward motion causes following movements of both eyes to the right or ipsilateral side, and similarly stimulation of the left NOT with leftward motion causes leftward conjugate following movements. Each NOT projects

signals via the inferior olive to the vestibular nuclei and possibly to the flocculus via the climbing fibers of the cerebellum.³⁵ The NOT provides a visual signal to the vestibular nucleus, and the motor response is the same as for velocity signals originating from the semicircular canals.

The cortical region that organizes motion signals is the medial superior temporal lobe (MST). This region is important for generating motion signals for both pursuit and OKN.³⁴ Binocular cortical cells receive projections from both eyes and code ipsilateral motion from the contralateral visual field at higher velocities than the subcortical system.³⁶ The cortical cells project to the ipsilateral NOT.

Until the age of 3–4 months, the monocular subcortical projections predominate because the cortical projection has not yet developed.⁴⁰ As a result, OKN in infancy is driven mainly by the crossed subcortical input. The consequence is that monocular stimulation only evokes OKN with temporal-to-nasal motion but not with nasal-to-temporal motion. After 3–4 months of development, the infant's cortical projections predominate and horizontal OKN responds to both monocular temporal-ward and nasal-ward image motion. The cortical projections to the NOT fail to develop in infantile esotropia and as adults these patients exhibit the same asymmetric OKN pattern as observed in immature infants.¹⁵ This anomalous projection is responsible for a disorder known as latent nystagmus in which a jerk nystagmus occurs when one eye is occluded with the slow phase directed toward the side of the covered eye. During monocular fixation, the stimulated retina increases the activity of neurons in the contralateral NOT via subcortical crossed projections, but it is unable to innervate the ipsilateral NOT via the ineffective cortical-tectal projection. The result is that both eyes' positions are drawn to the side of the stimulated NOT (i.e. the side of the covered eye). The fixation error is corrected with a saccade and a repeated sequence is described as latent or occlusion nystagmus.⁴¹

II. Foveal gaze lock (maintenance of foveal alignment with stationary and slowly moving targets)

A. Static control of eye alignment (fixation)

The oculomotor system enhances visual resolution by maintaining alignment of the fovea with attended stationary and moving targets.^{42,43} During fixation of stationary targets, the eyes sustain foveal alignment over a wide range of target locations in the visual field. Gaze direction is controlled by a combination of eye position in the orbit and head position.⁴⁴ Gaze is mainly controlled by eye position for targets lying at eccentricities of less than 15 degrees from primary position.⁴⁵ Steady fixation at larger gaze eccentricities is accomplished with a combination of head and eye position. Holding eye fixation at large eccentricities (>30 degrees) without head movements is difficult to sustain and the eye drifts intermittently toward primary position in gaze evoked nystagmus.⁴⁶ This drift is exacerbated by alcohol.⁴⁷ Even within the 15-degree range, the fixating eye is not completely stationary. It exhibits physiological nystagmus that is composed of slow horizontal, vertical, and torsional drifts (0.1 deg/sec), micro-saccades (<0.25 deg), and a small amplitude (<0.01 deg) high frequency tremor (40–80 Hz).⁴⁸

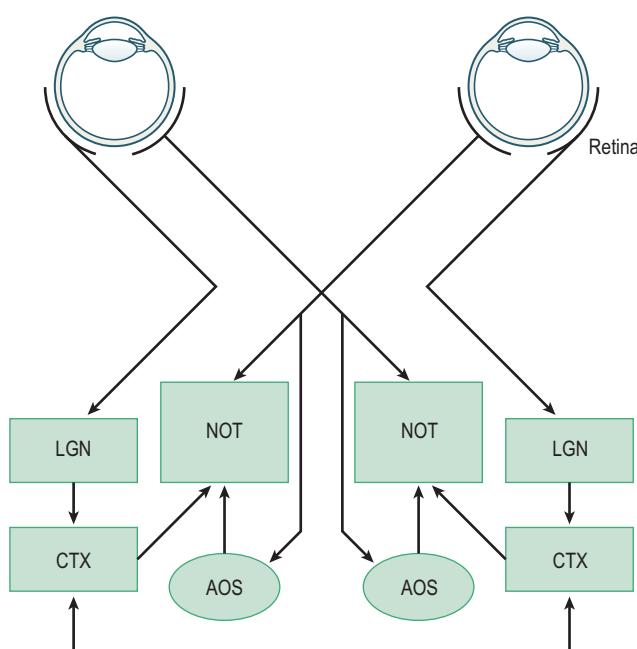

Figure 9.8 Simplified schematic illustrating the inputs to the NOT from subcortical crossed retinal projections and cortical-tectal projections. Each NOT gets direct retinal input from the contralateral nasal retina, which is excited by temporal-to-nasal motion. It also receives indirect cortical input (CTX) from the temporal retina of the ipsilateral eye, which tends to be excited more by nasal-to-temporal motion as well as input via the accessory optic system (AOS), and input from the contralateral visual cortex via the corpus callosum.³⁷ (Modified from Hoffmann KP, Distler C, Ilg U: J Comp Neurol 321:150, 1992.)

Some of the drifts and saccades are error producing, while others are error correcting when they serve to continually minimize motion and adjust the alignment of the target of regard with the fovea.^{49,50} The high frequency tremor reflects the noise possibly originating from asynchronous firing of individual motoneurons that is filtered by the mechanical properties of the eye. Gaze evoked nystagmus can be associated with impaired smooth pursuit and paramedian pontine lesions.⁵¹

Stereoscopic depth perception is enhanced by accurate binocular fixation.^{40,52} Precise bifoveal alignment requires that the eyes maintain accurate convergence at the distance of the attended target. Small constant errors of convergence during attempted binocular fixation (<15 arc min) are referred to as fixation disparity,⁵³ and these can impair stereo performance.⁵⁴ Fixation disparity is a closed-loop error because it occurs in the presence of retinal image feedback from binocular disparity. Fixation disparity results from incomplete nullification of an open-loop error of convergence known as heterophoria. Heterophoria equals the difference between the convergence stimulus and the convergence response measured under open-loop conditions (e.g. monocular occlusion). The magnitude of fixation disparity increases monotonically with the disparity stimulus to convergence when it is varied with horizontal prisms.⁵³ The slope of this function is referred to as the forced-duction fixation disparity curve.⁵³ Shallow slopes of these curves indicate that the heterophoria is reduced by adaptation during binocular or closed-loop conditions.⁴⁰ Vergence adaptation is very rapid. For example, when convergence is stimulated for only one minute with a convergent disparity and then one eye is occluded, the convergence response persists in the open-loop state.⁴⁰ Typically the convergent disparity is produced by prisms that deflect the perceived direction of both eye's images inward, or in the nasal-ward direction (i.e. the base of the prism before each eye is temporal-ward or "base-out"). This adapted change in heterophoria is constant in all directions of gaze and is referred to as concomitant adaptation. Prism adaptation is in response to efforts by closed-loop disparity vergence to nullify the open-loop vergence error (heterophoria). Prism adaptation improves the accuracy of binocular alignment and stereo-depth performance.

Horizontal vergence equals the horizontal component of the angle formed by the intersection of the two visual axes and it is described with three different units of measurement or scales that include the degree, prism diopter (PD), and meter angle (MA). *Prism diopters* equal 100 times the tangent of the angle. *Meter angles* equal the reciprocal of the viewing distance (specified in meters) at which the visual axes intersect as measured from the center of eye rotation. A target at one meter stimulates one meter angle of convergence (approximately 3.4 degrees) and one diopter of accommodation. Prism diopters can be computed from meter angles by the product of MA and the interpupillary distance (IPD), measured in cm. For example, convergence at a viewing distance of 50 cm by two eyes with a 6 cm IPD equals either 2 MA or 12 PD. The advantage to units in MA is that the magnitude of the stimulus to accommodation in diopters is approximately equal to the magnitude of the stimulus to convergence, assuming that both are measured from a common point such as the center of eye rotation. This

assumption produces large errors for viewing distances less than 20 cm because accommodation is usually measured in reference to the corneal apex that is 13 mm anterior to the center of eye rotation. The advantage to units in prism diopters is that they are easily computed from the product of MA and IPD. The advantage to units in degrees is that they accurately quantify asymmetric convergence where targets lie at different distances from the two eyes.

The Maddox classification⁵⁵ describes open- and closed-loop components that make up the horizontal vergence response. The classification includes three open-loop components that influence heterophoria. These include an adaptable intrinsic bias (tonic vergence), a horizontal vergence response to monocular depth cues (proximal vergence), and a horizontal vergence response that is coupled with accommodation by a neurological cross-link known as accommodative-convergence. Tonic vergence has an innate divergence posture (5 degrees) known as the anatomical position of rest.⁵⁶ Tonic vergence adapts rapidly to compensate for vergence errors during the first 6 weeks of life. At birth the eyes diverge during sleep, but after 6 weeks the visual axes are nearly parallel during sleep.⁵⁷ The adapted vergence, measured in an alert state, in the absence of binocular stimulation and accommodative effort, is referred to as the physiological position of rest. The physiological position of rest equals the sum of tonic vergence and the anatomical position of rest. Tonic vergence adaptation ability continues throughout life to compensate for trauma, disease, and optical distortions from spectacles and aging factors.

Proximal vergence describes the open-loop vergence response to distance percepts stimulated by monocular depth cues such as size, overlap, linear perspective, texture gradients, and motion parallax.^{58,59} This proximal response accounts for a large portion of the convergence response to changing distance.^{60,61} The open-loop convergence response is also increased by efforts of accommodation.^{62,63} The eyes maintain approximately 2/3 of a meter angle of convergence (4 prism diopters) for every diopter of accommodation.⁵³ A target at one meter stimulates one meter angle of convergence (approximately 3.4 degrees) and one diopter of accommodation. Thus when the eyes accommodate 1 diopter the accommodative-convergence response increases by approximately 2.3 degrees or 4 prism diopters which is only 68 percent of the convergence stimulus. The sum of the three open-loop components of convergence typically lags behind the convergence stimulus and produces an open-loop divergence error (exophoria) that is usually less than 2 degrees under far viewing conditions and 4 degrees at near viewing distances.⁶⁴ Esophoria describes open-loop vergence errors caused by excessive convergence that lead the stimulus. The distribution of heterophoria in the general population is not Gaussian or normally distributed. It is narrowly peaked about a mean close to zero,⁶⁵ indicating that binocular errors of eye alignment are minimized by an adaptive calibration process. During closed-loop stimulation, vergence error is reduced to less than 0.1 degree by the component of the Maddox classification controlled by visual feedback, disparity vergence, which is stimulated by retinal image disparity. Variation in any of the three open-loop components of convergence will influence the magnitude of heterophoria and the resulting closed-loop fixation

disparity. Fixation disparity acts as a stimulus to maintain activity of the disparity vergence so that it continues to sustain its nulling response of the underlying heterophoria during attempted steady binocular fixation.⁶⁶ Other dimensions of vergence also adapt to disparity stimuli. Vertical vergence adapts to vertical prism before one eye,⁶⁷ and cyclovergence adapts to optically produced cyclodisparity stimuli.^{68–70}

B. Dynamic control of eye alignment (smooth tracking responses to open- and closed-loop stimuli)

1. Conjugate smooth pursuit tracking

Smooth following pursuit movements allow the eyes to maintain foveal alignment with a moving target that is voluntarily selected.⁷¹ Pursuit is defined as the conjugate component of smooth following eye movement responses to target motion. As described below, disconjugate following responses to changes in target distance are referred to as smooth vergence. Conjugate pursuit differs from the delay portion of OKN, which is a reflex response to optic flow of the entire visual field. A conflict occurs between the pursuit and optokinetic systems when the eyes pursue an object that is moving across a stationary background. Pursuit stabilizes the moving target on or near the fovea but it causes optic flow or retinal slip of the stationary background scene. Conflicts can also occur between pursuit and the VOR if gaze is controlled with head tracking movements. Stabilizing the retinal image of a moving object with head movements produces a vestibular signal from the canals. Consequently, pursuit of a small moving target against a stationary background with eye or head movements requires that OKN and the VOR be ignored or suppressed. This is accomplished most effectively when the background lies at a different distance than the pursuit target.⁷²

Pursuit responds to target velocities ranging from several minutes of arc/sec to over 175 deg/sec.⁷¹ The gain or accuracy of pursuit is reduced as target velocity increases above 100 deg/sec.⁷³ The VOR has a much higher velocity range than pursuit. This can be demonstrated by comparing two views of your index finger. Either keep your finger stationary while you shake your head rapidly from side to side at 2–3 Hz, or shake your finger at the same frequency without moving your head. The eye cannot follow the moving finger, but it can follow the stationary finger while shaking your head even though the head-relative motion is identical in these two examples. The pursuit response is more accurate when the target motion is predictable such as with pendular motion.⁷⁴ Pursuit errors are reduced by modifying pursuit velocity and with small catch-up saccades. The combination of pursuit and catch-up saccades that appear at low stimulus velocities in patients with pursuit deficits is referred to as cogwheel pursuit. The ratio of eye velocity over target velocity (gain) or accuracy of pursuit is normally affected by target visibility (contrast) as well as drugs and fatigue.^{75,76}

The pursuit response to sudden changes in target velocity has a short latency (80–130 msec),⁷⁷ and is composed of two general phases referred to as open-loop and closed-loop (Fig. 9.9).⁷⁷ Pursuit is initiated during the open-loop phase and it is maintained during the closed-loop phase. The

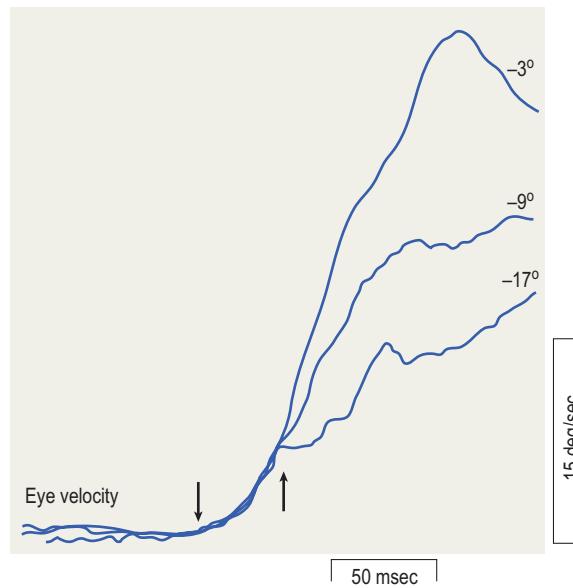

Figure 9.9 Eye velocity during the onset of pursuit to a 15 deg/sec ramp target motion, the ramp of motion beginning at different eccentricities as indicated at the right portion of each trace. The velocity of the early component (indicated by arrows) was the same for all starting positions, but the velocity of the late component varied.⁷⁷ (From Lisberger SG, Westbrook LE: J Neurosci 5:1662, 1985.)

open-loop response is divided into an early and late component. The early component is a feed forward phase that lasts for only 20 msec. During this early phase, there is a rapid acceleration of the eye (40–100 deg/sec/sec) that is in the correct direction but is independent of the stimulus velocity and initial retinal image position.⁷⁷ During the late open-loop component that lasts 80 msec, the initiation of pursuit depends strongly on target velocity and retinal image position.⁷⁸ Eye acceleration is highest in response to targets imaged near the fovea and decreases sharply with increasing eccentricity up to 21 degrees. These open-loop components are calibrated by adaptation.⁷⁸

Pursuit is maintained during the closed-loop phase in response to negative feedback from retinal image velocity (retinal slip) and position, as well as an internal estimate of target velocity relative to the head. If the eye lags behind the stimulus, the retinal image velocity is not nulled leaving a residual retinal image slip and position error away from the fovea. The pursuit system accelerates to correct both retinal position and velocity errors.⁷⁶ When pursuit is very accurate and there is no retinal error, the eye continues to pursue the target without the eye-referenced signals. Pursuit is maintained by an internal estimate of target velocity or a head referenced motion signal that is computed from a combination of retinal slip and an internal representation of eye velocity.⁷¹ This can be demonstrated by attempting to fixate an ocular floater or a retinal afterimage that is located near the fovea. Attempts to foveate the stabilized retinal image lead to smooth following eye movements even though the retinal image is always motionless. The eye is tracking an internal correlate of its own motion that causes the target to appear to move with respect to the head. Cognitive factors including attention, prediction, and learning are able to influence the execution of smooth pursuit.⁷⁹

2. Disconjugate smooth vergence tracking

Foveal alignment of targets that move slowly in depth is maintained by smooth vergence following eye movements.^{60,80} In addition to improving stereoscopic depth perception, smooth vergence provides information about changing target distance that affects size and depth perception.⁸¹⁻⁸³ Slow changes in smooth vergence respond to body sway and posture instability. While smooth vergence responses can be very inaccurate during natural rapid head movements, when the head is stationary they are very accurate at temporal frequencies up to 1 Hz.⁸⁴ At higher frequencies accuracy is reduced but it can improve with small disparity stimuli.⁸⁰ It is likely that accuracy of smooth vergence is task dependent. Smooth vergence accuracy is more demanding for spatial localization tasks that lack depth cues other than disparity, compared to tasks that have ample monocular cues for direction and distance. The accuracy of smooth vergence responses to changing disparity improves with predictable target motion.⁸⁴ Stimuli for smooth vergence tracking include magnitude and velocity of retinal image disparity⁸⁴ and perceptual cues to motion in depth, including size looming.^{58,80} Smooth vergence tracking is very susceptible to fatigue and central nervous system suppressants.⁸⁴

3. Adaptable interactions between smooth pursuit and smooth vergence

In natural scenes, motion of a target in the fronto-parallel plane is tracked binocularly with conjugate smooth pursuit. However in conditions of anisometropia corrected with spectacle lenses, the image motion of the two eyes is magnified unequally and this produces variations of binocular disparity that increase with target eccentricity from the optical centers of the lenses. Tracking motion of targets in the fronto-parallel plane then requires both smooth pursuit and smooth vergence eye movements such that one eye moves more than the other does. The oculomotor system can adapt to the binocular disparity that changes predictably with eye position. Adaptation produces open-loop non-conjugate variations of heterophoria that compensate for the horizontal and vertical disparities produced by the unequal magnifiers during smooth vergence tracking responses.⁸⁵ After only one hour of pursuit tracking experience with anisometropic spectacles, one eye can be occluded and the two eyes continue to move unequally during monocular tracking.⁸⁵ The adapted heterophoria is coupled to vary with both eye position and direction of eye movement.⁸⁶

C. Neuro-control of smooth foveal tracking

1. Smooth pursuit tracking system

Smooth following eye movements result from cortical motion signals in extrastriate cortex in areas MT and MST that lie in the superior temporal sulcus.^{87,88} Area MT encodes speed and direction of visual stimuli in three dimensions relative to the eye. MT receives inputs from the primary visual cortex and projects visual inputs to area MST and the frontal eye fields (FEF). Cells in MST fire in concert with head-centric target movement; i.e. they combine retinal and efference copy signals.⁸⁹ Each hemisphere of the MST codes motion to the ipsilateral side. Cells have two types of visual

motion sensitivity; they respond to motion of large-field patterns and small spots but the direction preferences for the two stimulus types are in opposite directions. The anti-directional large-field responses could facilitate pursuit of small targets moving against a far stationary field, and motion parallax stimuli. Efferents from MST and FEF project ipsilaterally to the NOT to generate OKN and to the dorsal lateral pontine premotor nuclei (DLPN) for pursuit tracking.³⁵

The DLPN plays a large role in maintaining steady-state smooth pursuit eye velocity, and the nucleus reticularis tegmenti pontis (NRTP) contributes to both the initiation and maintenance of smooth pursuit. Neurons in these areas are primarily encoding aspects of eye motion with secondary contributions from retinal signals such as those coded in the NOT.⁹⁰ Velocity signals are projected from DLPN to the floccular region and to the vermis lobules VI and VII of the cerebellum.³⁵ The DPN serves as a precerebellar relay for both pursuit and saccade-related information,⁹¹ and these two types of eye movements may represent different outcomes from a shared cascade of sensory-motor functions.⁹² The flocculus is thought to maintain pursuit eye movements during steady constant tracking while the vermis is important when the target velocity changes or when initiating pursuit. The role of the cerebellum is to sort out eye and head rotations in the tracking process and to sort out the ocular pursuit signal from visual and eye-head motor inputs.⁹³ From here, activity passes via parts of the vestibular nuclei, which perform the necessary neural integration of the velocity signal to a position signal that is sent to the eye muscle motor neurons.

2. Smooth vergence tracking system

Vergence results from the combined activity of intrinsic tonic activity, accommodative vergence, and responses to binocular disparity and perceived distance.⁸ The sensory afferent signals for vergence (binocular disparity and blur) are coded in the primary visual cortex (area V1).⁹⁴ Some cells in V1 incorporate vergence to code egocentric (head-referenced) distance.¹ Cells in area MT and MST respond to retinal disparity and changing size.⁹⁵⁻⁹⁷ Cells in the parietal cortex respond to motion in depth.⁹⁸ Efferent commands for vergence appear in cells in the frontal eye fields.⁹⁹ In the mid-brain the premotor NRTP, located just ventral to the rostral portion of the paramedian pontine reticular formation (PPRF), receives projections from the frontal eye fields and the superior colliculus.¹⁰⁰ Lesions in this region result in deficits of slow-continuous and fast-step vergence control.^{101,102} The NRTP projects to the cerebellum, and appears to be associated with vergence and accommodation.¹⁰³ The dorsal vermis is involved in the conversion of 3D pursuit signals to control signals for vergence eye movements.^{104,105} The posterior interposed nucleus (PIN) of the cerebellum projects to supraoculomotor regions that contain near response cells in the mesencephalic reticular formation (MRF).^{106,107} The supraoculomotor nucleus contains both burst and tonic neurons.¹⁰⁸ The burst cells code velocity signals for smooth vergence, and the tonic neurons code position signals to maintain static vergence angle. Excitatory connections of the supraoculomotor nucleus project to the oculomotor nucleus, driving the medial recti.^{107,109,110} Inhibitory connections project to the abducens nucleus to inhibit the lateral rectus.¹⁰⁸

The supraoculomotor nucleus relays control of both accommodative and disparity vergence.¹⁰⁹

III. Foveal gaze shifts: target selection and foveal acquisition

A. Rapid conjugate shifts of gaze direction (saccadic eye movements)

Saccades are very fast, yoked eye movements that have a variety of functions.^{111,112} They produce the quick phase of the VOR and OKN to avoid turning the eyes to their mechanical limits. They reflexively shift gaze in response to novel stimuli that appear unexpectedly away from the point of fixation. Saccades shift gaze during reading from one group of words to another. Saccades search novel scenes to assist us in acquiring information. They also return gaze to remembered spatial locations. Two primary functions in all of these tasks are to move the eye rapidly from one position to another and then maintain the new eye position. The rapid movement is controlled by a pulse and slide innervation pattern and the position is maintained by a step innervation.

The separate components of innervation for the saccade match the characteristics of the plant (i.e. the globe, muscles, fat, and suspensory tissues). The rapid changes in orbital position are made by the saccade at a cost of considerable energy. Saccade velocities can approach 1000 deg/sec.¹¹¹ In order to achieve these high velocities a phasic level of torque is needed to overcome the viscosity of orbital tissues, most of which is in the muscles.⁵⁶ The phasic-torque is generated by a large brief force resulting from a pulse or burst of innervation. The torque is dissipated or absorbed by the muscles, so that the force developed by the pulse of innervation does not reach the tendon (see Chapter 8 – Three-Dimensional Rotations of the Eye). At the end of the saccade, a lower constant force resulting from a step innervation generates a tonic level of torque that is needed to hold the eye still against the elastic restoring forces of the orbital tissues.¹¹² The eye positions resulting from the pulse and step forces must be equal to produce rapid gaze shifts. Pulse-step mismatches will result in rapid and slow components of gaze shifts. For example, if the pulse is too small, the saccade will slide (post-saccadic drift, called a glissade) to the new eye position at the end of the rapid phase of the saccade. The slide component is adaptable as has been shown by long-term exposure to artificially imposed retinal image slip immediately after each saccade.¹¹³ The adapted post-saccadic drift cannot be explained by an adjustment of the pulse-step ratio, suggesting that the slide innervation is an independent third component of saccadic control (pulse-slide-step). Slide innervation produces a phasic-torque in addition to the pulse component that adjusts the duration and velocity of the saccade so that its amplitude matches the position maintained by the step component.¹¹³ The pulse, slide and step are all under independent, cerebellar control, with the primary goal of protecting vision by preventing retinal slip, and a secondary goal of making accurate saccades.

The amplitude of the saccade determines its dynamic properties (e.g. its peak velocity and duration). The main sequence diagram plots these two dynamic parameters as a function of amplitude (Fig. 9.10).⁹⁵ As saccade amplitude

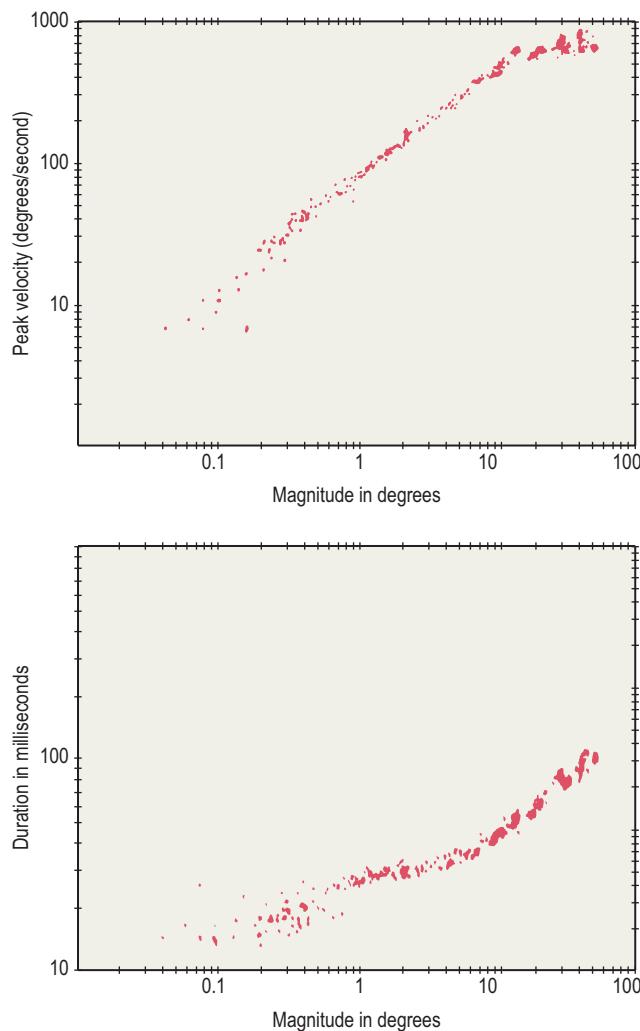

Figure 9.10 Main sequence diagram (Box 9.2). Peak velocity and saccade duration are plotted against magnitude of human saccadic eye movements.¹¹⁴ (Redrawn with permission from Bahill AT, Clark MR and Stark, L: Math Biosci 24:191, copyright 1975 by Elsevier Science Publishing Co, Inc.)

Box 9.2 Main sequence for saccades

The main sequence (peak velocity and duration of saccades) illustrates abnormalities of the spike frequency and duration of the pulse innervation for saccades

increases from 0.1 to 10 degrees, duration increases from 20 to 40 msec and peak velocity increases from 10 to 400 deg/sec. Peak velocity saturates for saccades larger than 20 degrees, such that the amplitude of larger saccades increases primarily with duration. Abnormal saccade amplitudes (dysmetria) can either be too small (hypometric) or too large (hypermetric). Large gaze shifts are normally accomplished with a sequence of hypometric saccades that are composed of a series of short-latency corrective saccades in the same direction.¹¹¹ The normal latency of a saccade to an unpredictable stimulus is 180–200 msec.⁴⁸ However, corrective saccades occur with shorter latencies (100–150 msec). Saccade latency can be reduced by a blank or gap interval before the

Box 9.3 Saccade disorders

Saccade disorders are of accuracy (dysmetria), velocity (glissades) and inappropriate timing (intrusions)

saccade, resulting in an express saccade with latencies less than 100 msec.¹¹⁵ Saccade latencies to predictable target changes, such as occur when watching a tennis match, can be reduced to zero (Box 9.3).⁷⁴

Although saccades are too brief to utilize visual feedback during their response, they do use fast internal feedback based upon an internal representation of eye position (efference copy signal) that helps control the position of the eye on a moment-to-moment basis.¹¹⁶ Thus saccadic eye movements are not ballistic in that they are guided by extra-retinal information during their flight. The goal of the saccade is to reach a specified direction in head-centric space. Normally the perceived head-centric direction of a target does not change when the eye changes position. However, spectacle refractive corrections that magnify or minify the retinal image produce changes in perceived direction with eye position. Because the entrance pupil of the eye translates when the eye rotates, prior to the saccade the eye views a non-foveal eccentric target through a different part of the lens than after the saccade when the target is viewed directly along the line of sight. The prismatic power of the lens increases with distance from the optical center of the lens such that when viewing a target through a magnifier, the saccade amplitude needed to fixate an eccentric target is larger than the gaze eccentricity sensed prior to the saccade. Saccades are controlled by a feedforward system that does not utilize visual feedback during the motor response. Consequently, initial saccadic responses to visual distortion produced by the magnifier are hypometric. However, using position errors after the saccade, the system adapts rapidly (within 70 trials) to minimize its errors.¹¹⁷ In cases of anisometropia in which the retinal images are magnified unequally by the spectacle refractive correction, the saccadic system adapts to produce unequal or disconjugate saccades that align both visual axes with common fixation targets.^{118–120} The same adaptive process is likely to calibrate the conjugate saccades and maintain that calibration throughout life in spite of developmental growth factors and injury.

B. Disconjugate shifts of gaze distance (the near response in symmetrical convergence)

Large abrupt shifts in viewing distance stimulate adjustments of several motor systems including accommodation, convergence, and pupil constriction.⁶⁰ Separate control systems initiate and complete these responses.¹²¹ Initially the abrupt adjustments are controlled by feedforward systems that do not use visual feedback until the responses are nearly completed. However they are guided by fast feedback from efference copy signals to monitor both the starting point of the near response and the accuracy of its end point.^{61,122} Visual feedback is unavailable during the response because the blur and disparity cues are too large at the beginning of the gaze shift to be sensed accurately. The motor responses are initiated by high-level cues for perceived distance and by

voluntary shifts of attention. Retinal cues from blur and disparity are only used as feedback to refine the responses once the stimuli are reduced to amplitudes that lie within the range of visual sensitivity, i.e. as the eyes approach alignment at their new destination. The three motor systems are synchronized or coordinated with one another by cross-links. When they approach their new target destination, accommodation and convergence use visual feedback to refine their response.

The cross-couplings are demonstrated by opening the feedback loop for one motor system while stimulating a coupled motor system that is under closed-loop control. For example, accommodative convergence, measured during monocular occlusion, increases linearly with changes in accommodation stimulated by blur.^{62,63} Similarly, convergence accommodation, measured during binocular viewing through pinhole pupils, increases linearly with changes in convergence stimulated by disparity.¹²³ The pupil constricts with changes in either accommodation or convergence to improve the clarity of near objects.¹²⁴ These interactions are greater during the dynamic changes in the near response than during the static endpoint of the response.¹²⁵

The cross-couplings between accommodation and convergence are illustrated with a heuristic model (Fig. 9.11).¹²⁵ Three of the Maddox components are represented in the model by an adaptable slow tonic component, the cross-links between accommodation and convergence, disparity driven vergence and blur driven accommodation (fast phasic components). The enhanced gain of the cross-link interactions associated with dynamic stimulation of vergence and accommodation results from the stimulation of the cross-links by the phasic but not the tonic components. When accommodation or convergence is stimulated, the faster transient-phasic system responds first, but it does not sustain its response. The slower and more sustained adaptable tonic system gradually takes over the load of keeping the eyes aligned and focused by resetting the level of tonic activity. Because the cross-links are mainly stimulated by the phasic component, accommodative vergence and vergence accommodation are stimulated more during the dynamic response than during steady fixation when the tonic components control eye alignment and focus.

Traditionally, only the horizontal component of vergence has been considered as part of the near response. However, vertical and cyclovergence must also be adjusted during the near response to optimize the sensory stimulus for binocular vision.^{126–129} The primary goal of the near response is to minimize large changes in horizontal, vertical, and cyclodisparities at the fovea that normally accompany large shifts in viewing distance. Horizontal disparities arise from targets that are nearer or farther than the convergence distance, assuming that the horopter equals the Veith–Muller circle. The isovergence circle describes the locus of points that stimulates a constant vergence angle in all directions of gaze,³ and it is equivalent to the Veith–Muller circle described in Chapter 36 (see Fig. 9.2). Convergence and divergence stimuli lie closer or farther, respectively, from the isovergence circle. Vertical disparities arise from targets in tertiary gaze directions at finite viewing distances, because these targets lie closer to one eye than the other and their retinal images have unequal size and vertical eccentricity (vertical disparity) (Fig. 9.12). Torsional disparities arise from elevated targets

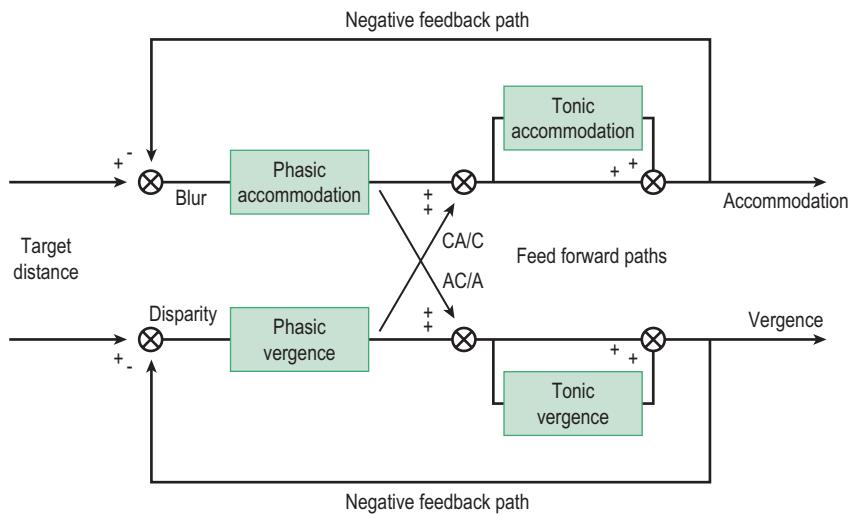

Figure 9.11 Model of cross-link interactions between vergence and accommodation. A fast phasic system drives the cross-links from accommodation to convergence (AC/A) and from convergence to accommodation (CA/C). The slow-tonic system adapts to the faster phasic system and gradually replaces it. Cross-link innervation is reduced when the tonic system reduces the load on the fast phasic system. (Modified from Kotulak J, Schor CM: The dissociability of accommodation from vergence in the dark. Invest Ophthalmol Vis Sci 1986; 27: 544. Reproduced from Association for Research in Vision and Ophthalmology)

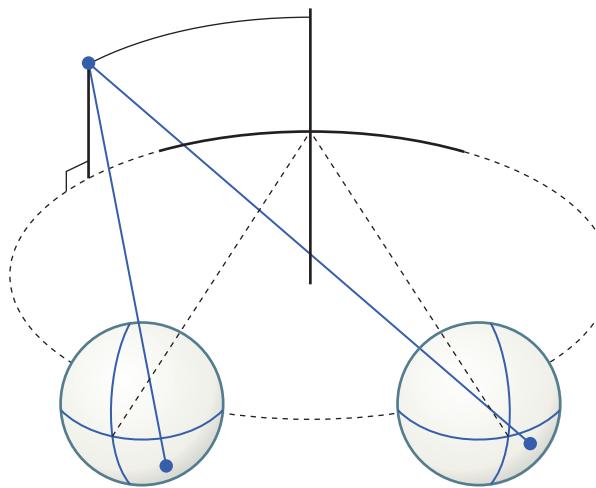

Figure 9.12 For convergence at a finite viewing distance, points in tertiary directions subtend unequal vertical visual angles at the two eyes, which produce vertical disparities.

at finite viewing distances, because during convergence, Listing's law predicts that the horizontal meridians of the two eyes will be extorted in upward gaze and intorted in downward gaze. These torsional eye postures would produce incyclodisparity in upward gaze and excyclodisparity in downward gaze.¹²⁶ With large shifts of viewing distance, horizontal, vertical, and cyclodisparities can exceed the stimulus operating range for continuous feedback control of disparity vergence. Initially the near response is stimulated by perceived distance and voluntary changes in horizontal vergence respond without disparity feedback in feedforward control. Unlike horizontal vergence, neither vertical vergence nor cyclovergence is normally under voluntary control. They participate in the near response through cross-couplings with motor responses that are under voluntary control. This allows potential vertical and torsional eye alignment errors to be reduced during the near response without feedback from retinal image disparity.¹³⁰

Empirical measures demonstrate that the gains for the three coupling relationships for horizontal, vertical, and

cyclovergence are optimal for reducing disparity at the fovea to zero during the open-loop phase of the near response.^{125,128,129,131} The tuned coupling gains for all three vergence components of the near response are the product of neural plasticity that adapts each of these cross-couplings to optimize binocular sensory functions.^{69,132,133} Plasticity also exists for other couplings. For example, vertical vergence and cyclovergence can both be adapted to vary with head roll.^{68,134,135} The coupling of pupil constriction with accommodation and convergence may also be under adaptive control. The pupil constriction component of the near response does not appear until the end of the second decade of life,¹²⁴ suggesting that it responds to accommodative errors resulting from the aging loss of accommodative amplitude. The pupil constriction component of the near response is an attempt to restore clarity of the near retinal image.

C. Interactions between conjugate and disconjugate eye movements (asymmetric vergence)

In natural viewing conditions it is rare for the eyes to converge symmetrically from one distance to another. Usually, gaze is shifted between targets located at different directions and distances from the head. Rapid gaze shifts to these targets require a combination of conjugate saccades and disjunctive vergence. In asymmetric convergence, the velocity of disparity vergence, accommodative vergence and accommodation are enhanced when accompanied by gaze shifting saccades.^{136–138} Without the saccade, symmetrical vergence responses are sluggish, reaching velocities of only 10 deg/sec.⁸⁴ Symmetrical vergence has a latency of 160 msec and response time of approximately 1 second. Similarly accommodation that is not accompanied by a saccade has a peak velocity of only 4 deg/sec, a latency of approximately 300–400 msec and response time of approximately 1 second. However when accompanied by a saccade, vergence velocity approaches 50 deg/sec,¹³⁷ and accommodation velocity approaches 8–9 deg/sec.¹³⁸ Latency of accommodation accompanied by saccades is also reduced by 50 percent so that the accommodative response is triggered in synchrony with the saccade that has a latency of only 200 msec. As shown in Figure 9.13, response times for both accommodation and accommodative vergence are reduced dramatically when accompanied by saccades. Figure 9.14

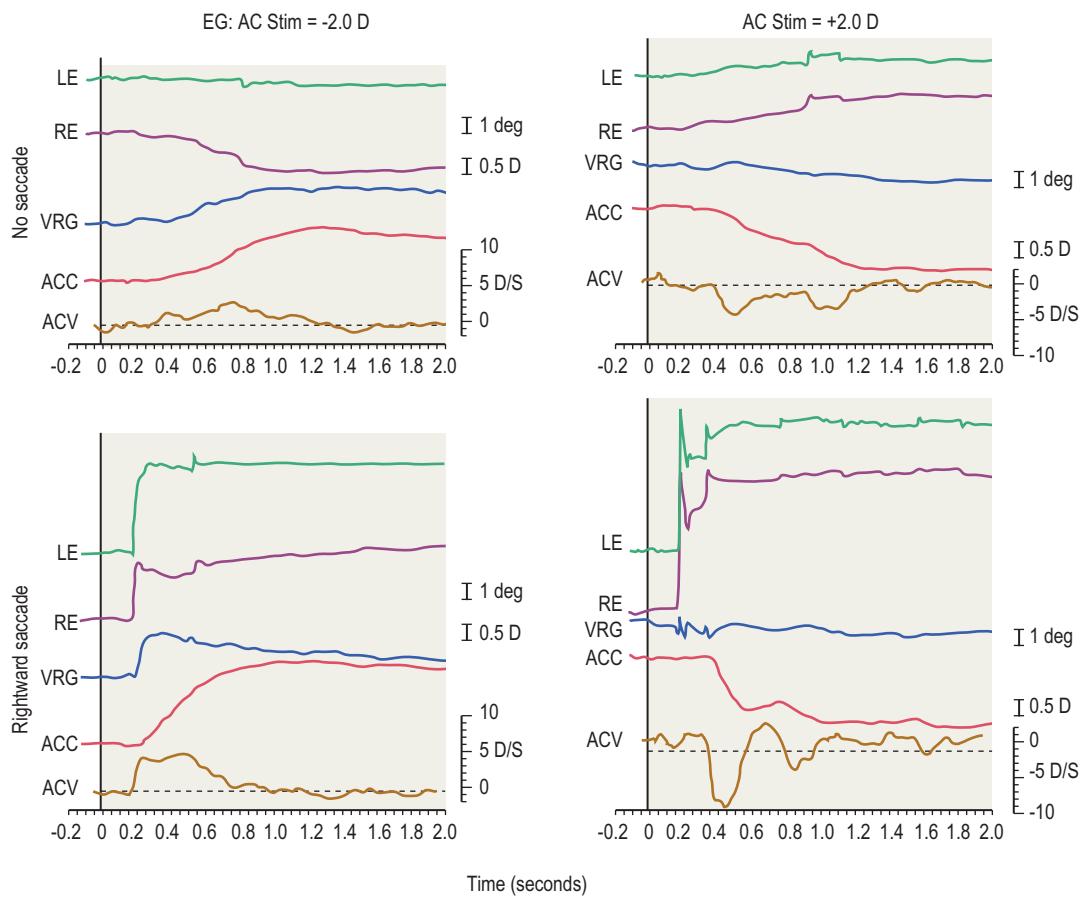

Figure 9.13 Examples of eye movement and accommodation traces during 6 deg rightward Saccade (bottom panels) and No-Saccade (top panels) conditions (left panel = trials requiring *increased* accommodation; right panel = trials requiring *decreased* accommodation). Time 0 corresponds to ACStim onset. The following conventions apply: LE = Left (viewing) eye position; RE = Right (non-viewing) eye position; VRG = Vergence position (LE-RE); ACC = Accommodation (D); ACV = Accommodation velocity (D/sec) = derivative of ACC. (Modified from Schor CM, Lott L, Pope D, et al.: Saccades reduce latency and increase velocity of ocular accommodation. Vision Res 1999; 39: 3769. Reproduced from Association for Research in Vision and Ophthalmology.)

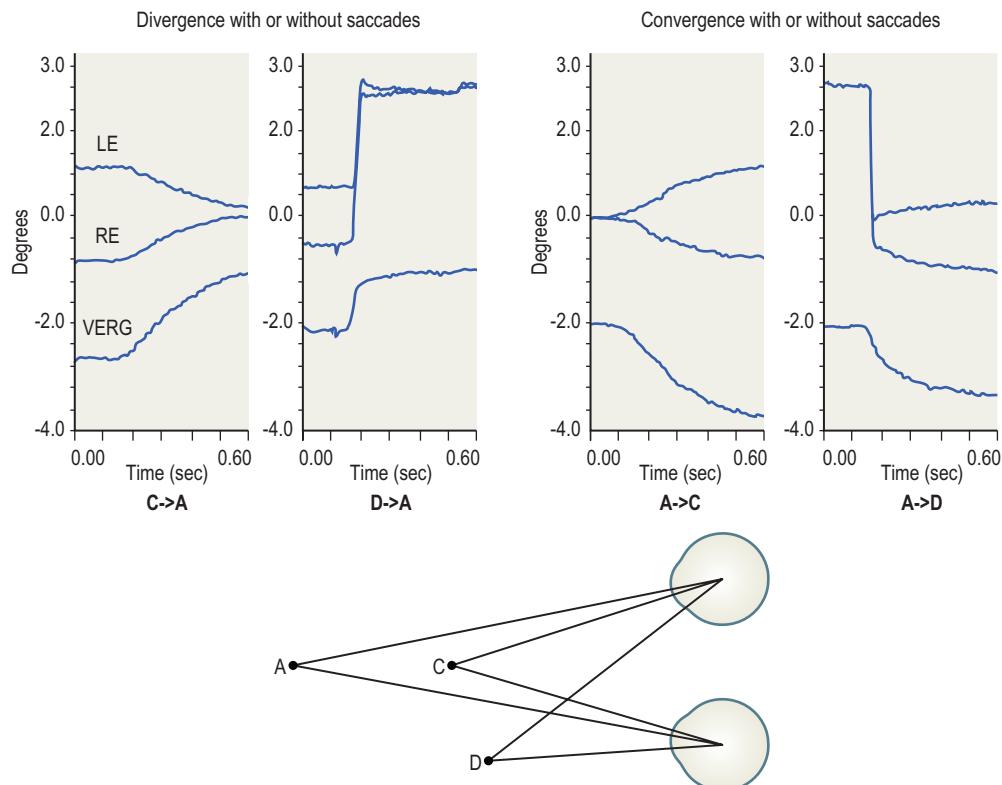

Figure 9.14 Vergence changes with or without an accompanying saccade, shown for a rhesus monkey. LE, Left eye; RE, right eye VERG vergence change. Vergence traces (right-left eye position) are offset for clarity. Convergence is negative. Note the increase in vergence velocity when a saccade is conjoined with vergence. The facilitation is greater for divergence because of the inherent divergence associated with horizontal saccades.⁸ (From Leigh JR, Zee DS: The neurology of eye movements, 3rd edition, Oxford University Press 1999.)

compares symmetric and asymmetric disparity vergence. The high velocity asymmetric vergence appears to result in part from yoked saccades of unequal amplitude. These unequal saccades result from an asynchronous onset of binocular saccades. The abducting saccade begins before the adducting saccade, causing a brief divergence.^{139,140} There also appears to be additional accelerated vergence and accommodation responses that are triggered with the saccade.^{140–142} Both the vergence and accommodation responses continue after the completion of the saccade but overall the responses are completed in less time than when not accompanied by a saccade.

D. Neuro-control of foveal gaze shifts

1. Saccadic gaze shifting system

The frontal eye fields (FEF) mediate voluntary control of contralateral saccades. The FEF is active whether saccades occur or not.¹⁴³ The activity is related to visual attention, and when saccades occur the related activity in the FEF precedes them by 50 msec. The surface of the FEF has a coarse retinotopic organization. Stimulation of a particular area causes a saccade to change eye position in a specific direction and amplitude. These cells are active before saccades to certain regions of visual space. These regions are called the movement field of the cell, and they are analogous to the receptive fields of sensory neurons in the visual cortex. Stimulation of FEF cells in one hemisphere causes conjugate saccades to the contralateral side. Vertical saccades require stimulation of both hemispheres of the FEF. Modalities that can stimulate movement fields include vision, audition, and touch. The FEF project two main efferent pathways for the control of saccades. One projection is to the superior colliculus (SC). The other projection is to the midbrain, to the paramedian reticular formation (PPRF) and the rostral interstitial medial longitudinal fasciculus (riMLF) for the control of horizontal and vertical saccades, respectively.^{144,145} The fibers from the frontal eye fields descend to the ipsilateral superior colliculus and cross the midline to the contralateral PPRF. Neither the superior colliculus nor FEF are required exclusively to generate saccades. Either one of them can be ablated without abolishing saccades, however if both are ablated, saccades are no longer possible. The function of the SC is to represent intended gaze direction resulting from combinations of head and eye position. Stimulation of a specific region in the intermediate layers of the colliculus can result in several combinations of head and eye position that achieve the same gaze direction relative to the body.¹⁴⁶ Cells in the superior colliculus respond to all sensory modalities including vision, audition, and touch. The spatial locations of all of these sensory stimuli are mapped in the colliculus relative to the fovea. Like the FEF, stimulation of one SC causes a conjugate saccade to the contralateral side; stimulation of both sides is necessary to evoke purely vertical saccades.

The output of the SC and FEF project to two premotor nuclei, the PPRF and the riMLF, that shape the velocity and amplitude of horizontal and vertical components of saccades, respectively.^{88,144} The PPRF projects to the ipsilateral abducens nucleus, which contains motor neurons that innervate the ipsilateral lateral rectus and interneurons that project to the contralateral oculomotor nucleus to innervate the medial rectus. The PPRF also projects inhibitory connections to the contralateral PPRF and vestibular nucleus to

reduce innervation of the antagonist during a saccade. The riMLF projects to the ipsilateral trochlear nucleus (IV) and to both oculomotor nuclei (III). Four types of neurons including burst cells, tonic cells, burst-tonic cells, and pause cells control saccades in several premotor sites. The pulse component of the saccade is controlled by medium-lead burst neurons. Long-lead burst neurons discharge up to 200 msec before the saccade and receive input from the SC and FEF. They drive medium-lead burst neurons (MLB) that begin discharging at a high frequency (300–400 spikes/sec) immediately at the beginning of the saccade and throughout its duration. Duration of MLB activity ranges from 10 to 80 msec. They project to the motor nuclei and control pulse duration and firing frequency, which determine saccade duration and velocity. Inhibitory burst neurons inhibit antagonist muscles by suppressing neurons in the contralateral abducens nucleus.

Initiation of the pulse is gated by the omnipause neuron (OPN), which is located in the nucleus of the dorsal raphe, below the abducens nucleus (Fig. 9.15). Normally the OPNs prevent saccades by constantly inhibiting burst cells. The OPN discharges continuously except immediately prior to and during saccades, when they pause. Omnipause neurons engage the saccade by releasing their inhibition of the burst cells. The same OPN inhibit saccades in all directions.

Upon completion of the saccade, the new eye position is held by the discharge step of the tonic cell. Integrating the pulse derives the discharge rate of the premotor tonic cell. At least two sites are known to integrate horizontal pulses; these are the medial vestibular nuclei and the nucleus prepositus hypoglossi (NPH). Pulses for vertical saccades are integrated in the interstitial nucleus of Cajal (INC). The flocculus of the cerebellum is also involved in integrating the velocity signals to position signals controlling eye movements. Some anomalies occur that appear to result from lesions of the integrator. In these cases the eyes make a saccade and then drift back to primary position. Affected patients are unable to hold fixation away from primary position and a jerk gaze nystagmus develops in which the slow-phase drift of the eyes is toward primary position and the fast phase is toward the desired eccentric gaze direction. Combined eye position and velocity signals are carried by burst-tonic neurons. They are active during ipsilateral saccades and inhibited during contralateral saccades.

2. Vergence gaze shifting system: the near triad and interactions with saccades

The supraoculomotor nucleus in the mesencephalic reticular formation contains near response cells. This is a heterogeneous population made up of cells that respond to accommodative stimuli, or vergence stimuli or a combination of accommodation and vergence stimuli.^{107,109,110,141} This nucleus contains burst, tonic, and burst-tonic cells that are characteristic of premotor nuclei for saccades. Velocity signals related to disparity stimuli activate burst cells, and a position signal from tonic innervation is derived by integration of the burst cell activity. These cells are believed to provide velocity and position signals to the medial rectus motoneurons in the control of vergence as well as commands to the Edinger-Westphal nucleus to stimulate accommodation.⁹ The Edinger-Westphal nucleus, located at the rostral portion of the midbrain at the oculomotor nucleus, contains

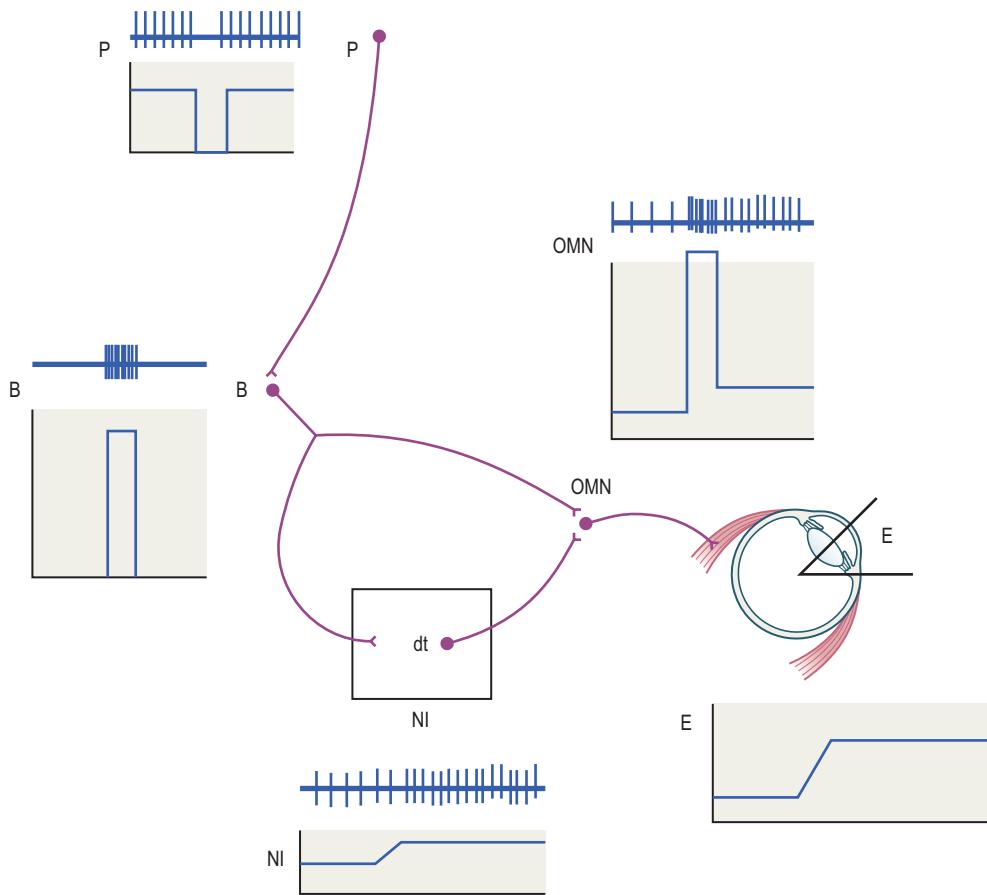

Figure 9.15 The relationship among omnipause cells (P), burst cells (B) and cells of the neural integrator (NI), in the generation of the saccadic pulse and step. Omnipause cells cease discharging just before each saccade, allowing the burst cells to generate the pulse. The pulse is integrated by the neural integrator (NI) to produce the step. The pulse and step combine to produce the innervation change on the ocular motoneurons (OMN) that produces the saccadic eye movement (E). Vertical lines represent individual discharges of neurons. Underneath the schematized neural (spike) discharge is a plot of discharge rate versus time.⁸ (From Leigh JR, Zee DS: The neurology of eye movements, 3rd edition, Oxford University Press 1999.)

parasympathetic motor neurons that project to the ciliary muscle, and drive accommodation.⁹ Each hemisphere of the Edinger-Westphal nucleus projects to its ipsilateral eye. Parasympathetic outflow of the Edinger-Westphal nucleus also results in miosis (pupillary contraction). Inhibition of the Edinger-Westphal nucleus causes pupil dilation.

Saccades enhance the velocity of both vergence and accommodation. Current models of saccade-vergence interactions suggest that OPNs in the midbrain gate the activity of both saccade bursters and vergence bursters.¹⁴⁰ Accelerated vergence caused by saccadic facilitation results from a release from inhibition of vergence bursters by reduced firing of the OPNs, which share their inhibition with saccadic and near response bursters. This facilitation is correlated with an augmentation of firing rate of a sub-set of convergence burst neurons of the near response cells.^{141,142} This model has been developed further to include the potential for saccadic facilitation of accommodation.^{141,142} Because near response cells provide innervation for both accommodation and vergence, release of inhibition from OPNs augments activity of both accommodation and vergence when associated with saccades.¹³⁸ This augmentation would not only enhance velocity of the near response, but it would also gate or

synchronize innervation for vergence and accommodation with saccades.

Neurological disorders of the oculomotor system

Neurological disorders have greater variability across individuals than is found for the normal oculomotor system. The sources of variability come from the location and extent of lesions, associated anomalies or syndromes, different sources or causes of the problem, history of prior treatment interventions, and adaptive responses that attempt to compensate for the disorder. A multi-perspective classification can reflect this individual variation. It views the anomaly in different ways and highlights very different types of information about the condition. Its versatility describes the range of anomalous behaviors that may develop as a function of various combinations of causal factors. The pattern of associated conditions or syndromes facilitates estimating the prognosis for cosmetic and functional correction. Oculomotor disorders are classified in terms of behavioral descriptions,

etiology, and neuro-anatomical sites of involvement. Behavioral categories can be descriptive such as the magnitude and direction of a strabismus (an eye turn), gaze restrictions, saccadic disorders, and nystagmus. They can also be described by an associated cluster of anomalies that collectively characterize a disease (syndrome).

Categories of etiology include congenital, developmental, and acquired. Congenital disorders appear in early infancy (<18 months). Developmental anomalies can result from interference of normal sensory-motor interactions during the first 6 years of life that constitute the critical period for visual development. Both congenital and developmental disorders are associated with anomalies throughout the oculomotor pathways, including sensory or afferent components of the visual system and they are classified in terms of syndromes. Acquired disorders can result from trauma or disease and they are classified in terms of specific anatomical sites of involvement and by syndromes.⁸

I. Strabismus

Non-paralytic strabismus falls into both congenital and developmental categories (Box 9.4). A strabismus or tropia describes a misalignment of the two eyes that is not corrected by disparity vergence during binocular fixation. In congenital and developmental forms of strabismus, the eye turn is usually concomitant, meaning that its amplitude does not vary with direction of gaze with either eye fixating. Usually non-paralytic strabismus is a horizontal deviation, where convergent and divergent eye turns are referred to as esotropia and exotropia respectively. Esotropia is more common than exotropia in childhood. Infantile or early-onset esotropia appears within the first 18 months of life and is associated with two forms of nystagmus that include latent or occlusion nystagmus (LN) and asymmetric optokinetic nystagmus, as well as cog-wheel temporal-ward pursuits (asymmetric pursuit) that were described earlier in this chapter. It is also associated with a vertical misalignment of the eyes when one eye is occluded, that is referred to as dissociated vertical deviation (DVD). When either the right or left eye is occluded, the covered eye rotates upward. This distinguishes DVD from a vertical strabismus in which one of the two eyes remains elevated with respect to the position of the other eye, independent of which eye is fixating. The combination of LN, asymmetric OKN, asymmetric pursuit and DVD are referred to as the infantile strabismus syndrome (Box 9.5).¹⁴⁷

The presence of this syndrome in an adult is a retrospective indicator of an early age of onset for a strabismus. The

early onset of eye misalignment prevents sensory fusion and causes one eye to be suppressed. This disrupts the development of both monocular and binocular sensory functions and can lead to the development of amblyopia, anomalous correspondence and stereoblindness that are described in Chapter 36. Accommodative esotropia is a developmental form of non-paralytic strabismus (Box 9.6) that results from either large uncorrected hyperopic refractive errors or abnormally large interactions between the cross coupling between accommodation and convergence. Uncorrected hyperopia produces a mismatch between the stimulus between accommodation and convergence. Excessive convergence is caused by accommodative attempts to clear the retinal image and the cross coupling between accommodation and convergence. The disparity-divergence system is unable to align the eyes and compensate for the accommodative esotropia.

Acquired strabismus usually results from lesions in the brainstem produced by trauma or disease that affect the integrity of the cranial nerves of the final common pathway. The lesions result in muscle palsies that cause deviations between the two visual axes that increase as gaze is directed into the field of action of the affected muscle (paralytic strabismus). The deviation of the paretic eye when the normal eye fixates (primary deviation) is usually smaller than the deviation of the normal eye when the paretic eye fixates (secondary deviation). This non-concomitant variation of eye turn is a diagnostic feature of paralytic strabismus. Lesions of the third, fourth, and sixth nerve are referred to as oculomotor palsy, trochlear palsy, and abducens palsy, respectively. Paresis of the muscles innervated by the III nucleus, i.e. the medial rectus, vertical recti, inferior oblique, levator of the lid and the pupilloconstrictor muscle, result in a fixed-dilated pupil and ptosis, with the eye remaining in a downward and abducted position. Trochlear palsy is characterized by a hyper deviation of the affected eye that increases during adduction and depression of the affected eye and head tilt to the side of the affected eye. Abducens palsy is characterized by an esotropia that increases during abduction of the affected eye.

II. Gaze restrictions

Lesions in premotor nuclei, supranuclear and cortical sites restrict movements of both eyes (Box 9.7). The medial longitudinal fasciculus (MLF) is the fiber bundle that interconnects premotor regions with the III, IV, and VI cranial nuclei. Any lesion that disconnects these fibers from the premotor

Box 9.4 Etiological classification of motor disorders

Motor anomalies are classified as congenital, developmental, and acquired

Box 9.5 Infantile strabismus syndrome

The infantile strabismus syndrome consists of asymmetric horizontal OKN and pursuits, dissociated vertical deviation (DVD), and latent nystagmus (LN)

Box 9.6 Accommodative esotropia

Accommodative esotropia results from the combination of uncorrected hyperopia and a high AC/A ratio

Box 9.7 Functional classification of motor disorders

- Peripheral and nuclear lesions are categorized as paresis and paralysis
- Premotor, internuclear, and supranuclear lesions are categorized as gaze restrictions or palsies

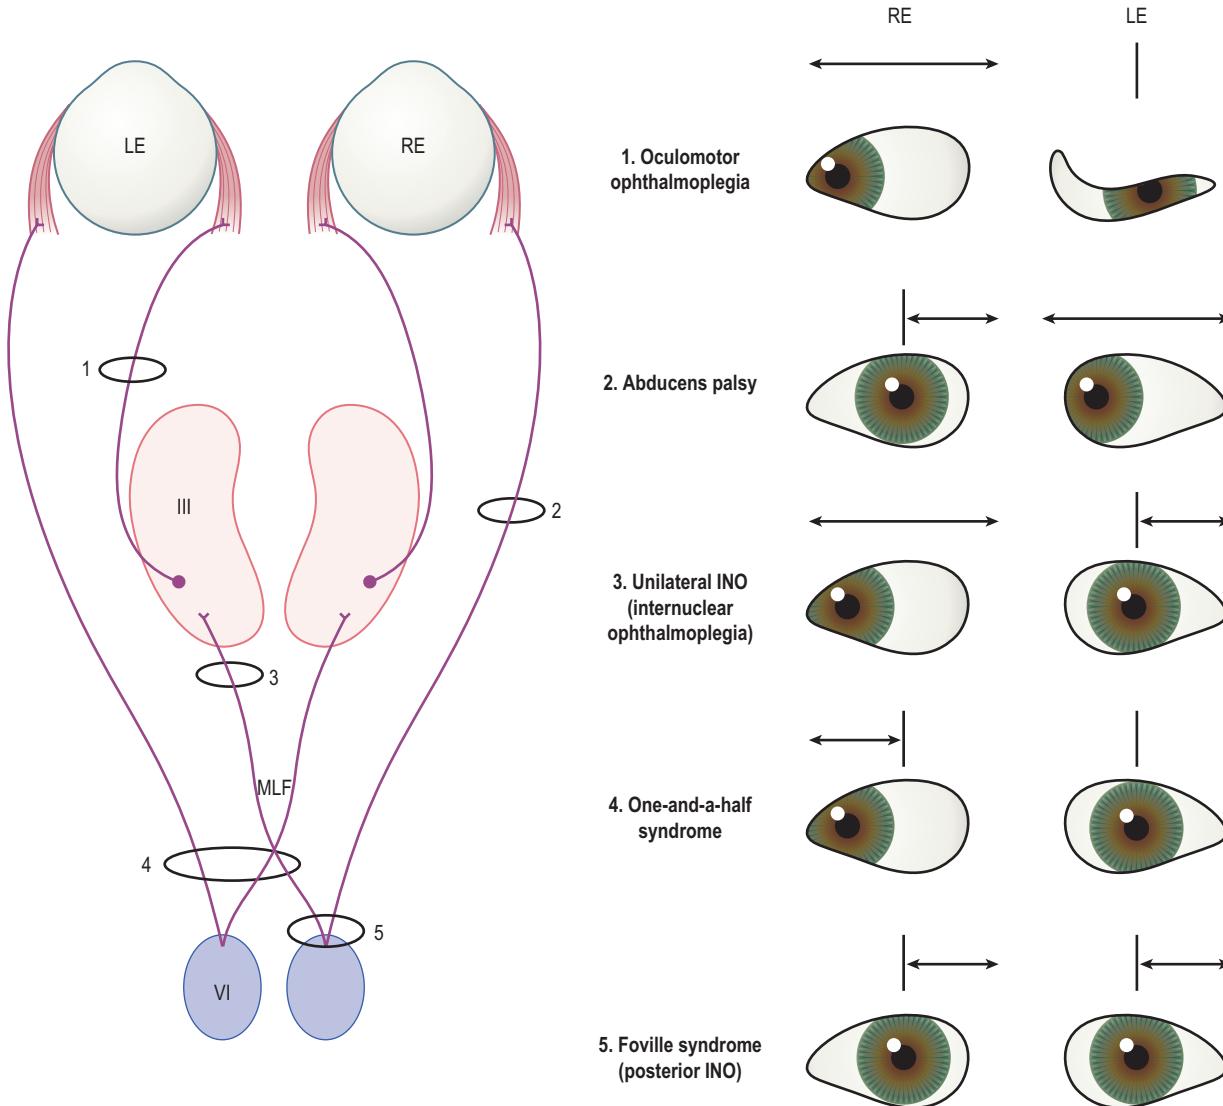

Figure 9.16 Subcortical disorder: gaze palsies. Eye positions shown reflect attempted right gaze in each case, but the arrows show the full range of horizontal gaze for each eye. (Original drawing by Scott B Stevenson, courtesy University of Houston.)

to the motor nuclei is referred to as ophthalmoplegia (Fig. 9.16). Lesions caudal to the oculomotor nucleus cause exotropia and failure of adduction, however convergence of the two eyes is spared. Internuclear ophthalmoplegia (INO) refers to an adduction failure caused by disruption of interneuron projections from the abducens nucleus to the contralateral III nerve nucleus. The affected eye is unable to adduct to the contralateral side and the eye drifts in the temporal-ward direction. Sparing of convergence distinguishes this lesion from oculomotor palsy. Patients with INO can develop a convergence nystagmus in an attempt to bring the exotropic eye into primary gaze. One-and-a-half syndrome is a combination of horizontal gaze palsy and INO that is caused by a lesion of the abducens (affecting the ipsilateral lateral rectus) and interneurons projecting from both abducens nuclei (affecting the ipsilateral and contralateral medial recti).

Foville's syndrome is a unilateral lesion at or near the abducens nucleus which causes conjugate gaze palsies,

contralateral limb paralysis, and ipsilateral facial paralysis. Lesions of the abducens nucleus block horizontal movement of both eyes to the side of the lesion because interneurons that project from the abducens nucleus to the contralateral oculomotor nucleus are also affected. Because the abducens is the final common pathway for all lateral conjugate eye movements, lesions there affect saccades, pursuit and the VOR. Lesions in the PPRF only limit horizontal saccades of both eyes to the ipsilateral side and cause drift of the eyes to the contralateral side. Lesions of the DLPN only affect horizontal pursuit toward the side of the lesion.

Lesions rostral to the III nucleus cause paralysis of vertical gaze (Parinaud's syndrome) and failure of convergence, but retention of normal horizontal gaze ability. Parinaud's syndrome occurs with lesions in the vicinity of the riMLF and INC and affects all vertical eye movements including saccades. It often results from tumors of the pineal gland that compress the superior colliculus and pretectal structures. Unilateral lesions in this area may also cause skew deviations

in which there is a vertical deviation of one eye. Unilateral lesions can also cause unilateral nystagmus where the affected eye has a slow upward drift and fast downward saccade (down beat nystagmus).

Cortical lesions produce gaze restrictions of both saccades and pursuits. Lesions of the primary visual cortex produce blindness in the corresponding parts of the visual field contralateral to the lesion (scotoma). Pursuit and saccade targets presented in the scotoma are invisible to the patient. If the entire visual cortex in one hemisphere is destroyed, the vision near the fovea may be intact (macular sparing), allowing the patient to track targets over the full range of eye movements. Like the primary visual cortex, lesions in MT produce contralateral scotomas of the visual field. Saccades to fixed targets may be accurate but pursuit responses to moving targets presented in the affected field will be absent or deficient. Lesions in MST produce visual effects similar to MT, but they also produce a unidirectional pursuit deficit for targets in both visual hemifields moving toward the side of the lesion. Lesions in the posterior parietal cortex (PP) produce attentional deficits, which make pursuit and saccades to small targets more difficult than larger ones. Lesions of the FEF produce a deficit for horizontal pursuit and OKN toward the side of the lesion and saccades to the contralateral side. Lesions to the SEF impair memory-guided saccades.

III. Saccade disorders

Saccade disorders consist of abnormal metrics (velocity and amplitude), and inappropriate, spontaneous saccades that take the eye away from the target during attempted fixation. Saccades are classified as too fast or slow if their velocity does not fall within the main sequence plot of velocity versus amplitude (see Fig. 9.10). However, saccade velocity may be normal while its amplitude is in error. If saccades are too small, the eye could start to make a large saccade and would accelerate to an appropriate high velocity but then be stopped short of the goal by a physical restriction or by rapid fatigue, such as in ocular myasthenia. Saccades can also be interrupted by other saccades in the opposite direction (back-to-back saccades) such as is observed in voluntary nystagmus. These are truncated saccades. Slow saccades can result from muscle palsies and a variety of anomalies in premotor neurons.^{8,148}

Cerebellar disorders can cause saccade *dysmetria* (inaccuracy). Saccades can be too large (*hypermetric*) or too small (*hypometric*) relative to the target displacement. Inaccuracy can lead to macrosaccadic oscillations when the eye repeatedly attempts to correct its fixation errors with inaccurate saccades. Either the pulse or the step component of the saccade can be inaccurate (Fig. 9.17). If the pulse is too small the saccade will be slow, and if the step is not constant but decays, eye position will drift toward primary position; repeated attempts to fixate eccentrically will result in gaze-evoked nystagmus. If the pulse and step are mismatched, there will be post-saccadic drift or glissade to the final eye position.

Cerebellar disorders and progressive supranuclear palsy can cause saccadic intrusions. These are conditions in which spontaneous saccades occur at the wrong time and move the eye away from the target during attempted fixation. Ocular flutter is characterized by rapid back-and-forth horizontal

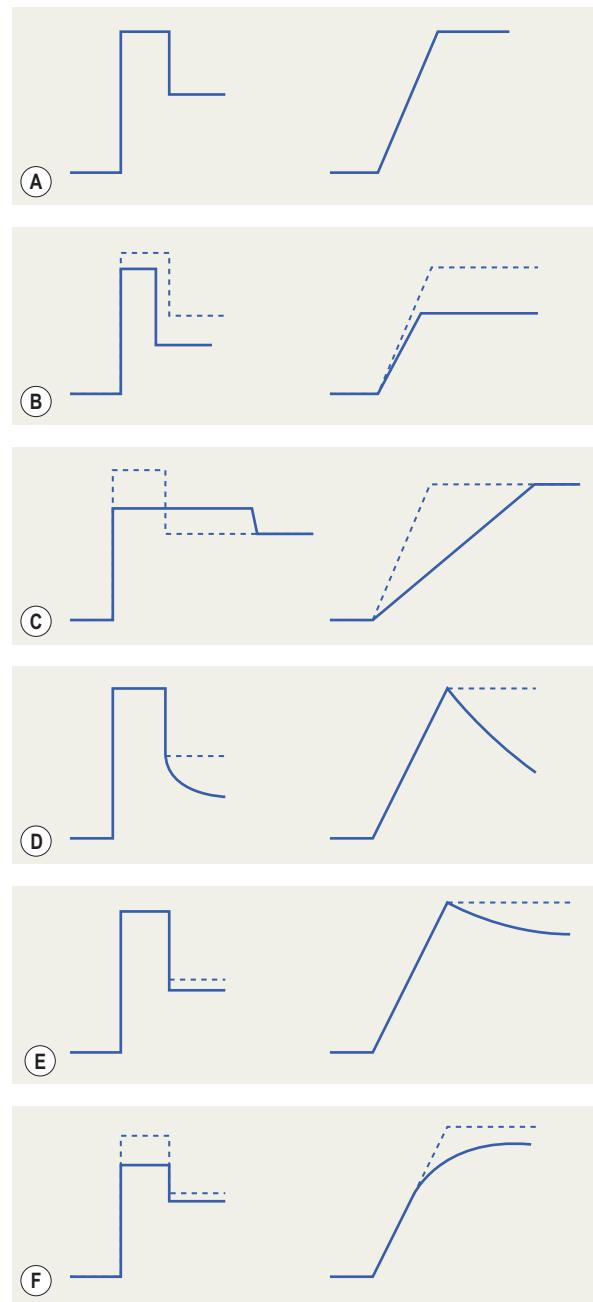

Figure 9.17 Disorders of the saccadic pulse and step. Innervation patterns are shown on the left, and eye movements on the right. Dashed lines indicate the normal response. (A) Normal saccade. (B) Hypometric saccade: pulse amplitude (width X height) is too small but pulse and step are matched appropriately. (C) Slow saccade: decreased pulse height with normal pulse amplitude and normal pulse-step match. (D) Gaze-evoked nystagmus: normal pulse, poorly sustained step. (E) Pulse-step mismatch (glissade); Step is relatively smaller than pulse. (F) Pulse-step mismatch due to internuclear ophthalmoplegia (INO): the step is larger than the pulse, and so the eye drifts onward after the initial rapid movements. (From Leigh JR, Zee DS: The neurology of eye movements, 3rd edition, Oxford University Press 1999.)

saccades without normal saccade latency or intersaccadic interval. Opsoclonus is ocular flutter in all directions. There are also square wave jerks that move the eye away from a point of fixation and then back again. These movements have a normal intersaccadic interval.

Box 9.8 Waveform classification of nystagmus

Nystagmus can have pendular or jerk (saw-tooth) waveforms. Jerk nystagmus disorders are of the slow phase of unsteady fixation. Null point is the gaze distance and direction where nystagmus amplitude is minimal.

IV. Nystagmus

Nystagmus refers to a regular pattern of to and fro movements of the eyes, usually with alternating slow and fast phases (see Fig. 9.6). The direction of the nystagmus is specified according to the direction of the fast phase (e.g., "jerk right"), because the fast phase is more visible than the slow phase. When the velocity of the eye oscillations is equal in both directions the waveform is classified as pendular (Box 9.8).

Congenital nystagmus appears early in life and is often associated with albinism, aniridia, and congenital acromatopsia. It is a jerk waveform of nystagmus that has a null point or gaze direction where the amplitude is minimized. The differentiating characteristic of CN is that the speed of the slow phase *increases* exponentially, until a resetting quick phase occurs. In all other forms of nystagmus, the speed of the slow phase is constant or decreases before the quick phase. Persons with CN can adopt a head turn to allow their gaze direction to coincide with the null point. Convergence also dampens CN and in some cases individuals adopt an esotropia in an attempt to block the nystagmus at the expense of binocularity (nystagmus blocking syndrome). Latent nystagmus described earlier in this chapter is a developmental form of nystagmus associated with early-onset esotropia or abnormal binocular vision and it is thought to be related to asymmetric OKN that is also associated with disrupted development of binocular vision.⁴⁰

Vestibular nystagmus can result from central and peripheral anomalies of the vestibular gaze stabilization system. The vestibular system is organized in a push-pull fashion where the inputs from each side of the head are normally balanced when the head is stationary. When an imbalance exists, the eyes behave as if the head were constantly rotating. The amplitude of the nystagmus is highest when gaze deviates in the direction of the fast phase (Alexander's law). In some cases of vestibular nystagmus, the direction of the nystagmus reverses every 2 minutes (periodic alternating nystagmus, PAN). The reversal reflects the action of the normal cerebellar adaptive control mechanism to correct an imbalance in the vestibular system. Rebound nystagmus is a related condition associated with gaze-evoked nystagmus that was described earlier in this chapter. In gaze-evoked nystagmus, when fixation is held eccentrically, the slow phase is toward primary position. In rebound nystagmus, the amplitude of the nystagmus is reduced after 30 or more seconds of sustained fixation. However, when the eyes return to primary position, the nystagmus reverses direction, i.e. rebounds. The attenuation and reversal of slow phase direction demonstrates an attempt by the cerebellum to reduce the slow drifts during attempted steady fixation caused by a leaky tonic innervation for eye position.

Nystagmus can also have vertical and torsional components. For example, see-saw nystagmus is an acquired pendular form of nystagmus in which there is a combination of

vertical and torsional oscillation of eye orientation. The eyes bob up and down by several degrees in opposite directions (skew movements). As one eye elevates and intorts, the other eye depresses and extorts. The exact cause is unknown, but see-saw nystagmus is associated with visual loss in bitemporal hemianopia and optic chiasm disorders. The nystagmus is thought to result from an inappropriate ocular counter-roll during head tilt orchestrated by the cerebellum in association with the otoliths.

All of the oculomotor anomalies described above show some evidence of attempts by the oculomotor system to correct them using the same adaptive mechanisms that normally calibrate the various classes of eye movement systems. However, the anomalies are beyond the corrective range of the adaptive processes. If it were not for these adaptive processes, these anomalies would be far more prevalent and the oculomotor system would be extremely susceptible to permanent injury resulting from disease and trauma. The consequences would be very dramatic. For example, about 50 years ago a physician named John Crawford lost function of his vestibular apparatus as a result of an overdose of streptomycin used to treat tuberculosis located in his knee. He reported that every movement of his head caused vertigo and nausea, even when his eyes were open. If his eyes were shut, the symptoms intensified. He attempted to steady his head by lying on his back and gripping the bars at the head of the bed. However even in this position the pulse beat in his head became a perceptible motion, disturbing his equilibrium. It is difficult to imagine how we would survive without the adaptive processes that continually calibrate our oculomotor system and allow us to distinguish between motion of our head and eyes from motion of objects in the world.

Ocular Circulation

Charles E. Riva, Albert Alm & Constantin J. Pournaras

Introduction

The ocular circulation is unique and complex due to the presence of two distinct vascular systems, namely the retinal and uveal systems. The part of this circulation, the one that supplies the fundus of the eye, has the useful property that it can be observed using the ophthalmoscope, an optical instrument introduced by Helmholtz in the middle of the 19th century. In the early 1960s, the fundus camera, a device based on the principle of indirect ophthalmoscopy, allowed the recording of the passage of fluorescein through the human retinal vascular system, from which Hickam and Frayser derived the first quantitative measurements of retinal hemodynamics.¹ Technological developments in the field of optics and lasers have since led to a variety of non-invasive techniques, which have permitted the investigation of various parameters pertaining to human ocular hemodynamics and the response of these parameters to a number of physiologic and pharmacologic stimuli. These techniques have provided information on human ocular circulatory physiology and may help in understanding the role of ocular blood flow in the pathogenesis of eye diseases of vascular origin. Yet much of our basic knowledge of ocular blood flow regulation is based on data from animal experiments; thus, in the following, basic principles from animal experiments will be presented together with the human data available.

Anatomy of the ocular circulation

Knowledge of the anatomy and the regulatory mechanisms of the various ocular vascular beds is crucial for understanding the pathophysiologic changes occurring during the evolution of several systemic and local diseases threatening vision. The delivery of metabolic substrates and oxygen to the retina in higher mammals, including humans and other primates, is accomplished by two separate vascular systems, the retinal and the choroidal systems. In lower mammals, such as rabbit and guinea pig, the retinal vessels are present in only a small area of the retina or are lacking. In this case, the retinal metabolism depends almost completely upon the choroidal circulation.²

The ocular vessels are all derived from the ophthalmic artery (OA), a branch of the internal carotid artery. The

retinal and choroidal vessels differ morphologically and functionally from each other. The OA gives off two to three main ciliary arteries (CAs), i.e. the nasal and the temporal, which supply the corresponding hemispheres of the choroid via branches of the posterior CAs (PCAs)^{3,4} and recurrent branches of the anterior ciliary arteries (ACAs). The ACAs arise from the extraocular muscular arterial branching from the OA.⁵ The central retinal artery (CRA) may branch from the same segment of the OA as the PCAs or from one of the main PCAs.^{6,7} It enters the optic nerve from below, approximately 10–15 mm behind the globe,⁸ from where it assumes its central position in the optic nerve up to the optic disk (Fig. 10.1).

Vascular supply of the retina

The retinal circulation is an end-arterial system without anastomoses. The CRA emerges at the optic disk where it divides into two major branches. These in turn divide into arterioles extending outward from the optic disk, each supplying one quadrant of the retina, although multiple branchings of the retinal arterioles towards the peripheral retina may occur. Retinal arteries and veins divide by dichotomous and side-arm branchings. The terminal arterioles branch off at almost right angles from the main vessel. In approximately 25 percent of human eyes, a cilioretinal artery emerging from the temporal margin of the optic disk supplies the macular region,⁹ exceptionally feeding the foveal region (Fig. 10.2).

The larger vessels lay in the innermost portion of the retina, close to the inner limiting membrane. Their walls are in close spatial relationship with glial cells, mainly astrocytes (Fig. 10.3).¹⁰ Astrocytes play important roles in constraining retinal vessels to the retina and in maintaining their integrity.¹¹ At the arterio-venous crossing sites the deeper vessels may indent the retina as far as the outer plexiform layer.² The retinal arterioles give rise to a plexus of capillaries (~5 µm in diameter). These capillaries form an interconnecting two-layer network. The first layer is located in the nerve fiber and ganglion cell layer and the second lies deeper, in the inner nuclear layer. In the peripapillary area an additional capillary network lies in the superficial portion of the nerve fiber layer, constituting the radial peripapillary capillaries distributed around the optic disk and along the temporal superior and inferior retinal vessels.¹²

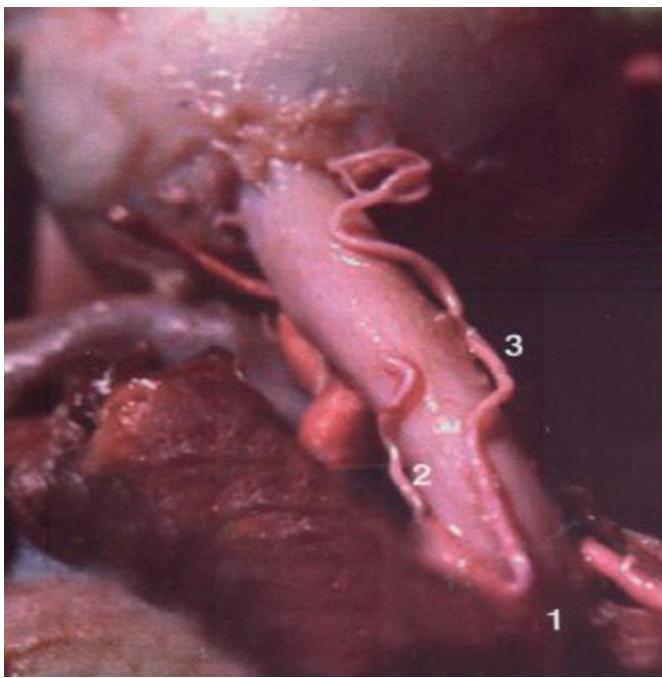

Figure 10.1 Ophthalmic artery (1) branching to the central retinal artery (2) and a main lateral ciliary artery (3). (From Ducasse et al 1986.⁵²⁹)

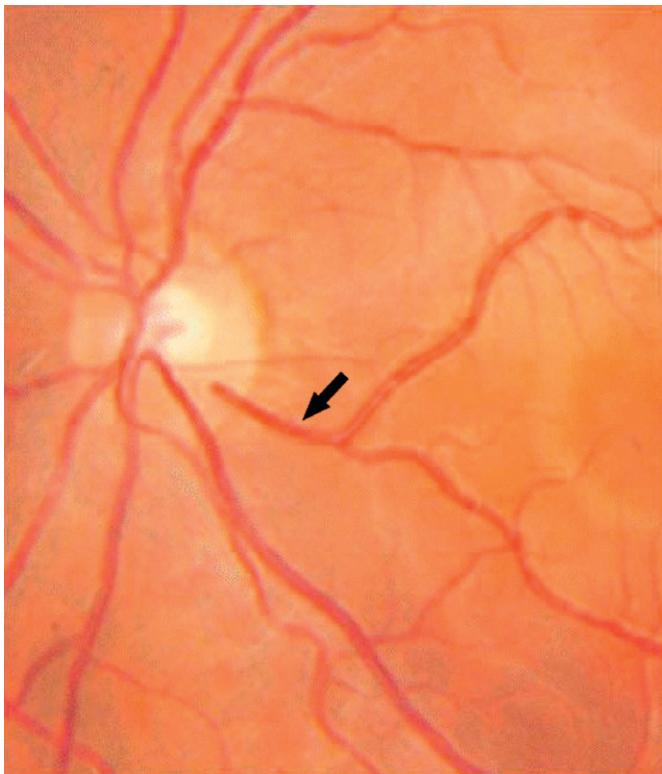

Figure 10.2 Ciloretinal artery branching around the foveal area.

Towards the periphery, the deep capillary net disappears leaving a single layer of wide-mesh capillaries. Similar anastomotic capillaries connect the perifoveal terminal arterioles with the venules, leaving a capillary free zone of 400–500 µm in diameter. At the extreme retinal periphery

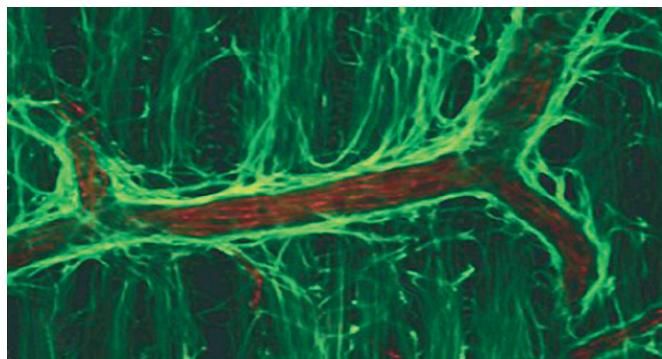

Figure 10.3 Spatial relationship between astrocytes and endothelial cells. Double immunostaining showing GAFP-positive astrocytes (green) in close relation to endothelial cells delimitated by occludin positive interendothelial junctions (red). (From Pournaras et al 2008.⁵³⁰)

an approximately 1.5 mm wide area is avascular. A capillary free zone also surrounds the arterioles, probably resulting from the local high oxygen tension affecting the capillary remodelling during maturation of the retinal vascular system.¹²

The terminal vessels, namely the precapillary arterioles and the postcapillary venules, are linked through the capillary bed, the venous system presenting a similar arrangement as the arterioles' distribution. The central retinal vein (CRV) leaves the eye through the optic nerve to drain venous blood into the cavernous sinus.

Vascular supply of the choroid

The vasculature of the choroid derives from the OA via branches of the 2–3 nasal and temporal main CAs and the ACAs, which supply the corresponding hemisphere of the choroid.^{3,4} The main CAs branch into 10–20 short PCAs, which enter into the globe at the posterior pole and assume a paraoptic and perimacular pattern¹³ before branching peripherally in a wheel-shaped arrangement, and two long PCAs. Secondary and tertiary branches of the short PCAs are subsequently divided into the major choroidal arteries.^{3,4} Some branches of these PCAs are selectively directed to the macular region vessels, namely the very short CAs.¹⁴

Paraoptic pattern

Medial and lateral paraoptic short PCAs converge towards the ONH and form an elliptical anastomotic circle, the so-called circle of Haller and Zinn, through the formation of superior and inferior perioptic optic nerve arteriolar anastomoses¹³ (Fig. 10.4) The circle of Haller and Zinn is incomplete in 23 percent of cases and complete with narrowed sections in 33 percent of cases.¹⁵ These variations could possibly make this part of the optic nerve head (ONH) circulation particularly vulnerable to ischemic attacks. Paraoptic short PCAs also supply the peripapillary choroid, whereas distal short PCAs supply only the peripheral choroid.¹⁵

Perimacular pattern

The PCAs follow long, oblique intrascleral courses and travel in the virtual suprachoroidal space, giving off recurrent branches to the macula and to the anterior choroid at the

ora serrata. Recurrent branches supply choroidal areas at 3 and 9 o'clock meridians.¹⁶ The ACAs perforate the sclera at the insertion of the tendons of the muscles and pass through the suprachoroidal space to enter the ciliary body. They primarily supply the ciliary body and iris; in addition, the ACAs are divided into recurrent branches that supply the anterior choroid.¹⁷ The choroid is composed of the choriocapillaris layer, the medium vessels layer (Sattler's layer) and the outer layer of large vessels (Haller's layer). In primates, the medium layer contains large arteries measuring 40–90 µm, large veins measuring 20–100 µm and nerves.¹⁸ The choriocapillaris and the medium-sized choroidal vessels lie between the apical retinal pigment epithelium (RPE) of neuroepithelial origin and the outer choroidal pigment of neural crest origin. Two collagenous structures, one on the inside (Bruch's membrane) and one on the outside (subcapillary fibrous tissue), are connected by the intercapillary pillars. Most medium-sized vessels are external to the subcapillary fibrous tissue.¹⁹ Some branches of the short PCAs are selectively directed to the macular region. They have a

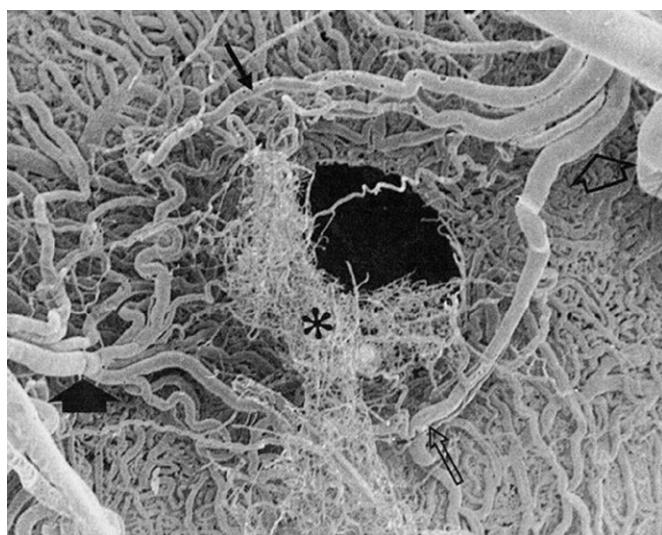

Figure 10.4 Scanning electron microphotograph of circle of Haller and Zinn formed by branches of lateral paraoptic short PCAs (empty arrowhead) and a medial paraoptic short PCA (empty arrowhead) forming a superior (long solid arrow) and inferior anastomosis (long empty arrow). Star: Retrolaminal capillaries plexus. (Reprinted from Olver et al⁵³ by permission from Macmillan Publishers Ltd, copyright 1990.)

spiral-shaped configuration, consistent with the vascular pattern of the arterial phase in indocyanine angiography. This pattern differs from that of those short PCAs which are not directed to the macular area, in that it expands in a typical chevron (V-shaped) configuration (Fig. 10.5A).²⁰

In vivo studies show that the PCAs and all their branches right down to their terminal arterioles and the choriocapillaries have segmental distribution with no functional anastomoses between them and thus behave as end-arteries.^{4,21} The borderline area between the territories of distribution of any two end-arteries is defined as watershed zone, considered as an area of comparatively poor blood flow supply, more vulnerable to hypoxia-ischemia.²² In exudative age-related macular degeneration (AMD), a stellate pattern of the watershed zone is often observed.²³ Choroidal neovascularization arises within this watershed zone in 88 percent of AMD patients.²³ The relation between the site of choroidal neovascularization and the macular watershed zones suggests that these zones may be vulnerable to choroidal neovascularization induced by hypoxia-ischemia in AMD.

The choriocapillaris are distributed as a dense network of one layer of freely connected capillaries in the peripapillary and submacular area. This pattern changes to a lobule-like arrangement in the posterior pole and to a palm-like organization more peripherally.²⁴ Each lobule, 0.6–1.0 mm diameter, consists of a capillary meshwork with radial and circumferential arrangement with an arteriole in the middle and a venule at its periphery (Fig. 10.5B).^{24,25} Lobules in the equatorial part of the choriocapillaris are larger (200 µm) than those located both at the posterior pole (100 µm), and in the submacular area (30–50 µm).¹⁴ The lobules subdivide the choroid into several functional islands. The choroidal capillaries are connected by a discontinuous row of "zonulae occludens". The part of the choriocapillaris that faces the RPE has large fenestrations, larger and more numerous in the submacular area,²⁶ covered by a thin membrane with a central thickening.^{27,28} Blood is discharged from the lobules of the choriocapillaris by collecting venules that join the afferent veins. At the posterior pole, a venule is located at the periphery of the lobule, stays on the same plane of the lobule, and possibly also drains adjacent lobules.¹⁶ Intervernular channels between choriocapillaries collecting venules and larger veins, direct arteriovenous anastomosis, and interdigitation between the choriocapillaris and venules are present in humans.^{16,24} The meshwork of the venous plexus

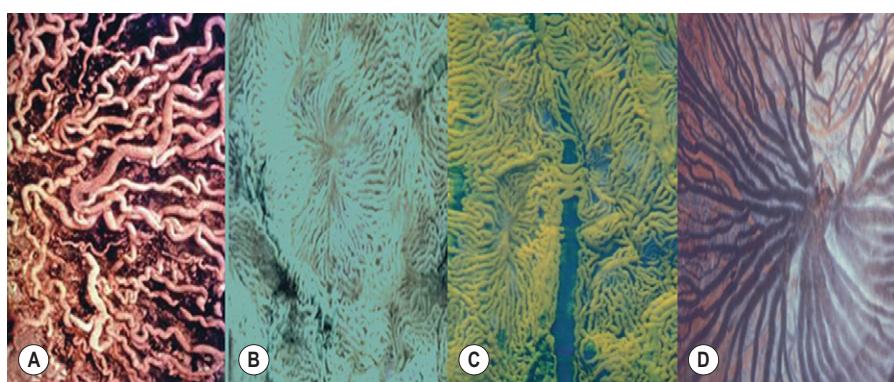

Figure 10.5 (A) V-shaped configuration of the posterior short ciliary arteries. (B) Subfoveal choriocapillaris lobules. (C) Vertical venous trunk seen through the dense net of the choriocapillaris. (D) Net of a vortex vein: efferent veins centripetally towards the ampulla. (From Cerulli et al 2008.⁵³²)

becomes less dense with increasing distance from the macula and the vessels become straighter, losing the tortuous aspect, which is characteristic of the macular region (Fig. 10.5C,D). Vessels of larger lumen form the subcapillaris plexus and eventually flow into the vortex veins.¹⁶ Four to six vortex veins are located 2.5–3 mm posterior to the equator, closer to the vertical meridian than to the horizontal one and drain into the superior and inferior orbital veins.²⁹ Some drainage also occurs through the anterior ciliary veins of the ciliary body. Segmental venous drainage with watershed areas oriented horizontally through the disk and fovea and vertically through the papillomacular area is observed.^{30,31}

Fine structure and innervation of retinal and choroidal vessels

Retinal arteries differ from arteries of the same size in other organs in that they have an unusually well-developed smooth muscle layer and lack an internal elastic lamina (Fig. 10.6). The smooth muscle cells are oriented both circularly and longitudinally, each being surrounded by a basal lamina that contains an increasing amount of collagen toward the adventitia.³² Retinal arteriolar precapillary annuli are observed in a number of animals at the arterial side-arm branches, but not in humans.³³

The capillary wall is composed of three distinct elements: endothelial cells, intramural pericytes, and a basement lamina. At their thickest point the endothelial cells present a nucleus bulging into the vessel lumen and express several cytoplasmic processes. Tight junctional complexes are found along the opposing surfaces of adjacent cells.³⁴ The continuous endothelial cell layer is surrounded by a basal lamina within which there is a discontinuous layer of intramural pericytes in almost a one-to-one ratio with the endothelial cells. The recognition that pericytes are highly contractile cells, coupled with their uniquely high representation in the retinal microvasculature has led to the hypothesis that these cells play an important role in the regulation of retinal blood flow.^{35,36,37} However, direct *in vivo* evidence for this role is still lacking.

Histologic studies and autonomic nerve stimulation experiments reveal a rich supply of autonomic vasoactive nerves to the choroid but not to retinal vessels. Sympathetic nerves derived from the superior cervical sympathetic ganglion innervate the choroidal vascular bed as well as the CRA up to the lamina cribrosa but not further into the retina.^{38,39} Nevertheless, along the ONH and within the retina, α - and β -adrenergic receptors⁴⁰ and receptors for angiotensin II are present.⁴¹ As sympathetic nerve fibers to other tissues, the choroidal sympathetic nerve fibers are immunoreactive to neuropeptide Y.⁴²

In the human choroid there are not only numerous nerve fibers but also choroidal ganglion cells (CGCs).^{43,44} Histochemical and immunohistochemical studies performed in whole mount preparations allowed precise classification and quantification of these CGCs. A comparative study of different mammalian eyes demonstrated that larger numbers of CGCs (up to 2000/eye in humans) are present only in eyes of primates with a well-developed fovea centralis, namely humans and higher monkeys.⁴⁵ These CGCs stain for neural nitric oxide (NO) synthase (nNOS) and vasoactive intestinal polypeptide (VIP).^{45,46} Targets innervated by these CGCs

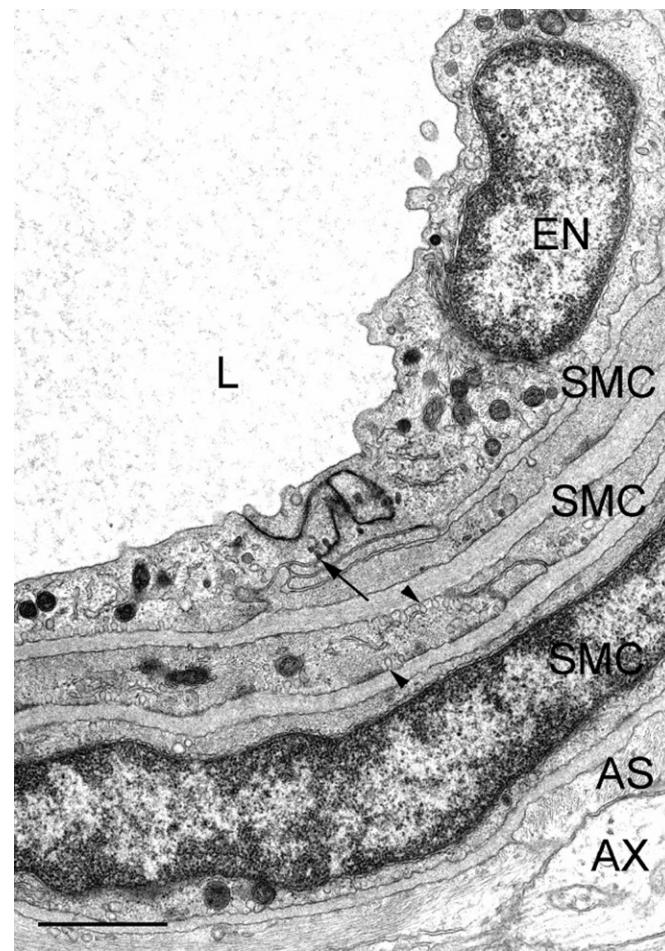

Figure 10.6 Electron microscopy image of the wall of an artery in the inner pig retina. The vessel wall is composed of the endothelium (EN) and three layers of smooth muscle cells (SMC), with numerous caveolae (arrowheads). Note high contrast in intercellular cleft and vesicular pits up to the site where a tight junctional element is located (arrow). L = lumen, AS = astrocytic processes, AX = axon. (From Pournaras et al 2008.⁵⁹)

include arteries and non-vascular smooth muscle cells attached to the choroidal elastic network and the walls of the choroidal arteries. Thus, these CGCs seem to be involved in control of choroidal thickness and blood flow. In addition, the postganglionic nerve fibers of the CGCs presumably support the vasodilative function of the facial nerve.⁴⁷

The parasympathetic system provides vasodilating fibers to the choroid through the facial nerve,⁴⁸ as confirmed by stimulation experiments in rabbit, cat, and monkey.^{49,50} VIP immunoreactive nerve fibers, originating in the pterygopatine ganglion, have been observed around choroidal blood vessels in several species, including man.⁵¹ Furthermore, the parasympathetic perivascular nerves are immunoreactive for both nNOS and VIP.^{45,52} Additional neuropeptides like peptide histidine isoleucine (PHI) and pituitary adenylate cyclase polypeptide (PACAP) could be present in some of the parasympathetic nerve fibers as well.⁵³

Vascular supply of the anterior segment

The vascularization of the anterior segment originates from the ACAs and the long PCAs. These PCAs have an intrascleral

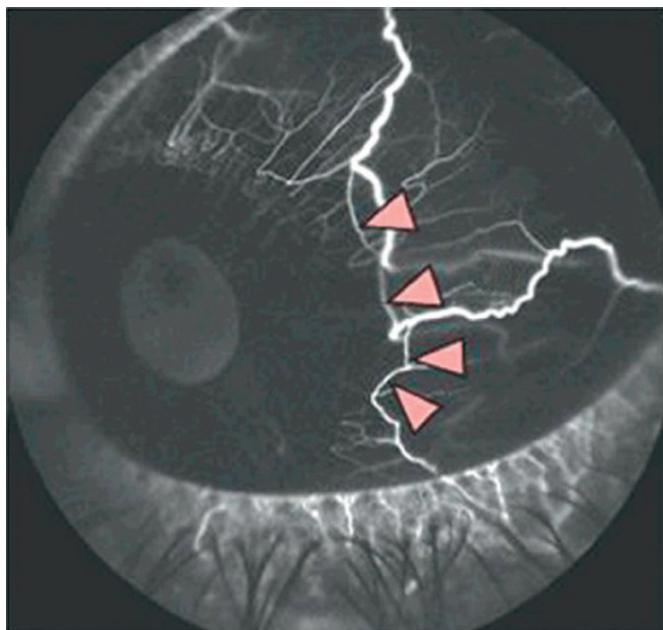

Figure 10.7 ICG angiography indicating the episcleral arteries running forward in the episcleral space assuming a circumferential course near the limbus and forming the episcleral arteriolar circle (arrowheads). (From Pournaras et al 2008.⁵³⁰)

course beneath the medial and lateral rectus muscles.⁵⁴ They run forward to the ciliary body and the iris, where they give rise to their terminal branches. The ACAs have an extraocular course within the rectus muscles.⁵⁴ Close to muscle tendons, they exit the muscles and run radially towards the limbus within Tenon's capsule. Close to the limbus they give rise to superficial (episcleral) and deep (scleral) branches.^{54,55} The episcleral arteries run forwards in the episcleral space; near the limbus they assume a circumferential course and anastomose each other to form a fragmentary episcleral arterial circle (Fig. 10.7).

Penetrating vessels through the sclera give rise to branches that vascularize the iris (major arterial circle of the iris) and the ciliary body (intramuscular arterial circle). In addition, species-dependent intramuscular arterial circle located within the ciliary body has been described.⁵⁶ The penetrating vessels give rise, through recurrent branches, to a communication between the ACAs and PCAs.¹⁷

The vascular supply of the ciliary processes is complex and species-related.⁵⁶ Three territories of supply have been described in humans.¹⁷ The first territory, situated mainly at the broadened base of the anterior edge of the major ciliary process, is irrigated by anterior arterioles leading to a capillary network. The capillaries drain into venules located deep in the ciliary processes with little connection to the other vascular territories. The second territory is also derived from the anterior portion of the major ciliary processes and drains into a broad marginal vein at the inner edge of the ciliary process. The third territory provides blood irrigation to the posterior of the major ciliary processes and the minor ciliary ones. A schematic representation of the vascular supply of the human ciliary body is shown in Figure 11.2B.

The arterial supply of the iris originates mainly from the long PCAs and the ACAs. The long PCAs divide themselves in terminal branches to form the big arterial circle of the iris circumscribing the pupil. This circle receives also the contribution of the ACAs. Thus, the iris is supplied by the posterior and anterior ciliary net.^{54,57} Vessels with radial trajectory and a corkscrew arrangement to take care of pupillary movement arise from the iris big arterial circle to reach the rim of the pupil. They divide to form the minor arterial circle of the iris.⁵⁸ The capillaries within the iris are difficult to see; they are localized mainly in the pars pupillaris. The venules originate from the pars pupillaris of the iris and run in parallel, but in more depth than the arteries to the root of the iris, increasing their diameter.⁵⁸ At this level, they receive also a contribution from the ciliary body and head for the suprachoroidal space before reaching the vortex veins.

Transport through blood-retinal barriers

Optimal cell function requires an appropriate, tightly regulated environment. This regulation is determined by cellular barriers, which separate functional compartments, maintain their homeostasis, and control transport between them. The close inter-relationship of epithelia and vascular endothelium with extracellular structures, namely extracellular matrix and glycocalyx, may modulate the dynamic responsiveness of barrier cells. As reviewed elsewhere,⁵⁹ two major pathways control the passage through barriers, namely the transcellular pathway involving vesicles, specific carriers, pumps, and channels and the paracellular pathway through the intercellular cleft.

Transcellular pathway (transcytosis)

The transcellular pathway actively and passively transports water, ions, non-electrolytes, small nutrients, and macromolecules in an energy-dependent manner. Most proteins are transported non-selectively within vesicles, either in their fluid phase or adsorbed at the vesicular membrane (vesiculo-vacuolar transport).⁶⁰ Constitutive transcytosis (the process by which macromolecules are transported across the interior of a cell) of albumin across the vascular endothelium is particular in that each transcytotic routing, whether receptor-mediated, by adsorption or as bulk fluid, is implicated in regulating the transvascular oncotic pressure gradient of albumin.^{61,62} Fenestrations of the endothelial cell membrane are characterized by high permeability.⁶³ They are found in choroid plexi of the brain, in the choroid and in the neovessels formed during the angiogenic processes (Fig. 10.8).

Paracellular pathway

Tight junctions confer firm intercellular adhesion and regulate paracellular permeability through the intercellular cleft. Indeed, barrier properties depend on the specific molecular architecture of the tight junctions. Tight junctions are polymeric adhesion complexes with a transmembrane component composed of occludin (Fig. 10.9), claudins and junction adhesion molecules, linked to a cytoplasmic plaque containing, among other components, zonula occludens protein and cingulin.

The plaque itself is anchored to the actin cytoskeleton and to various signaling molecules that participate in the control of cell proliferation and differentiation.^{64–67} In general, water,

ions and small non-charged solutes employ the paracellular pathway by passive diffusion and with low selectivity along electrochemical and osmotic gradients that are built up by the activity of transcellular transporters or, by external gradients of solutes.⁶⁸ The characteristics of both paracellular and transcellular pathways determine the preference for small solutes for either pathway and, therefore, are important parameters for drug absorption. Drugs with high lipid solubility readily cross the lipid cell membrane bilayer, but could still be poorly absorbed into the eye due to efflux pumps in the ocular barriers (see Chapter 17).

Extracellular structures

Glycocalyx

The apical and luminal surfaces of epithelial and endothelial cells are endowed with macromolecules that are bound to the plasma membrane and build up the glycocalyx.⁶⁹ This coat, composed of glycoproteins, proteoglycans, and glycosaminoglycans, is polyanionic and thus negatively charged. Molecules like fibrinogen and albumin, enzymes, cytokines and growth factors, associate with the glycocalyx thanks to their cationic charge. By these particular electrostatic features, the glycocalyx acts as a charge-selective barrier that determines the accessibility of certain molecules to the plasma membrane.⁶²

A major function of the glycocalyx of the vascular endothelium is to sense mechanical forces generated by the blood flow and modulate the shear stress-induced release of NO.⁷⁰ Long-standing degradation of distinct components of the glycocalyx contributes to increased vulnerability of the endothelial cells, barrier function, block mechanotransduction and lead to inhibition of NO production that eventually abolishes vasodilation.

Extracellular matrix

This matrix (ECM) consists of higher-order assemblies of numerous components that are secreted in a cell-type-specific manner.^{71,72} The major barrier tissues, epithelium and vascular endothelium, both synthesize a specialized ECM scaffold, the basal lamina, at their basal and abluminal side, respectively. Basal lamina serve as cell attachment sites by means of a variety of transmembrane receptors⁷³ that are able to transmit signals between cell and ECM in either direction. The best known among these receptors are the integrins, the specificity of which is determined by the molecular characteristics of the underlying ECM. Disruption of integrin-matrix binding causes the detachment of the cells from their substrate and also causes an increase in the permeability of tight junctions.^{74,75} The interactions of cell

to cell-matrix are of great importance to insure intercellular permeability in microvascular systems. Physical, oxidative stress, and inflammatory events may affect the permeability of the intercellular junctions.^{76,77}

Inner blood-retinal barrier

The endothelium of intraretinal blood vessels is considered as the main component of the inner blood-retinal barrier (BRB) resembling the blood-brain barrier in that both separate blood from neural parenchyma. The presence of a complex network of tight junctions, the absence of fenestrations and a relative paucity of caveolae make up the tightness of the iBRB. Numerous transport systems account for the selectivity of the barrier,^{78–81} such as the transport system for glucose across the retinal capillary endothelial cells of the inner BRB, which is mediated by the sodium-independent glucose transporter GLUT1.⁸²

Pericytes

Both pericytes and smooth muscle cells provide structural support to the vasculature. The increased density of pericytes in the retinal microvasculature as compared to other organs^{83,84} has led to the presumption that pericytes play a role in the regulation of retinal perfusion by contraction and relaxation.^{37,85} Circumstantial evidence for contractility of pericytes is the expression of a number of contractile proteins, in particular α -smooth muscle actin, desmin, and non-muscle myosin.^{86–88} Moreover, pericytes express receptors for vasoactive substances, enabling them to respond by contraction or relaxation. Recent work suggests that pericytes, rather than endothelial cells, control capillary diameter, because diameter changes do not occur in pericyte-free regions. Thus, pericytes would play a major role in redirecting blood flow at the capillary level.⁸⁹ However, direct *in vivo* evidence for this role in the retina is still lacking.

Pericytes modulate barrier permeability since they express a high number of caveolae that appear to be involved in transcellular transport.⁹⁰ Moreover, pericytes and smooth muscle cells participate in the permeability properties of the basal lamina by secretion of matrix components.^{86–88} Deficient contractility of pericytes and smooth muscle cells may thus have a negative impact on the regulation of blood flow that, in turn, may impair pericyte-endothelial interactions, critical for the maintenance of the BRB.

Glial cells

In the retina, both astrocytes (Fig. 10.3) and Müller cells participate in vessel ensheathment, whereby astrocytes are confined to the optic nerve fiber and the ganglion cell layer.⁹¹ Glial cells play an important role in vessel integrity and barrier properties, both via direct contact⁹² and through release of humoral factors.⁹³ Glial cell line-derived neurotrophic factor (GDNF) has been recognized to enhance barrier tightness,⁹⁴ whereas transforming growth factor- β (TGF- β) appears to decrease it.⁹⁵ Several other growth factors and cytokines, such as tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6), and vascular endothelial growth factor (VEGF) are produced by retinal glial cells⁹⁶ and affect the tightness of the iBRB. VEGF directly downregulates tight junctional proteins, evoking a decrease in transendothelial resistance⁹⁷ (Box 10.1).

Box 10.1 Anti-VEGF treatment of age-related macular degeneration (AMD)

VEGF is the predominant vasoproliferative factor involved in the development of retinal or subretinal neovascularization, occurring either during the evolution of retinal ischemic microangiopathies, or exudative neovascular AMD. Ocular neovascularization regresses following intravitreal injections of monoclonal antibodies inhibiting isoforms of VEGF-A. Anti-VEGF treatment is actually the predominant approach for the treatment of neovascular AMD.

Outer blood-retinal barrier

The outer blood-retina barrier (BRB) is composed of three structural entities, the fenestrated endothelium of the choriocapillaris, Bruch's membrane, and the retinal pigment epithelium (RPE).

Fenestrated endothelium

The fenestrations of the choriocapillaris are covered by a thin membrane with a central thickening.^{27,28} They have high permeability,⁹⁸ similar to that of an isoporous membrane with a pore diameter of 4 Å,⁹⁹ which probably accounts for the maintenance of an adequate concentration of glucose and other nutrients at the RPE level.²⁷

Retinal pigment epithelium

The RPE cells are equipped with an elaborate transcellular pathway system and an apico-lateral seal formed by intercellular junctions, the adherens junction and the tight and gap junctions, as well as, in some species, desmosomes.¹⁰⁰ The RPE is considered as a relatively tight epithelium with a 10 times higher paracellular than transcellular resistance (Fig. 10.10).^{101,102}

Nutrients and vitamin A are transported in basolateral to apical direction from the blood to the photoreceptors. In the opposite direction, transcellular transport from the subretinal space towards the choriocapillary bed is required for removal of metabolites, water, and ions. The transepithelial ion transport is linked to the transport of lactic acid, the major metabolic end product of neuronal function.

Bruch's membrane

Using electron microscopy, five distinct layers of Bruch's membrane have been defined: the two basal laminae of the RPE and the endothelium of the choriocapillaris, the inner and outer collagenous layers, and a central discontinuous elastic layer.^{103,104} Bruch's membrane provides tensile strength and, thanks to the presence of proteoglycans, constitutes a reservoir of growth factors. Its overall negative charge is due to the high content of glycoconjugates and it is responsible for charge-selective restriction to the passage of ions and solutes.

Blood-aqueous barriers

Secretion of the aqueous humor and its transport towards the posterior chamber is controlled by the blood-aqueous barrier (BAB). These barriers, which possess active transport

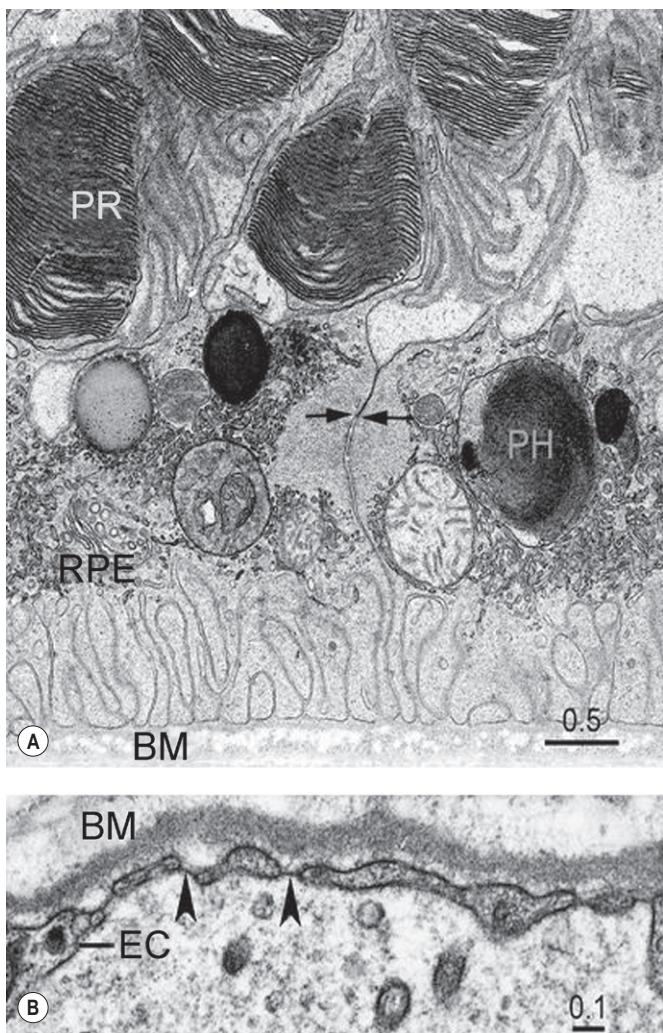

Figure 10.10 (A) Electronic micrography of the outer blood-retinal barrier. The retinal pigment epithelium (RPE) encloses the extremities of the external segments of the photoreceptors (PR) by means of long apical digitations, which are indicated by the two opposed arrows. At the basal pole, the plasma membrane forms numerous invaginations, the extremities of which rest on the basal lamina and form a part of Bruch's membrane (BM). PH = phagosome resulting from the internalization and lysosomal digestion of external segments. (Bar: 0.5 μm). (B) Detail of the fenestrated endothelium of the choriocapillaris. The fenestrations of the endothelium cell (EC) are indicated by arrowheads. The contrast of the membranes and basal lamina was increased by tannic acid. (Bar: 0.1 μm). (From Rungger-Brändle & Leuenberger 2008.⁵³³)

mechanisms, include the endothelium of the iris capillaries, the iris posterior epithelium, and the non-pigmented posterior epithelium of the iris. The passive permeability of the BAB depends on the ionic concentration gradients.

Composed of iris capillaries and pigmentary epithelium, the anterior BAB allows the transcellular transport by means of vesicles. The paracellular transport is controlled by the extension of the tight junctions. Associated with the ciliary and retinal pigment epithelium, the iris pigment epithelium seems to constitute an obstacle to the passage of type T activated lymphocytes.¹⁰⁵ The anterior surface of the iris, formed by only one layer of fibroblasts, does not constitute a barrier.

It allows free access of the aqueous humor to the stroma and the iris muscles, thus causing the rapid resorption of drugs present in the aqueous humor.

The posterior BAB is formed by tight junctions, which are present on the lateral pole of the cells of the non-pigmented ciliary epithelium (Fig. 10.11). These tight junctions are permeable to small, non-ionic molecules, such as sucrose.^{106–108} The capillary endothelium of the ciliary stroma possesses fenestrations that make its permeability relatively high. In contrast, the capillaries of the ciliary muscle appear relatively tight, similar to those of the iris.

Techniques for measuring ocular blood flow

Decades of technical developments have led to a number of methods to obtain quantitative information on ocular blood flow (BF) in animals and humans.

Techniques used in experimental animals

These techniques have been valuable for quantitative determinations of BF in experimental animals. They include direct measurements of BF through cannulation of uveal veins in rabbits and cats,¹⁰⁹ and radioactively labeled microspheres.¹¹⁰ Calorimetry,¹¹¹ or heated thermocouple,¹¹² radioactive krypton desaturation,¹¹³ hydrogen clearance,¹¹⁴ iodoantipyrine I¹¹⁵ It should be I 125, 5,¹¹⁵ laser speckle phenomenon-/flowgraphy,¹¹⁶ targeted dye delivery,¹¹⁷ leukocyte dynamics by fluography,¹¹⁸ and invasive laser Doppler flowmetry¹¹⁹ have been used to determine changes in flow in the various ocular tissues.

Intracardiac injections of radioactively labeled, non-labeled colored or fluorescent microspheres permit determination of regional BF to the different tissue beds within the eye by analyzing the distribution of the microspheres.^{120–124} Ideally, the relative quantity of particles recovered in each organ, compared to the total number of injected particles, equals the fraction of the cardiac output to each organ. The precision of the various microsphere techniques depends on several factors, including the number of particles trapped in the tissue sample. The accuracy of BF measurements within small tissue samples, such as the retina, the iris, or the optic nerve, can be improved if the number of samples is increased.¹²⁵

With direct cannulation of the uveal veins, the BF within the uveal tract has been measured in rabbits¹⁰⁹ and cats.¹¹² In cats, there is a large intrascleral venous plexus that permits sampling of venous blood from either the anterior uvea or the posterior choroid. This plexus has been used to determine arteriovenous differences of oxygen¹²⁶ and glucose.⁹⁸ A similar plexus exists in the retrobulbar space of the rabbit eye. Retinal arteriovenous differences can be studied in a variety of animals, including the pig, in which the retinal veins form a ring-shaped plexus around the optic nerve within the retrobulbar space.⁷⁸

Studies of the oxygen partial pressure profile within the retina with microelectrodes have provided information on the relative importance of the choroidal and retinal circulation in providing oxygen to the retina.^{127,128} Glucose consumption *in vivo* can be studied by determining the tissue

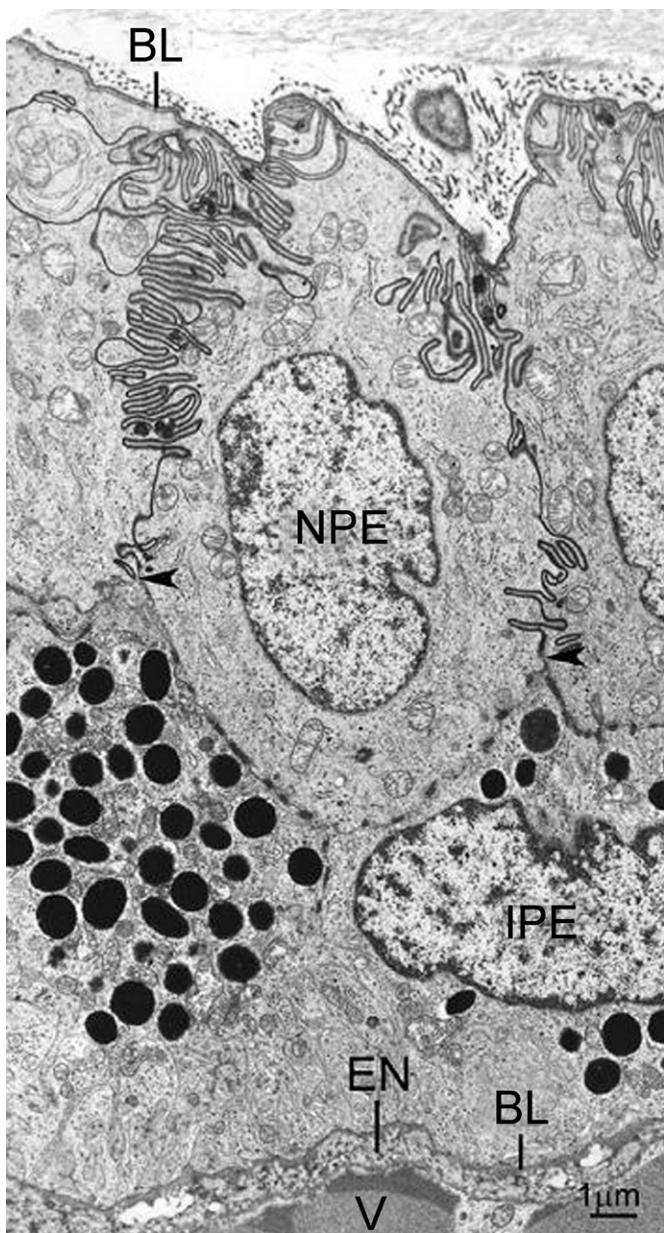

Figure 10.11 Pars plicata of the ciliary body of the rabbit eye. Electronic micrograph showing the internal retinal pigment epithelium (IPE) and the external, non-pigmented epithelium (NPE). The limitans lamina separating this layer of the vitreous body is a basal lamina (BL), which is tightly associated with the plasma membrane of the non-pigmented cells. Collagen fibers (shown as transversal or sometimes oblique cut) are present between the basal lamina of the pigmented epithelium of the perivascular space. Deep interdigitations are visible on the lateral faces of the non-pigmented cells, which adhere to the pigmented cells through numerous junctional complexes (arrowheads) including tight junctions. The contrast of the membranes and intercellular spaces is accentuated by the addition of tannic acid during tissue fixation. EN = choroidal endothelium; V = endovascular space. (Bar: 1 μ m) (From Rungger-Brändle & Leuenberger 2008.⁵³³)

uptake of labeled 2-deoxy-D-glucose. Although it is not a direct measure of BF, this technique gives an estimate of alterations in metabolic demands and has proved very useful for studying the effects of increased intraocular pressure (IOP) and light on the retina and the optic nerve.^{129,130}

Non-invasive techniques used in physiological and clinical research

A number of techniques have been developed to obtain quantitative information on the physiology, pharmacology, and pathology of the blood circulation in the different ocular vascular beds.

The diameter (D) of retinal vessels has been measured in the past from magnified fundus photographs using a caliper or by scanning across the vessels.¹³¹ In recent years, the Retinal Vessel Analyzer (RVA)¹³² has simplified markedly this measurement, allowing also the quasi-continuous recording of D changes evoked by various physiological maneuvers (dynamic measurements) (Fig. 10.12).

The mean circulation or transit time (MCT or MTT) of fluorescein injected intravenously through a retinal segment (Fig. 10.13A) has been assessed from digitized fluorescein angiograms. The gray scale level is used as an estimate of the relative dye concentration (dilution curves) in the artery feeding and the vein draining the segment and the MCT/MTT has been determined from these dilution curves (Fig. 10.13B). Specific conditions related to the retinal segment, the properties of the dye, the mode of its injection, the method of recording the dilution curves and the correction for dye recirculation must be fulfilled to obtain precise data on MCT/MTT.^{133–137} In the application of this technique to the eye, some of these conditions cannot be strictly satisfied, particularly in cases of retinal vascular pathology (for instance, in proliferative retinopathy, diffusion of fluorescein from the retinal vessels may distort the dilution curves), so that the measured MCT/MTT must be regarded as an approximation of the true MCT/MTT. Other parameters have been derived from the time course of the fluorescence intensity: the mean velocity of the dye (MVD)¹³⁸ in a retinal artery, the arterio-venous passage time (AVP),¹³⁹ which is the time difference between the first appearance of the dye at a reference point at the temporal retinal artery and that at the adjacent vein. Contrary to the MCT, which gives more weight to the peripheral retinal circulation, the AVP represents mainly the passage time of dye through the shortest segments close to the papilla and thus does not reflect the flow of fluorescein through the periphery of the retina. A study in monkeys, undertaken to determine the correlations between MCT and AVP and retinal BF, the latter measured by labeled microspheres, showed that these correlations were not statistically significant ($p > 0.05$),¹⁴⁰ even in the case of calculation of the MCT using the more sophisticated impulse response technique.¹³⁷ Clearly, MCT and AVP data should not be interpreted in terms of BF.

For studies on the choroidal circulation, indocyanine green (ICG) is a more suitable dye.¹⁴¹ ICG has two significant advantages over fluorescein for choroidal angiography: the fluorescence of ICG is in the near infrared and, therefore, not blocked by the pigment epithelium and ICG is almost completely bound to proteins, which means that it does not easily pass the walls of the choriocapillaris. Single choroidal vessels can be observed even late in the angiogram. The need for a special camera and frequent difficulty in interpretation of ICG angiograms have somewhat limited widespread acceptance. An obvious use for ICG is to examine subretinal neovascular membranes, where it is a valuable complement to, but not a substitute for, fluorescein angiography.¹⁴²

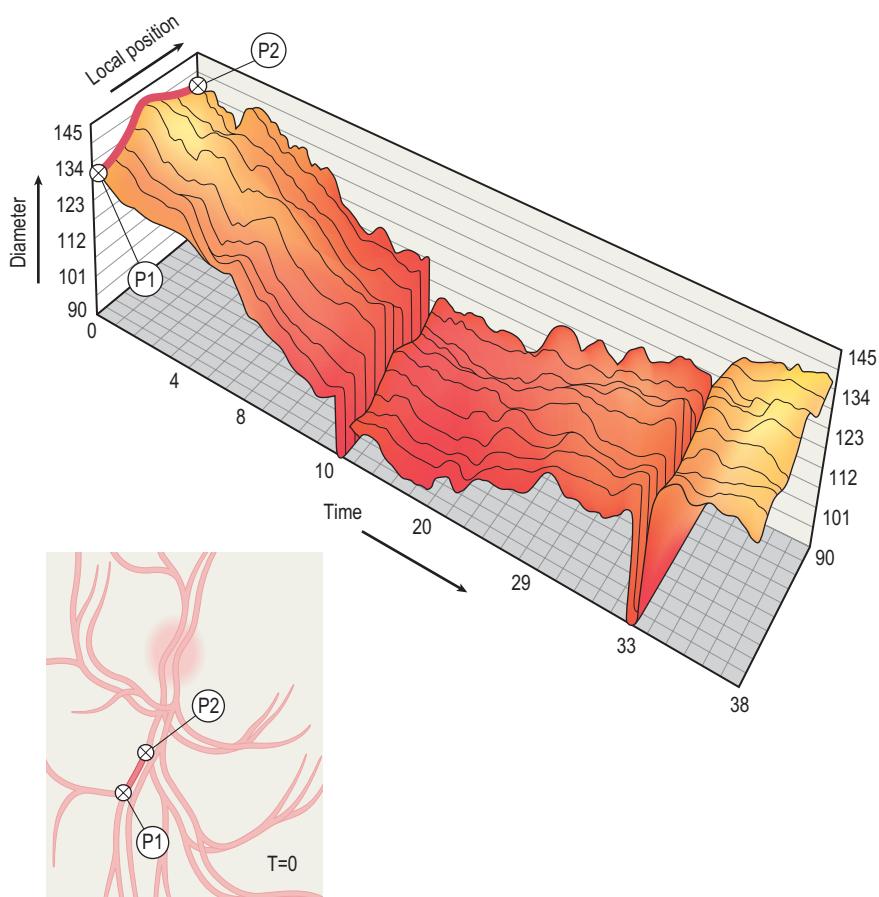

Figure 10.12 Diameter, D, of a retinal vessel along a segment P1–P2 and variation of D with time measured using the Retinal Vessel Analyzer (RVA). At time t = 0, the subject was given 100 percent O₂ to breathe. (From Seifert & Vilser 2002.⁵³⁴)

Using recently developed techniques allowing simultaneous optical coherence tomography and ICG fluorescence¹⁴³ may offer a new approach to clinical studies of choroidal blood flow.

Bidirectional laser Doppler velocimetry (BLDV) allows the measurement of *absolute* blood velocity. BLDV is based on the Doppler effect (Fig. 10.14). Retinal BF (in $\mu\text{l}/\text{min}$) in the main retinal vessels is calculated from the centerline velocity (V_{max}) of the red blood cells (RBCs) combined with D measurements of these vessels and calculating the instantaneous

$$BF_{\text{mean}} = \pi \frac{D^2}{4} V_{\text{mean}}$$

V_{mean} represents an average over the vessel cross-section. The average RBC velocity during the heart cycle is obtained by integrating V_{mean} over this cycle. For a parabolic velocity profile, $V_{\text{mean}} = V_{\text{max}}/2$. The assumption of this type of profile is justified when measurements are performed at straight portions of a vessel, a few vessel diameters away from an arterial branching or a venous junction (Fig. 10.15),^{144–146} as recently confirmed by Doppler Optical Coherence Tomography.^{147,148} In the human and primate monkey eyes, the velocity in the main retinal arteries shows a strong pulsatile component and V_{max} increases linearly with D, as found in most vascular beds.^{149,150}

Laser Doppler flowmetry (LDF) allows the measurement of the change in flux of RBCs in the superficial layer of the

ONH, the subfoveal choroid, and the iris. Calculation of this flux is based on the model of Bonner and Nossal (Fig. 10.16A).¹⁵¹ The change in flux is proportional to the change in BF if this change is not accompanied by a change in hematocrit. LDF can operate in a dynamic or scanning mode. The dynamic mode, which records the flux in a continuous way at discrete sites of the capillary bed, is particularly appropriate for recording changes of flux over time.¹⁵² The scanning mode provides a two-dimensional image of the flux in the capillaries of the optic disk and peri-papillary retina, as well as an intensity image of the retinal vessels perfused (Fig. 10.16B).¹⁵³

The temporal variations of laser speckle resulting from the interference of laser waves scattered by the tissue can be used to determine the velocity of the RBCs in the ONH, retinal and choroidal circulations.^{154,155} This laser speckle flowgraphy and the LDF approaches are different ways of looking at the same phenomenon.¹⁵⁶ Both techniques measure at a single point in the tissue. In both cases, adding scanning provides a map of the spatial velocity and flux.^{157,158} One important point when applying these laser-based techniques is that the measured flux depends on the scattering and optical absorption properties of the tissue. Therefore, direct comparison between flux values from different eyes may not be valid due to variations in the scattering properties resulting from differences in tissue structure and composition. Similarly for a valid comparison between flux values obtained at different times in the same eye by dynamic and scanning

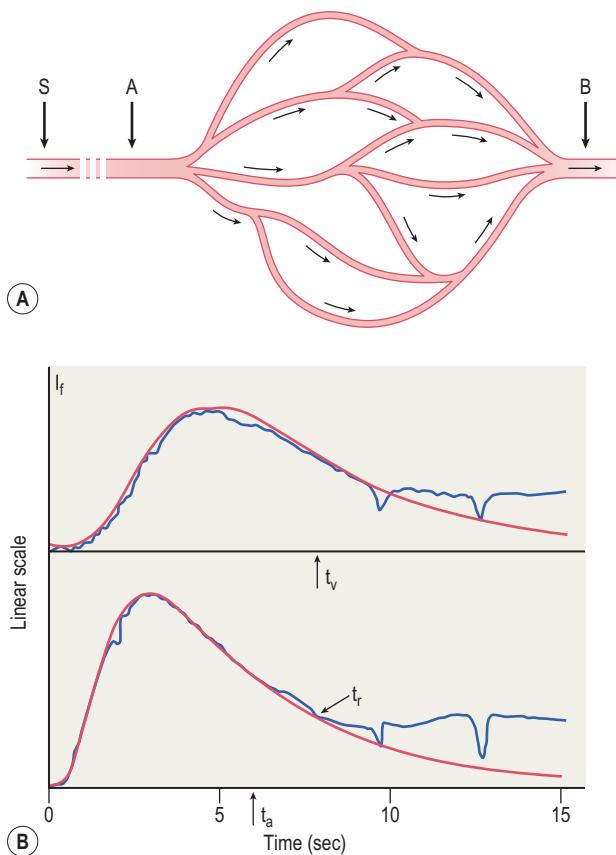

Figure 10.13 **(A)** Diagram of a retinal vascular segment extending from artery to a vein with paths of different lengths. S is the point of injection of the fluorescein dye, A the site of measurement of the fluorescence along the artery (inflow), and B the site of measurement of the fluorescence along the vein (outflow). **(B)** Fluorescein dilution curves obtained from an artery and vein of a retinal vascular segment in a human eye. t_a and t_v are the mean transit times of fluorescein measured from the first appearance of the dye in the artery. $t_a - t_v = MCT$, the mean segmental circulation time of fluorescein. I_f = fluorescence intensity. The smooth curves are the best log-normal fits to the recordings. These recordings were obtained using a two-point fluorophotometer.⁵³⁵ (From Riva et al 1978.⁵³⁶)

LDF and laser speckle flowgraphy, the tissue must be assumed to maintain the same scattering properties over time.¹⁵⁹

The velocity, number and velocity pulsatility of leukocytes moving in the retinal capillaries of the macular region has been quantified using the blue field simulation technique, which is based on the entoptic perception of one's own leukocytes.¹⁶⁰ Visual acuity must be better than 20/50 for a reliable measurement.¹⁶¹ The ability of a subject to do the blue field simulation test can be assessed by having subjects match the speed and number of two simulated leukocyte's motions displayed on computer screens. Blue field data have been confirmed by the objective SLO-adaptive optics imaging technique.¹⁶²

Color Doppler imaging combines B-scan imaging of tissue structure, color representation of blood velocity based on ultrasound Doppler-shifted frequencies, and pulse-Doppler measurements.^{163,164} At the level of the OA, CRA, and PCAs, the maximum and minimum values of the velocity are identified to determine the peak systolic (PSV)

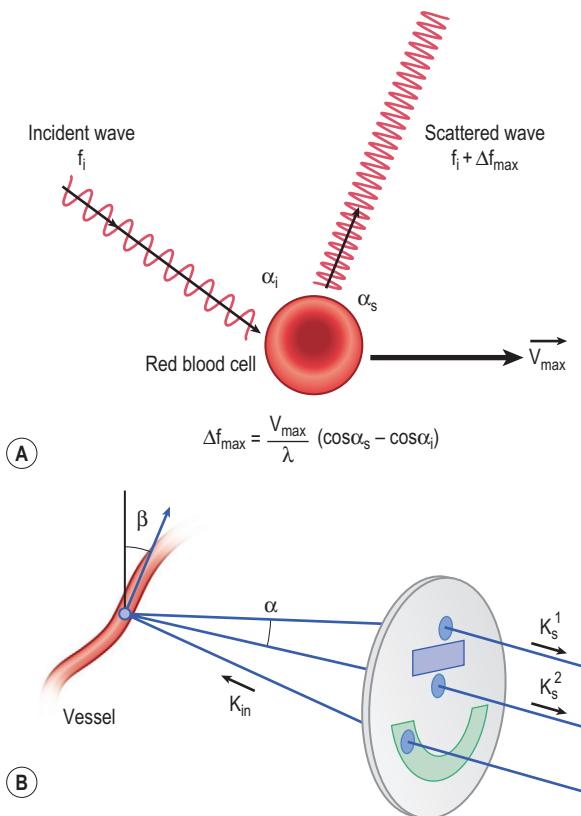

Figure 10.14 **(A)** The Doppler effect. The frequency of laser light scattered by a red blood cell (speed V_{\max}) is shifted by an amount Δf_{\max} compared to the frequency of the light incident (f_i) on the red blood cell. α_i and α_s are the angles between V_{\max} and the directions of the incident and scattered light, respectively. λ is the wavelength of the incident light. (With permission from Riva & Petrig 2003.⁵³⁹) **(B)** Principle of bidirectional LDV (BLDV). Laser light scattered from blood in a retinal vessel is detected along two directions K_s^1 and K_s^2 (angle α between them). β is the angle between the plane of the vessel at the site of measurement and the direction of the blood velocity. V_{\max} , the centerline velocity of the RBCs is determined from the maximum shifts in the Doppler shift power spectrum obtained in each scattering direction and the geometrical scattering parameters. The measurement is independent from the direction of the incident light defined by K_{in} .^{536,537} (From Riva et al 1981.⁵³⁷)

and end diastolic (EDV) values of this velocity from which a resistivity index (RI) is obtained:

$$RI = \frac{(PSV - EDV)}{PSV}$$

RI is often considered as a measure of the downstream vascular resistance. However, experimental data show that RI in CRA is not a satisfactory measure of this resistance.¹⁶⁵ Studies on cerebral vessels have not confirmed a useful correlation between RI and cerebrovascular resistance.¹⁶⁶

Pneumatonometric measurement of ocular pulse amplitude estimates the pulsatile component of choroidal BF (POBF).^{167,168} Since the ratio of pulsatile/non-pulsatile ocular BF cannot be assumed to be constant, especially in the event of changes in systemic blood pressure, pulsatile BF is not a good estimate of total ocular BF. Another technique that makes use of the pulsatile nature of the IOP is the interferometric measurement of the IOP-induced variation of the distance between cornea and retina to

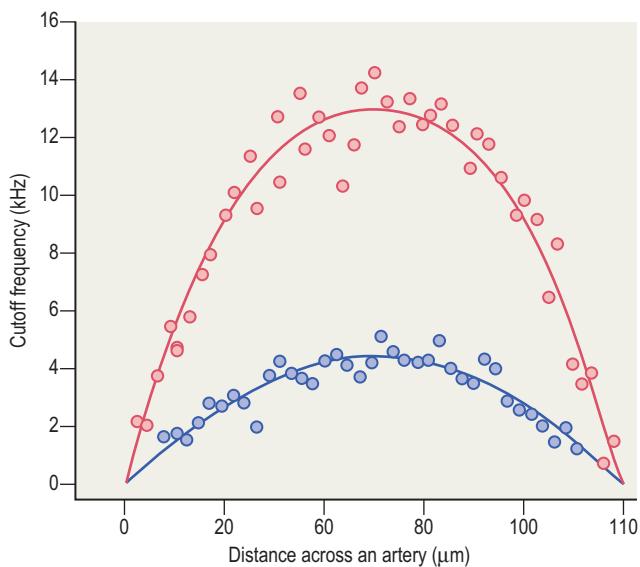

Figure 10.15 Profile of velocity of RBCs (\approx cutoff frequency of the Doppler power spectrum) in a main retinal vessel of a normal eye during the peak systolic and end diastolic phases of the cardiac cycle. The continuous lines are the best fits based on function of the type:

$$V(d) = V_{\max} \left[1 - \frac{|d - d_0|^K}{R_i} \right]$$

where $V(d)$ represents the velocity at a distance d from the internal wall. d_0 is the position of the center of the vessel. R_i is the internal radius of the vessel. V_{\max} is the centerline (maximum) velocity. $K = 2.38$ in the systolic phase and 1.94 in the diastolic phase. (From Logean et al 2003.¹⁴⁴)

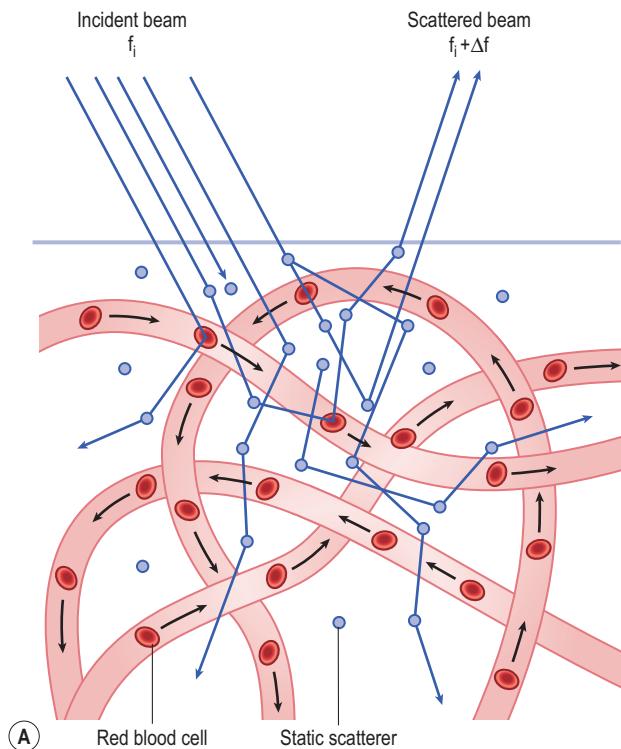

Figure 10.16 (A) Tissue scattering model of Bonner & Nossal¹⁵¹ provides the basis for Laser Doppler Flowmetry. The incident laser beam is scattered by the moving RBCs and non-moving tissue components. A spectrum of Doppler shifts, Δf , is detected in the scattered light reaching the detector due to the multitude of RBC velocities and scattering directions before the laser light reaches the detector. (Adapted with permission from Riva & Petrig 1997.¹⁵⁵) (B) Intensity and perfusion images of the optic nerve and peripapillary temporal retina obtained by laser scanning Doppler flowmetry. estimate changes in choroidal blood volume during the cardiac cycle.¹⁶⁹

The information given here on ocular BF techniques is far from exhaustive. Additional details can be found in a number of excellent reviews.^{164,170–172}

Ocular circulatory physiology

General hemodynamic considerations

BF through a blood vessel depends upon the perfusion pressure (PP), the pressure that drives blood through the vessel, and the resistance (R) generated by the vessels. For an incompressible uniform viscous liquid (dynamic viscosity η) flowing through a cylindrical tube (length L) with radius (r), BF is given by the Hagen–Poiseuille law: $BF = PP/R$, where $R = \eta L / 2\pi r^4$. Many factors make it difficult to directly apply this law to a microvascular bed. These include the η -dependence on local hematocrit, the changes in the velocity profile of the RBCs and shear rate at branchings and junctions and others. Another approach at characterizing BF through a system of vessels is based on Murray's law,¹⁷³ which says that through each vessel of a circulatory system with optimal design (blood flowing with minimal loss of energy) $BF = k(r^3/\sqrt{\eta})$. The constant k depends upon the lengths and the radius of the vessels.¹⁷⁴

The mean ocular PP driving blood through the eye is the mean blood pressure in the ophthalmic artery (OA) minus

the pressure in the veins leaving the eye. The venous pressure is close to the IOP.¹⁷⁵ With the subject in the sitting or standing position, mean ocular PP is about 2/3 of the mean brachial artery blood pressure (ABP), i.e.

$$\frac{2}{3} [ABP_{diast} + \frac{1}{3} (ABP_{syst} - ABP_{diast})] - IOP$$

The factor 2/3 stands for the drop in pressure between the heart and the OA. ABP_{diast} and ABP_{syst} are the brachial ABP during diastole and systole, respectively. It is understood that this expression for PP is based on a group average and therefore provides only an approximate value for a single individual. The value of η has been experimentally related to hematocrit at defined shear rates. It diminishes with increasing shear rate to become almost constant.¹⁷⁶ An increase in viscosity (e.g. in cases of hyperglobulinemia, high hematocrit, leukemia, sickle cell anemia) substantially alters retinal BF, which may induce a stasis in the veins and ultimately to their occlusion.¹⁷⁷

The main resistance to BF is located in the arterioles with half of the resistance in vessels with a radius of 10–25 μm . As R is proportional to $1/r^4$ even a small change in r will have a considerable effect on R . The vessel radius/diameter is modulated by the interaction of multiple systemic and local control mechanisms affecting the tone of the smooth muscle cells and perhaps the pericytes.

Ocular hemodynamic data under basal physiological conditions

Retina

Retinal BF represents only about 4 percent of total ocular BF.¹⁷⁸ In primates, total retinal BF obtained by the microsphere technique was reported to be between 25–50 ml/min/100g.^{110,179,180} In humans, recent measurements of total retinal BF (40.8–52.9 $\mu\text{l}/\text{min}$) using Fourier-Domain OCT¹⁸¹ are in the range of values obtained by BLDV.¹⁸² Retinal BF calculated from BLDV is larger in the temporal human retina than in the nasal region, supposedly due to the larger size (by 20–25 percent) and higher metabolic rate of the former. Retinal BF in the superior and inferior hemispheres are similar. This pertains also to BF in the superior and inferior parts of the macular region.¹⁸³

Choroid

In animals, choroidal BF is higher than in most tissues with estimates ranging from 500 to 2000 ml/min/100 g tissue (Fig. 10.17).^{110,112,114,126,184,185} There is no technique allowing reasonably precise measurements of choroidal BF in humans. The anatomical organization and dense vascularization of the choroid, as well as this high choroidal BF are very important. These properties optimize the partial pressure and concentration gradients for efficient diffusive exchange across the relatively long distance between the choroid and the retina for efficient delivery of oxygen and nutrients and the removal of carbon dioxide and metabolic waste.^{98,186–189} Thus about 65 percent of the oxygen and 75 percent of the glucose consumed by the monkey retina is delivered by the choroidal vessels.^{121,121a} Furthermore, in both primates and non-primates, the foveola is devoid of retinal vessels, presumably to enhance visual acuity and therefore is nourished solely by the choroid.^{185,190}

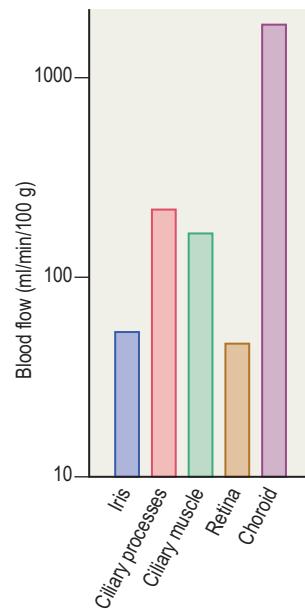

Figure 10.17 BF through tissues of monkey eye (values for BF through ocular tissues are from Alm et al 1973¹⁹⁸). (From Alm 1992.¹⁷⁸)

A possible function of the choroid is that of thermoregulation.^{180,191,192} In this case, the high BF would tend to maintain ocular temperature at or near body temperature during environmental cooling or heating, and also help protect the eye from thermal damage even under extreme conditions of temperatures and brightness. It also would prevent damaging increments in tissue temperature when light is focused on the fovea.^{188,193} In support of this role, scleral temperature falls several degrees when choroidal BF is reduced significantly.¹⁹¹

Ciliary circulation

Present knowledge of ciliary hemodynamics is limited due mostly to the inaccessible location and complexity of the ciliary vascular bed.¹⁸⁹ Direct measurements of ciliary arterial pressure have not been made, but a reasonable estimate for this pressure just outside the eye is 67 mmHg for humans in an upright position with an arterial blood pressure (ABP) of 100 mmHg. Episcleral venous pressure is approximately 9 mmHg in humans,^{194,195} which is a reasonable approximation for vortex vein pressure. However, the venous pressure inside the eye is determined by the IOP. In animals, it is 1–2 mmHg higher than the IOP.^{175,196,197} Capillary pressure is similarly IOP-dependent and approximately 8 mmHg higher than the IOP in the rabbit choriocapillaris.¹⁹⁷ Assuming that ciliary hemodynamics is similar in humans, the ciliary capillary and venous pressures should be approximately 25 and 17 mmHg, respectively, at a normal IOP of 15 mmHg.

Measurements by labeled microspheres in anesthetized monkeys indicate a ciliary BF of 81 $\mu\text{l}/\text{min}$.¹⁹⁸ Plasma clearance of ascorbate provides a rough estimate of ciliary plasma flow of 73 $\mu\text{l}/\text{min}$, or a ciliary BF of 133 $\mu\text{l}/\text{min}$ in the human eye, assuming a normal hematocrit.^{199,200}

Figure 10.18 Central retinal artery equivalent (CRAE) by mean of ABP in persons of different age groups. (From Wong et al 2003.²⁰⁹ Reproduced with permission from Association for Research in Vision and Ophthalmology.)

Vasomotion

Direct observation of the retinal and choroidal vasculature¹¹³ reveals no precapillary sphincters and BF appeared to be uninterrupted in all capillaries. In the retina of young cats some spontaneous contractions and dilatations in the small arterioles and precapillary sphincters have been observed, but there was much less vasomotion in the retinal vessels of adult cats.²⁰¹ Temporal fluctuations of ONH and subfoveal choroidal BF, with frequencies < 10 cycles/min and distinct peaks at the breathing and heart beat frequencies, have been measured in the eyes of cats,^{202,203} minipigs,²⁰⁴ and humans.^{205,206}

Effects of age on ocular blood flow

D of the main retinal arterioles and venules depends on age and blood pressure (Fig. 10.18). It is narrower in older than in younger people, independent of ABP and other factors, the decrease in D amounting to about 2 µm for each decade of increased age. Furthermore, independent of age and other risk factors, arteriolar D is narrower in subjects with higher ABP.^{207–209}

Studies of the effect of aging on blood velocity in the OA and CRA in women and men have failed to reveal uniform findings. However, clinical studies of the microcirculation of the retina and the ONH indicate that aging leads to a decrease in blood volume,²¹⁰ RBC velocity,^{210–212} and velocity and number of leukocytes in the macular area,²¹³ due presumably to the age-related morphologic decreases of retinal cells and nerve fibers.^{214,215} An age-dependent decrease in subfoveal choroidal BF has also been reported,²¹⁶ which is mainly due to a decrease in subfoveal blood volume reflecting, presumably, a reduction in the diameter and number of choriocapillaries in the subfoveal region.^{217,218}

Regulation of ocular BF

The regulation of ocular BF in the human eye is a complex process due to the presence of two vascular systems which

differ anatomically and physiologically: the retinal vessels, which supply the neural region of the retina and the prelaminar portion of the ONH, and the uveal blood vessels, which supply the rest of the eye. Contrary to the autonomically innervated extraocular and choroidal vessels, the retinal and ONH vessels have no neural innervation so that total reliance for matching metabolism must be placed on local vascular control mechanisms.³⁹

The mechanisms controlling BF in the different ocular vascular beds are of different types: systemic, local, neural, endothelial, endocrine, and paracrine. Not all operate in the various beds. Since the retinal and choroidal arterioles do not possess sphincters,³³ BF in these tissues is only a function of the muscular tonus of the arterioles and, possibly, the state of contraction of the pericytes, although the latter still remains to be demonstrated. Vessel tonus is modulated by the interaction of multiple control mechanisms: myogenic, metabolic, neurogenic, and humoral, which are mediated by the release of vasoactive molecules by the vascular endothelium or by the glial cells surrounding the vessels.^{219,220}

Autoregulation of ocular blood flow

Autoregulation of BF in a tissue is the intrinsic ability of this tissue to maintain BF relatively constant despite variations in the PP.²²¹ Investigation of this local process, which requires isolation of tissue from neural and hormonal influences, can be ideally carried out in the retina, a tissue that lacks sympathetic innervations and is largely uninfluenced by circulating hormones due to the presence of a tight blood–retinal barrier.²²²

Retina and ONH

A moderate reduction in ocular PP has only a minor or no effect on retinal and ONH BF in experimental animals^{110,115,121,122,223,224}. In humans such a reduction also induces an autoregulatory response, as evidenced by the resulting increase in D of arteries²²⁵ and the maintenance of constant retinal and ONH BF if PP is not reduced by more than 50 percent.^{226–228} An autoregulatory response is also

Figure 10.19 Time course of group average of calculated retinal vascular resistance (relative units) after a step increase of the IOP to about 35 mmHg by application of a suction cup to the limbus and a step decrease of the IOP at the removal of the cup. (From Riva et al 1986.²³⁰ Reproduced with permission from Association for Research in Vision and Ophthalmology.)

evoked by an increase in PP above normal induced by a decrease in the IOP below normal.^{227,229,230} The autoregulatory response of the retinal vascular resistance and BF to these rapid changes in PP is shown in Figure 10.19. Thanks to the autoregulatory capability of the retina and anterior part of the ONH, the oxygen tension (PO_2) in the inner half of the retina and anterior part of the ONH remains largely unaffected by moderate increases in IOP (decreases in PP).^{231–233}

Choroid

In animals, measurements of choroidal BF by various techniques have demonstrated a linear relationship between choroidal BF and ocular PP, indicating a lack of autoregulatory capacity of the choroid.^{110,114,121,184,234} The microsphere measurements obtained simultaneously from the retina and choroidal have demonstrated a marked difference in the autoregulatory ability of the two tissues.^{110,121} On the other hand, LDF data under manipulation of the ABP by occluders on the aorta and inferior vena cava in rabbits^{119,235} and bleeding in pigeons²³⁶ suggest that peripheral choroidal BF compensates for declines in ABP (decrease in PP) so as to remain relatively stable within a physiological range of PPs. This difference in response, which could be due to the different techniques used, still needs to be clarified.

In humans, measurements of subfoveal choroidal BF by LDF reveal a non-linear decrease in BF in response to a reduction in PP induced by increasing the IOP by suction cup,^{237,238} which suggests some autoregulatory capacity of the subfoveal choroid. A neural local mechanism involving the dense vasodilatory innervations of the human choroid, specifically localized in the temporal-central portion of the choroid adjacent to the fovea,⁴⁵ could be responsible for the observed behavior. The foveal avascular zone and most of the outer retina receive nutrition exclusively from the choroidal circulation. They may therefore be more susceptible to ischemia than other retinal regions. The observed subfoveal choroidal BF response may represent a protective mechanism against moderate increases in IOP above normal.

Anterior uvea

Animal studies with labeled microspheres have shown autoregulation of BF in the iris and ciliary body.^{110,121}

However, in humans, iris BF by LDF showed no evidence of being autoregulated when the ocular PP was decreased by raising the IOP by suction cup.²³⁹ Methodological or species differences and anesthesia have been invoked to explain the discrepancy between the results in animals and humans.²³⁹

Mechanisms underlying retinal and ONH autoregulation

It is likely that the mechanisms underlying autoregulation rely on a balanced contribution of myogenic and metabolic components (see below)²²² involving the interaction of factors released by the retinal metabolism and the vascular endothelium.²⁴⁰ It has been suggested that, when PP is acutely reduced by increasing the IOP, the vasodilatory response is induced by an increase in the concentration of lactate.^{226,230} Ionic, molecular, or gas modifications either of the blood or the surrounding tissue could also be involved in the vasomotor response.^{240,241} In the ONH, the autoregulatory response to a small decrease in PP was found to take place during a time of the order of a second,²²⁷ similar to the brain response.²⁴² The rapidity of this response points towards a metabolic mechanism. Studies on isolated cerebral and pial arteries of rats²⁴³ and monkeys,²⁴⁴ indeed suggests that a myogenic process develops much slower, on a time scale of 1–10 minutes. Recent evidence suggests a major role for NO in ONH autoregulation.²⁴⁵

Regulation of blood flow in response to increase in arterial blood pressure (ABP)

A number of studies have investigated the effect of an increase in systemic ABP on ocular BF. Most frequently, this increase is induced by static and dynamic exercises and posture changes, which both produce marked effects on sympathetic tone.

Static exercises

Isometrics increases heart rate, ABP, and sympathetic nerve activity.²⁴⁶ In humans, during isometrics, retinal, subfoveal choroidal, and ONH BF remain unchanged until the mean ocular PP is elevated by an average of 34–60 percent above

Box 10.2 Retinopathy of prematurity

Retinal vessel vasoconstriction under oxygen breathing in premature infants induces ischemia predominately at the peripheral single capillary layer, leading to the clinical manifestation of the initial stages of retinopathy of prematurity.

is significantly higher in the supine position than in the sitting position.²⁶⁶ This stimulus decreases retinal vessel D while peripheral and macular retinal BF remain rather unaffected,^{268,269} thus suggesting the presence of a local retinal compensatory response.

Regarding the choroidal circulation, recumbency increases subfoveal choroidal BF by approximately 11 percent,²⁶⁵ a value corresponding to the increase in ocular PP calculated from experimental data.^{266,270} This result and the linear relationship between subfoveal choroidal BF and ocular PP found in a subsequent study²⁷¹ are indicative of a passive response of this vascular bed to the increase in PP.

Regulation of blood flow in response to changes in blood gases

The role of arterial blood partial pressures of O_2 (P_aO_2) and CO_2 (P_aCO_2) on ocular BF regulation has been studied in animals and human subjects through the inhalation of various gas mixtures.

Hyperoxia

Increasing the P_aO_2 through the breathing of 100 percent O_2 results in a marked vasoconstriction of the retinal arterioles in both anesthetized animals^{272–274} and healthy human subjects,^{275–277} as well as a marked decrease in retinal BF (Fig. 10.21) in both the peripheral and macular region.^{275,276,278,279} This BF response is 3–4 times greater than that of the cerebral circulation.²⁸⁰ In contrast, choroidal BF does not change measurably when the P_aO_2 is increased.^{281–283} In humans, the selective endothelin (ET) receptor antagonist BQ-123 (see below) dose-dependently blunts the retinal response to hyperoxia, indicating that ET-1 contributes to the hyperoxia-induced retinal vasoconstriction.²⁸⁴

The response of the retinal PO_2 to hyperoxia is species-dependent. In cats, with 100 percent O_2 inspiration, the vitreal and inner retinal PO_2 increases by 30–40 mmHg.^{233,285,286} It reaches 53–88 mmHg in rats,^{287,288} and remains almost unchanged in monkeys (average 20 mmHg in the inferior retina and about 32 mmHg in the parafovea and foveal area) and in minipigs.^{273,289,290} The increased inner retinal PO_2 is not solely due to the O_2 derived from the retinal circulation, but also depends on the choroid, because during hyperoxia, O_2 diffuses all the way into the inner retina.^{286,288,291,292} In the optic disc of minipigs, the PO_2 increases moderately by about 5 mmHg during hyperoxia and increases much more (about 13 mmHg) after injection of acetazolamide under systemic hyperoxia, due to the vasodilatory effect of elevated systemic P_aCO_2 (Box 10.2).²⁹³

Hypoxia

In humans and anesthetized animals, a decrease in P_aO_2 induces in the retina a vasodilatation of the arterioles and an increase in BF^{272,294–296} which is similar to the increase in cerebral BF.^{280,297} The vasodilatation, which contributes to

Figure 10.20 Relative average change of retinal vascular resistance (A) and velocity of RBCs (B) in retinal veins, as a function of the change of the relative brachial ABP. Each data point represents the average of the mean value obtained from three subjects. (From Robinson et al 1986.²⁴⁷ Reproduced with permission from Association for Research in Vision and Ophthalmology.)

baseline (Fig. 10.20).^{247–251} Since the vessels of the retina and ONH have no neural innervations, the regulation must be achieved, at least in part, through a local increase in vascular resistance,²⁴⁷ as evidenced by the constriction of the retinal arterioles.²⁵² In the choroid, the sympathetic nervous system constricts the vessels in response to increased ABP.^{253,254} Both ET-1²⁵⁵ and NO²⁵⁶ appear to play an important role in the regulation of subfoveal choroidal BF during isometrics.

Dynamic exercises

In response to such exercises the IOP decreases,²⁵⁷ the ABP increases²⁵⁸ but peripheral and macular retinal, as well as choroidal, BF remain rather unaffected.^{259–262} The site of choroidal regulation (local or due to sympathetic activity) is still unclear. A sympathetic mechanism protecting the choroid from overperfusion has been postulated.²⁶²

Change in posture

The change from upright (or sitting) to supine induces a 16 percent decrease in heart rate, a small decrease in brachial diastolic ABP, no significant change in brachial systolic ABP,^{263–266} and an increase in IOP.²⁶⁷ The OA blood pressure

Figure 10.21 Effect of hyperoxia on (top) the diameter of retinal arteries in the four quadrants of the fundus and (bottom) the diastolic arterial velocity of a human retinal artery. (From Jean-Louis et al 2005²⁷⁷ and Riva et al 1983.²⁷⁶ Reproduced with permission from Association for Research in Vision and Ophthalmology.)

the maintenance of a rather stable P_{O_2} in the inner retina, could be due to the release of retinal lactate,^{294,298,299} a process presumably mediated by endothelium-derived NO.³⁰⁰ The increase in retinal BF allows inner retinal and vitreal P_{O_2} to remain relatively constant when the P_aO_2 is above 40 mmHg in cats and minipigs.^{121,301–303} However, below this point, inner retinal P_{O_2} falls. There is a similar protection of inner retinal P_{O_2} during modest elevation of the IOP.^{231,304} In contrast, the P_{O_2} measured close to the choroid and in the outer retina decreases linearly with the P_aO_2 .^{302,303,305}

Hypercapnia

Ocular blood vessels, like the cerebral vessels, are very sensitive to variations in the P_aCO_2 . In animals, hypercapnia dilates retinal vessels and shortens the MCT.³⁰⁶ Quantitatively, a rise in P_aCO_2 of 1 mmHg induces a 3 percent rise in retinal BF.³⁰⁶ In conscious humans, the achievable changes in P_aCO_2 are smaller. Some studies report a dilatation of retinal arteries,^{295,307} or shortening of the MCT,²⁹⁵ while others observe no such changes.³⁰⁸ Furthermore, hypercapnia

increases the mean fluorescein (plasma) velocity (MVD) in retinal arteries,³⁰⁹ macular leukocyte velocity,^{308,310} RBCs velocity in the peripapillary,³¹¹ perifoveal capillaries, and retinal and ONH BF.^{307,312,313}

Raising the $P_a\text{CO}_2$ increases choroidal BF in cats^{121,281} and humans,^{282,283} but not in rats.³¹⁴ The increase in the $P_a\text{CO}_2$ increases also retinal PO_2 .²³³ There is a tight parallelism between the $P_a\text{CO}_2$ and interstitial pH in the inner retina. Thus, an increase of the $P_a\text{CO}_2$ of 38 mmHg induces a decrease in pH of ≈ 0.16 units.³¹⁵ The fact that acidification of the blood by infusing HCl or by injecting lactate does not affect interstitial pH nor retinal BF²⁹⁹ suggests that interstitial rather than systemic acidosis contributes to the vasomotor response during hypercapnia.³¹⁵

The hypercapnia-induced increase in retinal BF occurs through a mechanism involving NOS-1,³¹⁶ the release of PGE₂²⁹⁴ or PGE₂-mediated endothelial NO.³¹⁷ Endothelial interaction between NO and PGs,^{318,319} likely controls the arteriolar tone during changes of $P_a\text{CO}_2$.³²⁰ Perfusion of the eye through the sublingual artery with indometacin, an inhibitor of PG synthase, induces a transient, reversible vasoconstriction of the retinal arterioles in normoxia/normocapnia.²⁹⁹ In rabbits intravenous administration of indometacin reduces retinal BF by about 20 percent without any effect on the uveal circulation.³²¹ An increase in $P_a\text{CO}_2$ ³²² following metabolic acidosis induced by intravenous injection of acetazolamide (a carbonic anhydrase inhibitor) increases preretinal and ONH PO_2 and dilates the retinal vessels.^{323–326}

Carbogen is a gas mixture containing 5 percent CO₂ and 95 percent O₂. The amount of CO₂ added to the O₂ was assumed to prevent the O₂-induced vasoconstriction and therefore maintain or even increase BF while providing the retina with increased oxygenation.³²⁷ This gas decreases retinal vessel D and retinal BF.^{328,329} It increases ONH and choroidal BF by LDF.^{283,330,331} Carbogen inspiration leads to elevations of inner and optic disk PO_2 that are greater than those observed with hyperoxia alone.^{233,288,323,324} The clinical value of this mixture is doubtful. It has no effect in fully developed retinal venous occlusions, whereas some improvement has been reported for selected cases of pre-occlusion of retinal veins.³³²

Metabolic control of retinal blood flow

In the retina, interactions between substances released either by endothelial or glial cells or by neurons affect the arteriolar tone, thus regulating the vasomotor responses. They may be either ionic or molecular or related to arterial blood gas modifications.^{36,219,220,240,333} These factors can be tone relaxing or tone contracting. The former include NO and prostacyclin (PGI₂), the latter endothelin-1 (ET-1), angiotensin II, and cyclo-oxygenase (COX) products, such as thromboxane-A₂ (TXA₂) and prostaglandin H₂ (PGH₂). Extracellular lactate leads to contraction or relaxation of the vessel wall, according to the metabolic needs of the tissue.³³⁴ In humans, lactate-induced retinal arteriolar dilation occurs predominantly via stimulation of NO synthase and subsequent activation of guanylyl cyclase. Lactate likely mediates either the release of endothelial vasoactive substances or interferes with the metabolism of cells

surrounding the arterioles (i.e. astrocytes, neuronal cells), leading to the release of vasoactive substances, such as NO and PGs.³³⁵ In addition, retinal arterial vasodilatation is mediated by an as yet unknown substance released by the retinal tissue and involving the activation of plasma membrane Ca²⁺-ATPase.^{336–338}

Retinal metabolism and vasoreactivity

The mammalian retina sustains an unusually high rate of glycolysis in that about 90 percent of the total glucose utilized is converted to lactate.²⁹⁸ In addition, 70 percent of O₂ consumption in the retina is due to oxidation of glucose to CO₂.³³⁹ Under normoglycemic conditions, neurons such as photoreceptor and ganglion cells, Müller glia, and pigment epithelial cells produce lactate aerobically and anaerobically at linear rates, even in the presence of a high starting ambient concentration of lactate. The anaerobic rate is 2–3-fold higher than the aerobic.³⁴⁰ Thus, the retinal cells produce lactate and the retinal neurons utilize glucose as their major energy substrate. An alternative hypothesis suggests that the retinal neurons utilize preferentially lactate derived from Müller cells.³⁴¹ In rats, mediated by the endothelium, extracellular lactate leads to a rise in calcium in pericytes and, in turn, to contraction of microvessels in conditions of rich energy supply. By contrast, hypoxic microvessels relax during exposure to lactate.³³⁴ This dual vasoactive capability may provide an efficient mechanism to match microvascular function to local metabolic needs.

In minipigs under normoxic conditions, however, pre-retinal microinjections (30–100 nl) of L-lactate (0.5 mol/l, pH 7.4) close to the retinal arterioles locally dilate the arteriolar wall.²⁹⁹ In addition, intravenous administration of sodium lactate increases retinal BF at steady state³⁴² or during flicker stimulation.^{343,344} High-dose lactate reduces the flicker-induced retinal D-response, whereas low-dose lactate increases it,³⁴² suggesting that the ratio of cytosolic free NADH to NAD⁺ plays a critical role in the maintenance of retinal vascular tone. Uptake of intravenous or intravitreal lactate by vascular endothelial cells or astrocytes via monocarboxylate transporters^{345,348} causes retinal arteriolar dilation predominantly via stimulation of NO synthase³³⁵ and subsequent activation of guanylyl cyclase. In turn, guanylyl cyclase/cGMP signaling triggers opening of KATP channels for vasodilation. This process suggests that lactate either mediates the release of endothelial vasoactive substances (i.e. NO) or interferes with the metabolism and release of vasoactive substances by cells surrounding the arterioles (i.e. glial cells). Recent data from minipigs suggest that neuronal-derived NO is indeed an important mediator of lactate-induced vasodilatation.³⁴⁹

Blood flow response to visual stimulation

Light/dark transition

Studies have examined the effect of such a stimulus on glucose uptake in the outer and inner retinal layers,¹³⁰ retinal vessel D³⁵⁰ and blood velocity^{351–353} and retinal and ONH tissue PO_2 .^{128,354} The emerging picture is still rather unclear. Thus, D of retinal vessels measured after a transition from a period of darkness to ambient light was found to be

respectively 2–3 percent and 5–8 percent, larger than during the light adaptation period prior to darkness. Blood velocity measured by LDV with a visible helium-neon laser was also found to be larger (40–70 percent) after the transition.^{351,352} These findings were attributed to a presumed increase in retinal metabolism occurring during darkness.³⁵¹ However, similar studies performed with near-infrared light^{350,353,355} suggest rather that these increases are induced by the transition itself.

Subfoveal choroidal BF decreases by 15 percent after a transition from light to darkness,¹⁹² an effect observed in both eyes, even if only one eye is subjected to the transition.³⁵⁶ This change was attributed to a mechanism centrally located and mediated by NO either from endothelial or neural source.^{356,357}

Flicker

Luminance flicker (illumination with alternating brightness) increases glucose uptake in the ganglion cell layer (Fig. 10.22),¹³⁰ retinal vessel D (Fig. 10.23),^{358–361} as well as retinal and ONH BF (Fig. 10.24).^{362–366} The characteristics of this functional hyperemic response, namely the temporal dynamics and magnitude dependency upon flicker frequency, luminance, modulation depth, color ratio for chromatic flicker, dark adaptation, area of the retina stimulated, site of measurement at the retina (macula versus periphery) have been described in great detail for the ONH.^{364,367–369} By comparison, little is known about these characteristics for the retina. Simultaneous measurements of ONH BF and the flicker electroretinogram indicate the presence, under certain conditions of flicker stimulation, of a coupling between the changes in ONH BF and retinal neural activity.³⁶⁹ The effects of various physiological and pathological conditions on the flicker-induced retinal and ONH hyperemic responses have been studied. For example, increases in ABP, IOP, hyperglycemia, untreated arterial hypertension, diabetes, and glaucoma all reduce this response.^{343,367,370–372}

Hypotheses on the function of this hyperemia include:³⁶⁸
 (a) increased glucose metabolism of the retinal tissue;^{130,373}
 (b) increased delivery of glucose required by the astrocytes which play a crucial role in neurotransmitter recycling;³⁷⁴
 (c) increased delivery of oxygen required by the increased

activity in neurons and axons;³⁷⁵ (d) NO production due to a signaling cascade fueled by cytosolic free NADH.³⁴⁴ Studies suggest that potassium³⁷⁶ and NO^{377–379} act as putative mediators of the hyperemia, and demonstrate that dopamine,³⁸⁰ adenosine,³⁸¹ lactate,³⁴³ as well as arachidonic acid metabolites released by glial cells²²⁰ modulate the response.

Control of arterial tone by endothelium or neuro-glial activity

The importance of endothelium-derived relaxing factors (EDRF) in regulating ocular BF^{36,219} was recognized more than 20 years ago following the pioneering work of Furchtgott.³⁸² These vascular tone-controlling substances have been reviewed in a number of previous publications.^{59,383,384}

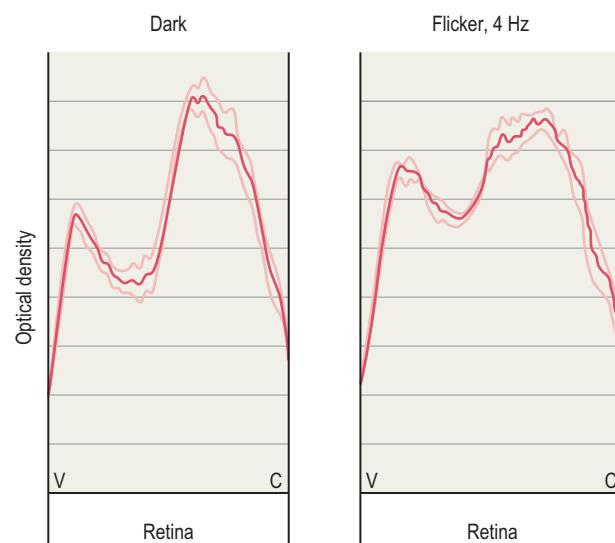

Figure 10.22 Optical density profile from autoradiograms of the central retina at a position 1–4 mm temporal to the optic disc at different conditions after an intravenous injection of labeled 2-deoxy-D-glucose. High density indicates high glucose uptake. V = vitreous, C = choroid. Flickering light increases glucose uptake in ganglion cell layer (red lines) compared to glucose uptake in the dark. (From Bill & Sperber 1990.¹³⁰ Reproduced by kind permission of Springer Science + Business Media.)

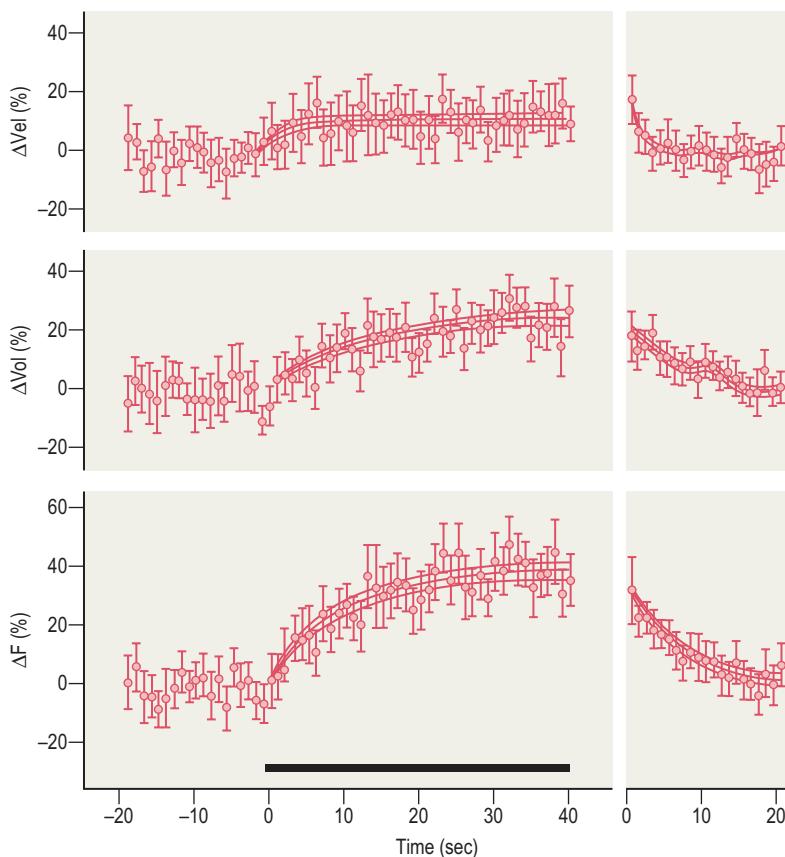

Figure 10.24 Mean (\pm 95 percent confidence interval, 15 healthy subjects) time course of changes (in percent) in velocity (ΔVel), volume (ΔVol) and flux (ΔF) of red blood cells measured at a temporal site of the human optic disc in response to a diffuse luminance flicker (15 Hertz, 25-degree field). Horizontal bar: flicker period. (From Riva et al 2004.³⁷¹)

Nitric oxide

One of these EDRFs is NO produced by nitric oxide synthase (NOS), which has three isoforms, classified as neuronal NOS (NOS-1) and endothelial NOS (NOS-3), both activated via a calcium/calmodulin complex, and NOS-2 that is independent of calcium and capable of generating large amounts of NO in the presence of inflammatory and immunological stimuli. In general, NOS-1 is found in neurons of the central and peripheral nervous system. In the mammalian retina, it is present in ganglion, amacrine, horizontal and photoreceptor cells, as well as in Müller glial cells.^{52,385–388} NOS-3 is mainly expressed by the vascular endothelial cells including the retinal^{389,390} and choroidal vessels³⁹⁰ and pericytes of the retinal capillaries.³⁹¹

Analogs of L-arginine such as NG-monomethyl-L-arginine (L-NMMA), NG-nitro-L-arginine methyl ester (L-NAME), and NG-nitro-L-arginine (L-NA) can be used as specific inhibitors of NO production.³⁹² These competitive inhibitors of NO production³⁸³ block all three isoforms of NOS.

The role of NO in the control of ocular BF has been discussed in a previous review.³⁸³ In summary, in isolated porcine ophthalmic and ciliary artery rings, L-NMMA induces dose-dependent contractions.^{393,394} NO is also capable of relaxing the contractile tone of retinal bovine pericytes³⁹⁵ and Müller cells,³⁹⁶ which may both be involved in the control of retinal BF. In addition, endothelium-derived NO, released under basal conditions or stimulated by bradykinin, regulates the ophthalmic circulation of the perfused porcine eye.³⁹⁷

In various animal species, a constant release of NO maintains the basal vascular diameter and BF in the various ocular tissues.^{377,378,398–402} In humans, systemic inhibition of NOS with intravenous administration of L-NMMA reduces ONH BF.⁴⁰³ The effect of L-NMMA can be reversed with high-dose of L-arginine, indicating that NO contributes to the maintenance of basal vascular tone in the choroid and the ONH. Furthermore, investigations in minipigs show that a continuous production of NO is necessary to maintain the arteriolar tone, at least in the inner retinal vessels.³⁷⁸ In addition, L-NMMA decreases D of retinal arterioles and venules⁴⁰⁴ and reduces retinal BF⁴⁰⁵ indicating that NO is also continuously released in retinal vessels under physiological conditions.

NO also appears to be involved in a variety of agonist-induced vasodilatations.²¹⁹ In humans this has been shown for histamine,⁴⁰⁶ insulin,⁴⁰⁷ hypercapnia,⁴⁰⁸ and adrenomedullin.⁴⁰⁹ In addition, NO plays a role in flicker-induced ONH hyperemic response in cats³⁷⁷ and in the human retinal vasculature.⁴⁰⁴ The role of NO in BF in the human eye is demonstrated by the ability of sodium nitroprusside and nitrates to increase BF in the various ocular tissues.^{410,411}

Endothelins

Three isoforms of endothelin, ET-1, ET-2, ET-3, have been identified in the vascular endothelium.⁴¹² ET-1 is also expressed in retinal neurons and astrocytes⁴¹³ and in the brain.⁴¹⁴ ET-1, the most potent vasoconstricting factor presently known, affects both pericytes and smooth muscle cells.³⁹⁵ It induces potent contractions in isolated ophthalmic, ciliary, and retinal arterioles^{393,415–417} and, in vivo, in

rabbit⁴¹⁸ and cat retinal vessels.⁴¹⁹ Moreover, ET-1 contributes to the vasoconstriction of human retinal arterioles.⁴²⁰ Furthermore i.v. administration of ET-1 strongly reduces cat ONH⁴²¹ and rabbit choroidal BFs.⁴²²

Two types of ET receptors, ET_A and ET_B, with different sensibilities for the three ligands have been identified in the retina and ONH from human and porcine eyes.⁴¹³ The ET_A receptor is expressed on pericytes and vascular smooth muscle cells⁴²³ and presents a high affinity to ET-1. The ET_B receptor has been detected in cultured bovine retinal pericytes⁴²³ and endothelial cells in culture.⁴²⁴ Systemic administration of the selective ET_A receptor antagonist BQ-123 prevents the decrease in retinal BF induced by exogenous ET-1.⁴²⁰

ET_B has two subtypes of receptors. The ET_{B1} receptor is expressed in endothelial cells and has equal affinity for each ET isoform and mediates vasorelaxation through the release of NO by endothelial cells in culture,⁴²⁴ in the pulmonary circulation of lambs,⁴²⁵ and in rabbit kidneys⁴²⁶ under physiological and hypoxic conditions.⁴²⁷ Furthermore, ET_{B1} receptors appear to influence ABP homeostasis by reducing plasma ET-1 levels and thus minimizing ET_A activation.⁴²⁸ In contrast to the vasodilating effect of ET_{B1} signaling, ET_{B2} receptors have a high affinity for ET-3 and directly mediate vasoconstriction.⁴²⁹ Dual block of ET_A and ET_B receptors by bosantan, a drug used in the treatment of pulmonary hypertension, increased retinal BF in healthy and glaucomatous eyes.⁴³⁰

NO and ET appear to be major players in choroidal BF regulation.^{383,431,432} In anesthetized rabbits, a dynamic interplay between NO-induced vasodilation and ET-induced vasoconstriction has been demonstrated as ocular PP is varied by mechanical manipulation of arterial pressure.⁴³¹ Thus, administration of L-NAME eliminates the NO-induced vasodilation and the unopposed ET vasoconstriction causes a dramatic downward shift of the ocular PP-choroidal BF relationship over a wide range of PPs. However, subsequent administration of the non-selective ET antagonist A-182086 reverses the vasoconstriction and returns the relationship back towards control.

Prostaglandins (PGs)

Major metabolites synthesized from arachidonic acid, namely prostacyclin (PGI₂) and contracting factors such as thromboxane A₂ (TXA₂) and prostaglandin H₂ (PGH₂), or superoxide anions are mainly produced in the cerebral circulation, under physiological conditions.^{219,433} Isolated pericytes of retinal capillaries⁴³⁴ and isolated rabbit retinas⁴³⁵ also release some subclasses of PGs (PGE₂, PGF_{2α}, PGI₂).

PGI₂ has been shown to exert a vasodilating action on isolated bovine retinal arterioles⁴³⁶ and in the rabbit eye.⁴³⁷ Microinjection of PGE₂ induces a segmental vasodilation of retinal arterioles in minipigs²⁹⁴ suggesting that, during normocapnia, the release of vasodilating PGs sets the basal arteriolar tone. PGE₂ and PGF_{2α} are the predominant PGs produced by the retina and choroid and may play a role during physiological regulation in response to hypercapnia^{294,438} and changes in ocular PP.^{438,439} The regulation of retinal BF may also involve glial-evoked dilation, mediated by the arachidonic acid metabolites epoxyeicosatrienoic acid (EET), whereas glial-evoked constriction is mediated by 20-hydroxy-eicosatetraenoic acid (20-HETE).²²⁰

In healthy subjects, intravenous injection of PGE₁ does not alter the parameters of retinal and choroidal circulations, suggesting that efficient autoregulation mechanisms operate in response to the injection.⁴⁴⁰ In the cynomolgus monkey eye, PGF_{2α}-IE has been shown⁴⁴¹ to cause a dramatic increase in anterior uvea BF, but only weak effect was detected with selective FP prostanoid receptor agonists and an EP₁ receptor agonist after topical administration. Intravenous infusion of latanoprost at a dose range of 0.6 ± 6 mg/kg had little effect on BF in most ocular tissues, and the same was true for 17-phenyl-PGE₂-IE, a relatively selective EP₁ receptor agonist, after intracardiac infusion at about the same dose range. Intravenous infusion of the EP₂ receptor agonist 19R-OH-PGE₂ markedly reduced the vascular resistance in the eye. No significant effect was seen on the blood volume in the ocular tissues with any of the FP receptor agonists after topical administration. PGF_{2α}-IE increased the capillary permeability to albumin in the anterior segment and possibly the retina, but 17-phenyl-PGF_{2α} IE and latanoprost/PhXA34 had no effect on capillary permeability in any of the ocular tissues. Based on the results of previous studies and recent experiments,⁴⁴¹ it is evident that PGF_{2α} has significant microvascular effects in the rabbit, cat and monkey eye, causing vasodilation and/or increased capillary permeability, whereas selective FP receptor agonists such as latanoprost exert no or minimal effects in the primate eye, and markedly reduced microvascular effects in the rabbit eye. However, little difference between PGF_{2α} and the selective FP receptor agonists was seen in the cat eyes. It also appears that the EP₁ receptor like the FP receptor is not involved in the regulation of vascular tone in the primate eye, whereas stimulation of the EP₂ receptor reduces the vascular resistance in the monkey eye.

PGF_{2α} is often used to induce vasoconstriction in vitro, an effect seen at very high doses. Analogs that are more selective for the prostanoid FP receptor such as the analogs used in clinical practice today, have no effect on vessel diameter,⁴⁴² and cannot be expected to affect blood flow in the posterior pole.

Neural, endocrine, and paracrine control

A number of endocrine and paracrine factors are involved in choroidal BF regulation, as described in more detail in a previous publication.³⁸⁴

Effects of vasoactive nerves

Sympathetic stimulation reduces choroidal BF in a variety of species,^{253,254,443–446} an effect which in rabbits is mediated partially via vasoconstrictive α-receptors and partially via non-adrenergic neuropeptide Y.⁴⁴⁷ Furthermore, NPY is a potent vasoconstrictor in the rabbit uvea, when infused intravenously.⁴⁴⁸ Contrary to this, NPY has only minor effects in the cat uvea, and the response to sympathetic nerve stimulation is completely blocked by α-adrenoceptor blockade.⁴⁴⁹ In rats, the decrease in anterior choroidal BF is mainly mediated via the α₁-receptor subtype. In addition, α-adrenoceptor blockade unmasks a sympathetically evoked choroidal vasodilator response. This residual vasodilatation appears to be mediated via the β₁-adrenoceptor subtype.⁴⁵⁰ Experimental studies in vivo as well as in vitro have shown that norepinephrine is released already at low stimulation

Box 10.3 NPY and ocular pathology

Activation of the NPY receptor Y1 causes proliferation of vascular smooth muscle cells (VSMC), activation of platelets and formation of foam cells, which has implicated NPY to play a role in atherosclerosis. Y2 receptors on VSMC stimulate angiogenesis via mechanisms involving VEGF, eNOS, and fibroblast growth factor (FGF).^{452,538} Polymorphism in the gene encoding for prepro-NPY is a risk factor for developing diabetic retinopathy in patients with type 2 diabetes.^{539,540} Experimental animal models have implicated a role of NPY and Y2 receptors in oxygen-induced retinopathy, indicating a possible role in the development of retinopathy of prematurity (ROP).^{540,541}

frequencies, whereas NPY is released at high frequencies.⁴⁵¹ In humans, NPY is only released during high levels of stress, e.g. exhaustive exercise, vaginal delivery, panic attacks, and cold exposure.⁴⁵² Thus, the role of NPY in normal blood flow regulation in the choroid is unclear. The sympathetic system presumably prevents hyper-perfusion during increased ocular PP⁴⁴³ induced, for example, during isometric exercises,⁴⁵³ a situation where NPY may play a role. NPY has also been implicated in ocular pathology (Box 10.3).

There is unequivocal evidence that parasympathetic (facial nerve) stimulation increases choroidal BF in a variety of species.^{49,50} Choroidal vasodilatation is blocked by ganglion blockade,⁵⁰ an effect indicative of a nicotinic synapse between the nervous system and the eye. A variety of neurotransmitters have been implicated in the choroidal vasodilator response to parasympathetic stimulation. These include acetylcholine, vasoactive intestinal peptide (VIP),⁴⁵⁴ pituitary adenylate cyclase activating polypeptide (PACAP),⁴⁵⁵ and NO;^{45,432,456} all of them are present in nerve cell bodies in pterygopalatine ganglion. VIP and neuronal NOS have also been localized to intrinsic choroidal neurons,^{45,46} that may be a part of the same nervous pathway. Physiological experiments indicate that the significance of the different neurotransmitters vary between species. In rabbits, VIP and PACAP are potent vasodilators when given intravenously,^{457,458} and the vasodilatation caused by facial nerve stimulation is only slightly affected by muscarinic blockade and NOS-inhibition.⁴⁵⁹ In the cat, the responses are reversed, that is the response to nerve stimulation is significantly reduced by combined muscarinic blockade and NOS-inhibition,⁴³² whereas intravenous infusion of VIP⁴⁶⁰ or PACAP (Nilsson, SFE, personal communication) has no effect on uveal blood flows. Thus, acetylcholine and NO seem to be the most important transmitters in the cat, whereas in the rabbit, peptides seem to play a larger role.

Adenosine

Adenosine, a breakdown product of cellular adenosine triphosphate, is a modulator of synaptic transmission and a potent vasodilator in many vascular beds. In newborn piglets adenosine induces retinal vasodilatation via the adenosine A₂-receptor subtype⁴⁶¹ and plays a role in hypoxia-induced vasodilatation and retinal autoregulation.⁴⁶² Adenosine increases choroidal BF in cats and both choroidal and ONH BF in humans.^{463,464} It plays a role in hypoxia-induced vasodilatation and retinal autoregulation by potentiating the

action of endogenous extracellular adenosine.⁴⁶² It also enhances the flicker-induced functional hyperemic response in the cat.³⁸¹

Endogenous and pharmacological substances

Role of administration route

The effect of exo- or endogenous vasoactive substances will to a large extent depend on the route of administration and the tissue. Close-arterial injections can provide high local concentration with little effect on the systemic circulation, and thus on ABP. A vasodilator may increase choroidal BF when given as a close-arterial injection, or reduce it due to a general vasodilatation and reduced ABP.⁴⁶⁵ For the retina the blood-retinal barrier will prevent most systemically administered drugs from reaching the smooth muscles. Only lipid-soluble drugs, such as papaverine, will pass the barrier.⁴⁶⁶ Circumvention of the blood-retinal barrier can also be achieved by injecting the drug into the vitreous body and it has been shown that adrenergic agonists, such as epinephrine, norepinephrine, and phenylepinephrine contract retinal vessels in vitro.^{467,468}

Also, drugs applied topically as eye drops are unlikely to have any clinically beneficial effect on ocular BF. There are little data on ocular pharmacokinetics in the human eye⁴⁶⁹ and data from animal studies cannot be extrapolated to the human eye due to the large difference in body weight. In most experimental animals the systemic dose will be about 20 times that in humans, and much of the drug that reaches the posterior pole will reach it by the systemic route. In monkeys one drop of nifradilol in one eye caused a local concentration in the posterior pole of the other eye that was about 82 percent of that in the treated eye 6 hours after administration.⁴⁷⁰

Thus there are no effective tools to improve BF in the posterior segment of the eye with today's drugs, but as many drugs used in the treatment of glaucoma have marked effects on blood vessels, significant changes can be expected in BF through the anterior uvea. They are, in fact, dosed in order to have an effect in the anterior segment of the eye. Further back in the eye, the tissue concentration will be lower, and in most studies on ocular pharmacokinetics in experimental animals the concentration found in the posterior pole is less than 10 percent of that in the anterior pole.⁴⁷¹

Vasoconstrictors

In the anterior segment both the unselective adrenergic agonist epinephrine⁴⁷² and the alpha₂ adrenergic agonist brimonidine⁴⁷³ decrease BF when applied topically as a single dose.

The role of adrenergic drugs in the control of BF in the back of the eye has attracted much interest because topical α-receptor agonists and β-receptor antagonists are used in glaucoma treatment. Exogenous norepinephrine does not affect retinal BF in experimental animals or healthy humans.^{466,474} Both increases and decreases in choroidal BF have been reported after systemic administration of norepinephrine in experimental animals,^{475,476} but the data are difficult to interpret due to the pronounced concomitant increase in ABP. β-receptors have been located in the retina and the choroid,^{477,478} and have been shown to be involved in vasodilation in the choroid during sympathetic

stimulation after blocking the adrenergic α -receptors.⁴⁷⁹ Still, stimulation of the β -receptor has no effect on retinal vessels *in vitro*^{468,480} and no consistent effect on ocular BF has been seen in clinical studies.⁴⁷¹

Alpha-receptor subtypes can be found in the ocular tissues of pigs and rabbits.⁴⁸¹ In porcine ciliary arteries the α_2 -receptor agonist brimonidine is a potent vasoconstrictor.⁴⁸² The majority of animal and human studies suggest a lack of influence of brimonidine on retinal, ONH, and choroidal BF.⁴⁷¹ The role of the dopaminergic system in the control of ocular BF appears to be complex. It has been reported that dopamine antagonists increase BF in all rabbit eye tissues.⁴⁸³ On the other hand, dopamine itself induces vasodilatation in the rabbit choroid via the D₁/D₅ receptor subtype.⁴⁸⁴ In humans, dopamine i.v. causes a slight but significant increase in retinal D.³⁸⁰ These results may reflect the complex interplay of the different types of dopamine receptors in the control of ocular BF with the D₁ and D₅ receptors mediating vasodilatation and the D₂, D₃, and D₄ receptors tending to mediate vasoconstriction.

Vasodilators

While intracranial stimulation of the oculomotor nerve induces a vasoconstriction in the rabbit iris,⁴⁸⁵ topical application of the cholinergic agonist pilocarpine in monkeys markedly increases anterior segment BF while having no effect in the back of the eye.¹⁹⁸

Potential effects on ocular circulation for two other commonly used glaucoma drugs, topical carbonic anhydrase inhibitors and prostaglandin F_{2 α} -analogs, have also been examined. However, in clinical use none of them can be expected to have an effect in the back of the eye. Systemic administration of carbonic anhydrase inhibitors, such as acetazolamide, have marked effects on cerebral BF,⁴⁸⁶ most likely secondary to increased local carbon dioxide tension. A similar effect is seen in the eye where systemic administration of acetazolamide or dorzolamide increases oxygen tension close to the optic disc in pigs.⁴⁸⁷ A tendency to increased oxygen tension could also be seen when dorzolamide was applied as eye drops applied every 2.5 min for 3 hours for a total dose of about 40 mg,⁴⁸⁸ but a single dose cannot be expected to have any significant effect.

Prostaglandin F_{2 α} is often used to induce vasoconstriction *in vitro*, an effect seen at very high doses. Analogs that are more selective for the prostanoid FP receptor such as the analogs used in clinical practice today, have no effect on vessel diameter,⁴⁴² and in monkeys topical application of the prostaglandin F_{2 α} -analog latanoprost in a dose 10 times the clinically used dose induced conjunctival hyperemia and a tendency to increased BF in the anterior sclera, but no effect in the back of the eye.⁴⁴¹

Ciliary blood flow regulation

Ciliary BF demonstrates some autoregulatory capacity in animals.^{189,489} In humans, data on this capacity are lacking due to the difficulties of developing a measuring technique in this inaccessible tissue. Several systems play a role in the regulation of ciliary BF, such as the cholinergic system,¹⁹⁸ NO and the adrenergic system.⁴⁹⁰⁻⁴⁹² Dopamine increases ciliary BF in rabbits, presumably by acting via D₁/D₅ dopamine receptor activation, as in the choroid.⁴⁸⁴

Ciliary BF plays an important role by supplying the necessary nutrients for the production of aqueous humor. It has been found that in anesthetized rabbits and monkeys aqueous production is independent of moderate reductions in ABP or ciliary BF.^{489,493,494} In rabbits aqueous flow is unaffected until ciliary BF declines below 74 percent of control; when BF is below this critical value, aqueous production becomes flow-dependent, decreasing with further BF decreases.⁴⁹⁴

Ocular blood flow and its regulation in diseases

Diabetes

The hypothesis that altered retinal BF plays a role in the development of diabetic retinopathy (DR) was made more than 25 years ago.⁴⁹⁵ It has since led to numerous investigations of BF in the various tissues of the eye in this disease aimed at getting some insight into the progression of DR. At present this knowledge is rather controversial since some of the observations appear to be contradictory.^{59,496} Discrepancies in the findings may be due to differences in the type of patients, i.e. type I versus type II diabetes, controlled versus poorly controlled diabetes, improvement in the degree of glucose control over the years, short- versus long-duration of the disease, and presence or absence of other concomitant diseases, such as systemic hypertension.⁴⁹⁷

Increased D of the retinal arterioles and veins is seen early in the disease.^{497,498} On the other hand, retinal BF seems to be unaffected in eyes with well-regulated diabetes until more severe retinopathy develops.⁴⁹⁸⁻⁵⁰¹ In patients with proliferative DR, retinal hemodynamics seems to depend on the specific pathologic features. For example, reduced retinal BF and vessel staining seem to be associated with severe capillary non-perfusion.⁵⁰²

Retinal vessels in eyes with minimal or no DR show a reduced vasoconstriction in response to isocapnic hyperoxia,⁵⁰³ and an altered retinal BF response, which is correlated with the degree of DR (Fig. 10.25).⁵⁰⁴ This altered reactivity occurs in the absence of any difference in baseline hemodynamic values⁴⁹⁹ and is related to the objectively defined magnitude of retinal edema.⁴⁹⁹

The ability of retinal BF to respond to changes in ocular PP is altered in diabetes, whether the PP is decreased through an increase of the IOP,⁵⁰⁵ increased by treatment with tyramine⁵⁰⁶ or by isometric exercises.⁵⁰⁷ This alteration is further accentuated by hyperglycemia⁵⁰⁶ and more prevalent in patients with autonomic dysfunction than in those with an intact autonomic nervous system.⁵⁰⁸ Presumably, the hyperglycemia prevents a normal autoregulatory response to the additional stress induced by the increase in PP.⁵⁰⁶

The response of D of retinal vessels to diffuse luminance flicker is blunted in insulin-dependent diabetic patients in comparison to healthy controls, due either to a vascular abnormality (endothelial dysfunction or loss of pericytes) and/or decreased neural activity response⁵⁰⁹ resulting from selective abnormalities of Müller glial cell function.⁵¹⁰ These cells probably play an important role in the coupling between retinal neural activity and BF.³⁶⁸ The blunting occurs

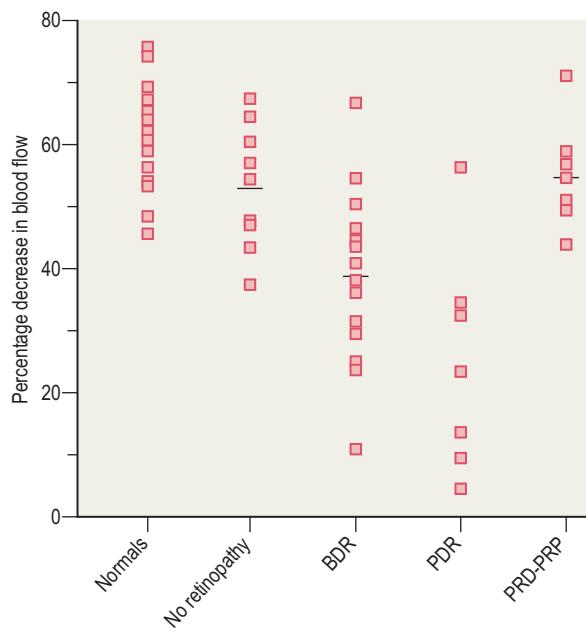

Figure 10.25 Decrease in retinal BF by BLDV at 5 min of 100 percent O₂ breathing in diabetic patients with various degrees of diabetic retinopathy. BDR = background retinopathy, PDR = proliferative retinopathy, PRD-PRP = proliferative retinopathy after panretinal photocoagulation. Horizontal bars = average value in each group. (From Grunwald et al 1984.⁵⁰⁴)

already in patients without DR and increases with the stage of DR.⁵¹¹

Excessive choroidal basement membrane thickening and degeneration,⁵¹² as well as capillary dropout, has been reported for eyes with DR.⁵¹³ Reduced subfoveal choroidal BF has been reported for patients with diabetes and particularly in those with macular edema.^{514,515} Altered regulation of this BF in response to increased PP by isometrics has been demonstrated in type 1 diabetic patients with DR, but not in those without DR.⁴⁵³ Contrary to the response in healthy subjects and diabetics with no DR, subfoveal choroidal BF increases linearly with PP in DR patients. For detailed information on BF and BF regulation in diabetes, see recent reviews.^{59,384}

Glaucoma

The role of vascular disturbances in the pathogenesis of glaucoma remains controversial, but most experts agree that elevated IOP alone does not explain the whole spectrum of individuals with open-angle glaucoma. Apart from IOP, a variety of other systemic and ocular risk factors for glaucoma have been identified, such as heart disease,⁵¹⁶ low systolic blood pressure, and low ocular perfusion pressure.⁵¹⁷

A large number of studies, using different clinical techniques, have demonstrated reduced ONH BF values in eyes with glaucoma when compared to normal eyes. Whether this is secondary to loss of neural tissue or a causative factor is, however, not known. As BF through the retina and the ONH is efficiently autoregulated, moderate increments in IOP would have no or little effect on BF through these tissues. The situation may be different in the presence of deficient autoregulation and ocular BF would then be affected even by small increments in IOP. An impaired autoregulation of

the retinal circulation was indeed found in eyes with glaucoma with the blue field simulation technique.⁵¹⁸ This investigation determined the maximum, acutely increased IOP above resting IOP at which retinal macular leukocyte speed is maintained constant by autoregulation. This maximum IOP was 25 ± 1.5 mmHg (± 1 SD) for the POAG patients and 30 ± 3.6 mmHg in the normal subjects. Studies with other techniques have also suggested that autoregulation of retinal and/or ONH BF is reduced in eyes with glaucoma. Thus retinal venous D response to short-term elevations in IOP was found to be altered⁵¹⁹ and changes in rim perfusion after a therapeutic IOP reduction⁵²⁰ suggest that autoregulation may be defective in eyes with glaucoma while intact in ocular hypertension. Also the increase of D in retinal veins and of ONH BF in response to flicker were found to be significantly diminished in glaucoma patients as compared with healthy volunteers,^{367,521} both indicative of an impairment of neurally mediated vasoreactivity. A reduced ONH BF-response was also observed in patients with ocular hypertension.³⁶⁷ Whether altered ONH BF regulation represents a risk factor for the development and progression in glaucoma remains to be shown.

Age-related macular degeneration

The pathophysiology of this disease is largely unknown.⁵²² In recent years, based on the assumption that early in the development of AMD there is thickening and loss of elasticity of ocular vessel walls due to atherosclerotic processes, it was proposed that reduced choroidal BF could play an important role in the pathogenesis of AMD.^{523–525} The hemodynamic model of AMD is supported by a number of in vitro studies showing an association between morphological changes in Bruch's membrane, loss of RPE, and capillary dropout.⁵²⁶ To investigate the possibility that a vascular component is involved in AMD subfoveal choroidal BF was measured, demonstrating lower LDF flow rates in eyes with AMD compared to healthy eyes.⁵²⁷ However, one cannot exclude that morphological changes in AMD eyes may well contribute to the difference. On the other hand, measurements of subfoveal choroidal BF changes in response to isometric exercises, have revealed an altered BF regulation.⁵²⁸ Thus, whereas these in vitro and in vivo studies have established a relation between AMD and choroidal BF alterations, it still remains to be demonstrated that these alterations represent a risk factor in the pathogenesis of AMD and choroidal neovascularization.

Production and Flow of Aqueous Humor

B'Ann True Gabelt & Paul L. Kaufman

In the healthy eye, flow of aqueous humor against resistance generates an intraocular pressure (IOP) of approximately 15 mmHg, necessary for the proper shape and optical properties of the globe.¹ The circulating aqueous nourishes the cornea and lens, structures which must be transparent and therefore devoid of blood vessels¹ as well as the trabecular meshwork (TM). The aqueous also provides a transparent and colorless medium of refractive index 1.33332 between the cornea and lens, thus constituting an important component of the eye's optical system.¹ The basic anatomy of the primate anterior ocular segment and the normal pathways of aqueous humor flow are illustrated schematically in Figures 11.1 and 11.2.

Aqueous humor is secreted by the ciliary epithelium lining the ciliary processes (as a consequence of active ionic transport across the ciliary epithelium and hydrostatic and osmotic gradients between the posterior chamber and the ciliary process vasculature and stroma), and enters the posterior chamber. It then flows around the lens and through the pupil into the anterior chamber. There is convection flow of aqueous in the anterior chamber – downward close to the cornea where the temperature is cooler, upward near the lens where the temperature is warmer (seen clinically when there is particulate matter in the anterior chamber – e.g. cells). Aqueous leaves the eye by passive bulk flow mainly via two pathways at the anterior chamber angle:

- (1) through the TM, across the inner wall of Schlemm's canal into its lumen, and thence into collector channels, aqueous veins, and the episcleral venous circulation – the trabecular or conventional route;
- (2) across the iris root, uveal meshwork, and the anterior face of the ciliary muscle, through the connective tissue between the muscle bundles, the suprachoroidal space, and thence out through the sclera – the uveoscleral, posterior, or unconventional route.

Whether or not there is a net osmotic resorption of some of the aqueous passing through the uvea by the uveal venous circulation has not been verified.^{2,3} In young individuals of various monkey species, total aqueous drainage is relatively evenly divided between the two pathways.^{4–8} In the human eye, the uveoscleral pathway has more recently been shown to play a more prominent role in aqueous outflow than was originally suggested by earlier studies.^{9,10} By using indirect

methods, such as fluorophotometry, uveoscleral outflow accounts for approximately 35–55 percent of total aqueous drainage in younger humans.^{10,11} In normal healthy subjects 60 years of age or older, uveoscleral outflow is significantly reduced compared to that of 20–30-year-olds (mean \pm SD = 1.10 ± 0.81 vs 1.52 ± 0.81 $\mu\text{l}/\text{min}$; $p < 0.009$).¹¹ Similarly, in rhesus monkeys >25 years of age (human equivalent >62 years of age) uveoscleral outflow is also dramatically reduced (0.33 ± 0.08 vs 0.63 ± 0.07 $\mu\text{l}/\text{min}$, mean \pm SEM).⁸ There is no significant net fluid movement across the cornea, iris vasculature, or vitreoretinal interface, although ion fluxes exist.^{12,13}

Due to the autonomic innervation and receptors of the relevant structures, adrenergic and cholinergic mechanisms play major roles in aqueous humor formation and drainage in terms of both normal physiology and glaucoma therapeutics,^{14–17} while evidence for other mechanisms, including serotonergic,¹⁸ dopaminergic,^{19–22} adenosinergic,^{23–27} nitrigenic,^{28–31} cannabinergic,^{32–35} prostaglandin(PG)ergic,^{36,37} and cytoskeletal (see review³⁸), has been established.

Aqueous humor formation

Physiology of aqueous humor formation

Until the early twentieth century, aqueous humor was regarded as a stagnant fluid.³⁹ Since that time, however, it has been shown to be continuously formed and drained³⁹ and the associated anatomic drainage portals (Schlemm's canal, collector channels, aqueous veins, ciliary muscle interstices) have been described.^{13,40}

Three physiologic processes contribute to the formation and chemical composition of the aqueous humor: diffusion, ultrafiltration (and the related dialysis), and active secretion.¹ Diffusion and ultrafiltration are responsible for the formation of the "reservoir" of the plasma ultrafiltrate in the stroma, from which the posterior chamber aqueous is derived, via active secretion across the ciliary epithelium. Energy-dependent active transport of sodium into the posterior chamber by the non-pigmented ciliary epithelium (Fig. 11.3) results in water movement from the stromal pool into the posterior chamber. It seems fairly certain that under normal conditions active secretion accounts for perhaps

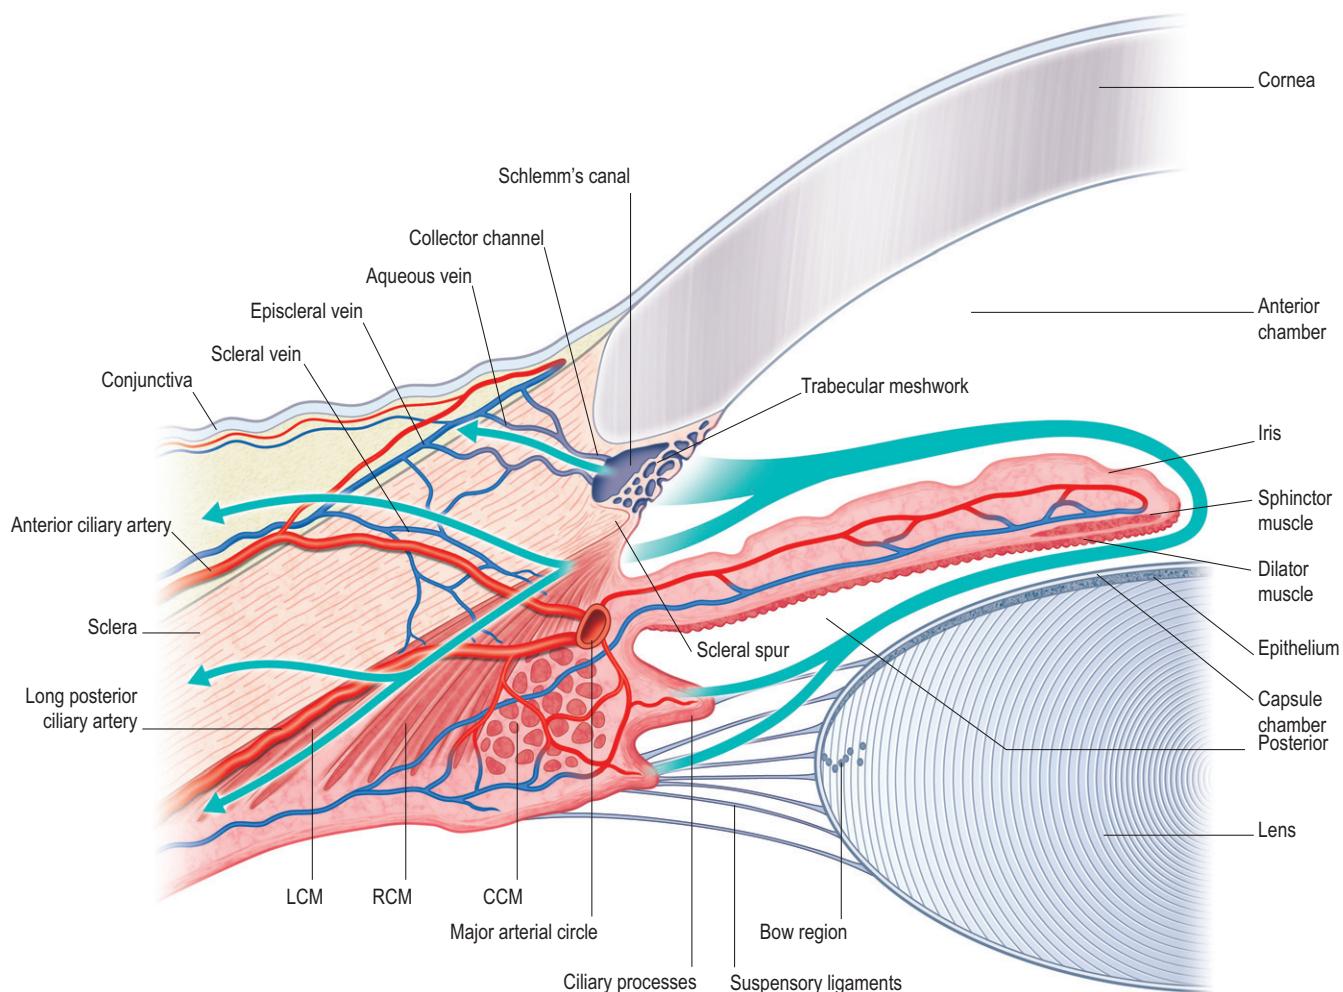

Figure 11.1 Schematic representation of the primate anterior ocular segment. Arrows indicate aqueous humor flow pathways. Aqueous humor is formed by the ciliary processes, enters the posterior chamber, flows through the pupil into the anterior chamber, and exits at the chamber angle via the trabecular and uveoscleral routes. (From Kaufman PL, Wiedman T, Robinson JR: Cholinergics. In Sears ML [ed]: Pharmacology of the eye: handbook of experimental pharmacology, Berlin, 1984, Springer-Verlag. Reproduced with kind permission of Springer Science + Business Media.)

80–90 percent of total aqueous humor formation.^{12,41–43} The observation that moderate alterations in systemic blood pressure and ciliary process blood flow have little effect on aqueous formation rate supports this notion.^{12,44}

Furthermore, Bill⁴⁵ noted that the hydrostatic and oncotic forces that exist across the ciliary epithelium–posterior aqueous interface favor resorption, not ultrafiltration, of aqueous humor. Active secretion is essentially pressure-insensitive at near-physiologic IOP. However, the ultrafiltration component of aqueous humor formation is sensitive to changes in IOP, decreasing with increasing IOP. This phenomenon is quantifiable and is termed facility of inflow, or pseudofacility, the latter because a pressure-induced decrease in inflow will appear as an increase in outflow when techniques such as tonography and constant-pressure perfusion are used to measure outflow facility.^{46–50} Although measurements vary, pseudofacility in the non-inflamed monkey and human eye constitute a very small percentage of total facility.^{50–54} Recently it has been argued that fluid transport rates exhibited by the ciliary epithelia are insufficient to account for the rate of aqueous humor formation and that there may

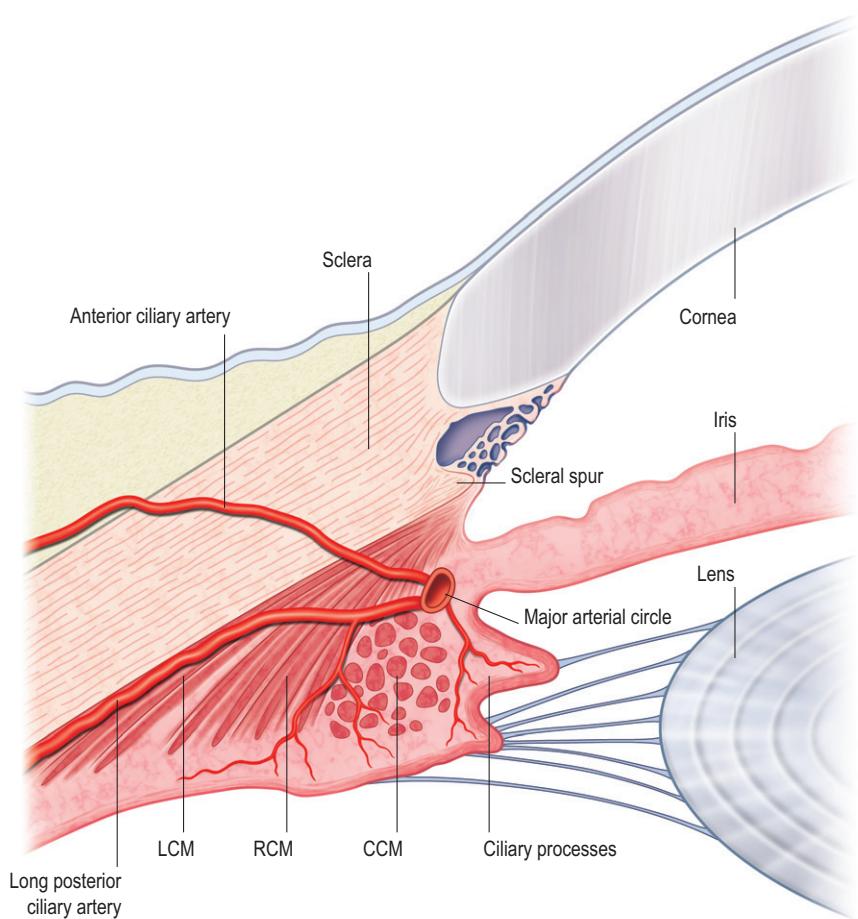

be some contribution from fluid directly entering the anterior chamber across the anterior surface of the iris.^{55,56}

In most mammalian species, the turnover constant of the anterior chamber aqueous humor is ~ 0.01 to $0.015 \times \text{min}^{-1}$, that is, the rate of aqueous humor formation and drainage is ~ 1.0 to 1.5 percent of the anterior chamber volume per minute.^{50,55,57} This is true also in the normal human eye, in which the aqueous formation rate is $\sim 2.5 \mu\text{l} \times \text{min}^{-1}$.^{11,58}

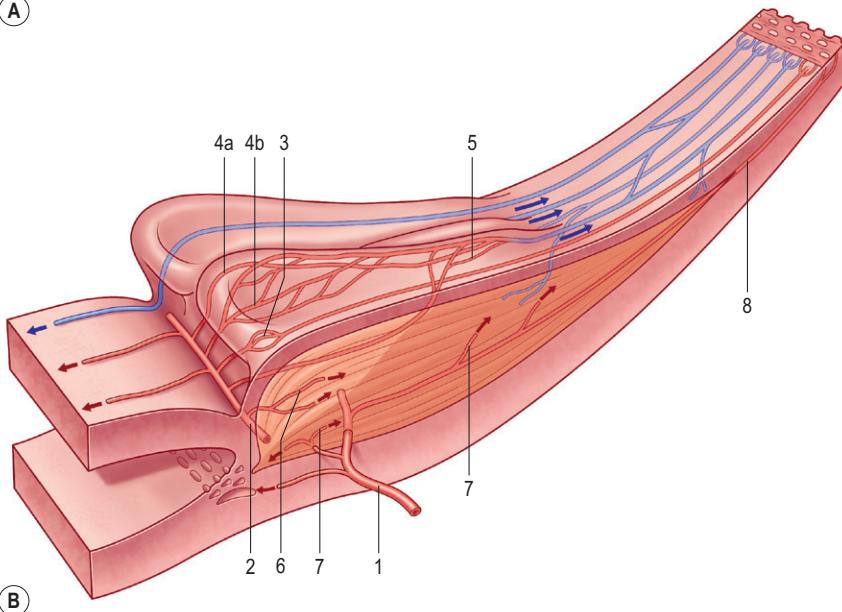

More comprehensive theoretic analyses of the fluid mechanics of aqueous production can be found elsewhere.^{1,56,59–62}

Biochemistry of aqueous humor formation

The structural basis for aqueous humor secretion is the bilayered ciliary epithelium.⁶³ This consists of the pigmented epithelium (PE) facing the ciliary stroma and the non-pigmented epithelium (NPE) facing the aqueous humor. The PE and NPE are connected to each other at their apical membranes through gap junctions, thereby forming a complex syncytium. Tight junctions are present between the apical borders

(A)

(B)

of NPE cells where they form a barrier that restricts paracellular diffusion.

The active process of aqueous secretion is mediated via selective transport of certain ions and substances across the basolateral membrane of the non-pigmented ciliary epithelium against a concentration gradient. Two enzymes

abundantly present in the non-pigmented ciliary epithelium are intimately involved in this process: sodium-potassium-activated adenosine triphosphatase (Na^+/K^+ -ATPase) and carbonic anhydrase.⁶⁴⁻⁷¹ Na^+/K^+ -ATPase is found predominantly bound to the plasma membrane of the basolateral infoldings of the non-pigmented ciliary epithelium.^{66,69-71}

As a result of the primary active transport of Na^+ , other ions and molecules are transported over the epithelium by secondary active transport. Thus, aqueous humor in humans exhibits increased levels of ascorbate, some amino acids, and certain ions such as Cl^- as compared to plasma.⁷² There is also a passive transporter for HCO_3^- .^{1,73} A summary of the biochemistry of aqueous secretion is shown in Figure 11.3.

Inhibition of the ciliary process Na^+-K^+ -ATPase by cardiac glycosides (e.g. ouabain) or vanadate (VO_3^- , VO_4^{3-}) significantly reduces the rate of aqueous humor formation and IOP in experimental animals^{66,74–81} and humans,⁷⁹ showing that the primary active transport of Na^+ is the primary driving force for the secretion of aqueous humor. To maintain

electroneutrality, anions must accompany the actively secreted Na^+ ; chloride can pass through chloride channels in the basolateral membrane and HCO_3^- can enter aqueous via exchange with chloride. The active transport of Na^+ and the accompanying anions create high osmolarity on the basolateral side of the NPE cells, which causes diffusion of water out of the cells. The movement of water is facilitated by aquaporins in NPE cells (aquaporins 1 and 4).^{82–84} AQP1 null mice have decreased IOP and aqueous humor production compared to normals.⁸² Sodium and chloride must continuously enter the pigmented epithelial cells for the continuous secretion of aqueous humor. This is achieved by Na^+-H^+ and $\text{Cl}^-/\text{HCO}_3^-$ antiports and by the $\text{Na}-\text{K}-2\text{Cl}$

cotransporter. In vivo as well as in vitro studies support the involvement of these transporters and channels in the formation of aqueous humor.^{85–87}

Transport of Cl⁻ ions plays an equally important role as the active transport of Na⁺ ions as the driving force for aqueous humor formation.^{88–90} In isolated bovine eyes, aqueous humor is formed mostly by processes involving active secretion and chloride transport.⁸⁸ In rabbit preparations, the release of Cl⁻ ions is enhanced by agonists of A3 adenosine receptors.⁸⁵ A3 adenosine receptor-activated agonists and antagonists, respectively, increase and lower IOP in mice.⁹¹ Bestrophin-2, a protein which regulates Ca²⁺-activated Cl⁻ conductance, is localized to the non-pigmented ciliary epithelium, suggesting that it may play a role in regulating aqueous humor formation. Mice deficient in bestrophin-2 have significantly diminished IOP.⁹²

In bovine eyes in vitro, 4,4'-diisothiocyanatostilbene-2,2'-disulfonic acid (DIDS, a probable inhibitor of the Cl⁻/HCO₃⁻ exchanger, the Na-HCO₃ cotransporter, and chloride channel) and 5-nitro-2-(3-phenylpropylamino)-benzoic acid (NPPB, a chloride channel blocker in non-pigmented cells) reduce aqueous humor formation by 55 percent and 25 percent respectively.⁸⁸ In mice, topical inhibitors of Na⁺/H⁺ antiports lower IOP.⁹³ Bumetanide (a specific inhibitor of Na-K-2Cl cotransport) and furosemide (a nonspecific anion transport inhibitor) reduce aqueous humor formation by 35 and 45 percent in bovine eyes in vitro.⁸⁸ Also, catecholamines such as epinephrine, norepinephrine, isoproterenol and dopamine, that stimulate aqueous humor formation in humans also stimulate Na-K-Cl cotransport.⁸⁹ However, topical application of bumetanide to mice⁹³ or monkeys⁹⁴ has no effect on IOP.

Carbonic anhydrase (CA) is abundantly present in the basal and lateral membranes and cytoplasm of the pigmented epithelium and non-pigmented epithelium of the ciliary processes.^{95–99} Isoenzymes of CA (II, IV and XII) are present in the ciliary processes.^{100,101}

The conversion of CO₂ and H₂O to carbonic acid and its subsequent dissociation to H⁺ and HCO₃⁻ provides the HCO₃⁻, which is essential for the active secretion of aqueous humor. Inhibition of the production of HCO₃⁻ also leads to an inhibition of the active transport of Na⁺ across the non-pigmented ciliary epithelium into the first-formed aqueous, thereby reducing active aqueous humor formation. There are several hypotheses to explain the relationship between reduction in non-pigmented ciliary epithelium intracellular HCO₃⁻ and inhibition of Na⁺ transport including:

- (i) inhibition of CA causing a decrease in HCO₃⁻ available for transport with Na⁺ from the cytosol of the non-pigmented ciliary epithelium to the aqueous, required to maintain electroneutrality;
- (ii) reduction in intracellular pH inhibiting Na⁺-K⁺-ATPase, and
- (iii) decreased availability of H⁺ decreasing H⁺/Na⁺ exchange and reducing the availability of intracellular Na⁺ for transport into the intercellular channel.

In addition, inhibition of renal and erythrocyte CA leads to a systemic acidosis which promotes inhibition of aqueous humor formation.¹⁰²

CA inhibitors given systemically can reduce secretion by up to 50 percent^{95,98,103–111} and have been in use for clinical

glaucoma therapy for over 50 years.^{102,104,107} It was once thought that the drug concentration at the ciliary epithelium required to produce nearly continuous, total ciliary CA inhibition necessary to achieve adequate and sustained reduction in aqueous humor formation (over 99 percent of the ciliary enzyme must be inhibited to achieve significant secretory suppression) might never be attainable via the eyedrop route. Fortunately, there are now available topically effective CA inhibitors such as dorzolamide^{112–116} and brinzolamide^{116–118} which may achieve substantial (albeit usually not quite as much) reduction in IOP as the earlier oral CA inhibitors but without their systemic side-effects.^{102,114,119}

Aqueous humor composition

The composition of aqueous humor differs from that of plasma as a result of two important physiological characteristics of the anterior segment: a mechanical epithelial/endothelial blood-aqueous barrier, and active transport of various organic and inorganic substances by the ciliary epithelium. The greatest differences are the low protein and high ascorbate concentrations in the aqueous relative to plasma (200 times less and 20 times greater, respectively).^{120–123}

The protein concentration in the peripheral portion of the anterior chamber, close to the meshwork, may be much higher than in the more central region because of protein entry directly from the peripheral iris, as demonstrated in monkey and human eyes.^{124–127} When the aqueous protein concentration rises much above its normal 20 mg/100 mL,¹²⁸ as in uveitis, the resultant light scattering (Tyndall effect) makes the slit-lamp beam visible as it traverses the anterior chamber (a phenomenon known as "flare").

The high ascorbate concentration may help protect the anterior ocular structures from ultraviolet light-induced oxidative damage.¹²⁹ Ascorbate functions as an antioxidant, regulates the sol-gel balance of mucopolysaccharides in the TM, or partially absorbs ultraviolet radiation,¹³⁰ as diurnal mammals have approximately 35 times the concentration of aqueous ascorbate compared to nocturnal mammals.¹³¹ Extensive and repeated oxidative stress in vivo may result in reduced TM cell adhesion, leading to TM cell loss which is associated with glaucomatous conditions.^{132,133}

Lactate is also normally in excess in the aqueous, presumably as a result of glycolytic activity of the lens, cornea, and other ocular structures.^{107,128} Other compounds or ions in excess in the aqueous relative to plasma are Cl⁻ and certain amino acids.⁷² Glucose, urea, and non-protein nitrogen concentrations are slightly less than in plasma.^{72,134} Oxygen is also present in the aqueous humor, at a tension determined to lie between 13 to 80 mmHg, depending upon the method of measurement.^{135,136}

Blood-aqueous barrier

The blood-aqueous barrier is a functional concept, rather than a discrete structure, invoked to explain the degree to which various solutes are relatively restricted in travel from the ocular vasculature into the aqueous humor. The capillaries of the ciliary processes and choroid are fenestrated, but

the interdigitating surfaces of the retinal pigment epithelia and the ciliary process non-pigmented epithelia respectively are joined to each other by tight junctions (zonulae occludens) and constitute an effective barrier to intermediate- and high-molecular-weight substances, such as proteins.^{128,137–147} The endothelia of the inner wall of Schlemm's canal are similarly joined,^{140,148} preventing retrograde movement of solutes and fluid from the canal lumen into the TM and anterior chamber. Tight junctions are also present in the iridial vascular endothelium¹⁴⁹ as well as between the iris epithelia.¹⁵⁰ For present purposes, one may say that the blood–aqueous barrier comprises the tight junctions of the ciliary process non-pigmented epithelium, the inner wall endothelium of Schlemm's canal, and the iris vasculature, and the outward-directed active transport systems of the ciliary processes (see below). A more universal concept of the blood–aqueous barrier must deal with the movement of smaller molecules, lipid-soluble substances, and water into the eye.¹²⁸

With disease-, drug-, or trauma-induced breakdown of the blood–aqueous barrier (Table 11.1), plasma components enter the aqueous humor. Net fluid movement from blood to aqueous increases, but so does its IOP dependence (pseudofacility).¹⁵¹ Total facility, as measured by IOP-altering techniques cannot distinguish pseudofacility from total outflow facility (C_{tot}) and therefore erroneously record the pseudofacility component as increased C_{tot} (hence the term, "pseudofacility") and therefore underestimate the extent to which the outflow pathways have been compromised by the insult. Under these circumstances, increased pseudofacility provides some protection against a precipitous rise in IOP; as IOP rises, aqueous inflow by ultrafiltration is partly suppressed, blunting (but not completely suppressing)^{138,152} further IOP elevation. Additionally, the inflammatory process which occurs during blood–aqueous barrier breakdown leads to a reduction in active secretion of aqueous humor, possibly via interference with active transport mechanisms.^{6,153} This in turn may actually produce ocular hypotony, despite compromised conventional outflow pathways

(due to plasma protein blockage of the TM). Prostaglandin release during inflammation may contribute to the hypotony by increasing aqueous outflow via the uveoscleral route.^{154,155} When the noxious stimulus is removed, however, the ciliary body may recover before the TM, and the resulting normalization of the aqueous humor formation and uveoscleral outflow rates in the face of still compromised conventional outflow pathways leads to elevated IOP, as seen from the modified Goldmann equation:

$$IOP = [(AHF - F_u)/C_{trab}] + P_e$$

where IOP = intraocular pressure, AHF = aqueous humor formation, F_u = uveoscleral outflow, C_{trab} = facility of outflow from the anterior chamber via the TM and Schlemm's canal, P_e = episcleral venous pressure (the pressure against which fluid leaving the anterior chamber via the trabecular-canalicular route must drain).¹⁵⁶

Active transport

The ciliary processes possess the ability to actively transport a variety of organic and inorganic compounds and ions out of, or to exclude them from, the eye, that is, to move them from the aqueous or vitreous to the blood against a concentration gradient. Para-aminohippurate (PAH), diodrast, and penicillin are examples of large anions that are actively transported out of the eye. These systems are similar to those in the renal tubules and satisfy all the criteria for active transport: saturability, energy and temperature dependence, Michaelis-Menten kinetics, inhibition by ouabain and probenecid, etc.^{72,157–166} In addition, another system can actively excrete injected iodide from the aqueous, resembling iodide transport in the thyroid and salivary glands.¹⁵⁹ The physiologic role of these outward-directed systems is unknown. With the discovery that prostaglandins may be actively transported out of the eye,^{167,168} some workers have suggested that such outward-directed mechanisms may rid the eye of biologically active substances which are no longer needed or may even be detrimental.^{157,161,169,170} The various

efflux transporters in ocular tissues are discussed in more detail in Chapter 17.

Pharmacology and regulation of aqueous humor formation and composition (Box 11.1)

IOP displays a circadian rhythm in animals and humans which is under the control of endogenous pacemaker structures including the suprachiasmatic nucleus, which control the activity of sympathetic and parasympathetic ocular innervation.¹⁷¹ Sympathetic and parasympathetic nerve terminals are present in the ciliary body^{172–174} arising from branches of the long and short posterior ciliary nerves. These nerve fibers are of both the myelinated and non-myelinated variety. Parasympathetic fibers originate in the Edinger-Westphal nucleus of the third cranial nerve, run with the inferior division of this nerve in the orbit, and synapse in the ciliary ganglion.¹⁷⁵ Vasodilatory parasympathetic nerve fibers originating in the pterygopalatine ganglion are likely to release nitric oxide and vasoactive intestinal peptide (VIP) in addition to acetylcholine (see Chapter 10). Nerves displaying VIP immunoreactivity are also detected in the ciliary processes, posterior third of the ciliary muscle and around small to medium-sized blood vessels in the posterior uvea of the cat.¹⁷⁶ Only a few VIP-positive fibers are found in the ciliary processes of humans and monkeys.¹⁷⁷ In the cat eye, pituitary adenylate cyclase-activating peptide (PACAP)-containing nerve fibers are detected in the iris, ciliary body and conjunctiva. PACAP immunoreactivity co-localizes with VIP in the sphenopalatine ganglion and with calcitonin gene-related peptide (CGRP) in the trigeminal ganglion.¹⁷⁸ Sympathetic fibers synapse in the superior cervical ganglion and distribute to the muscles and blood vessels of the ciliary body. Stimulation of the cervical sympathetic nerves in

vervet monkeys significantly increases the rate of aqueous humor formation.¹⁷⁹ Numerous unmyelinated nerve fibers surround the stromal vessels of the ciliary processes; these are most likely noradrenergic and subserve vasomotion.¹²⁸

Sympathetic denervation in monkeys does not alter resting aqueous humor formation and marginally affects the aqueous humor formation response to timolol or epinephrine.¹⁸⁰ In humans with unilateral Horner's syndrome, IOP, daytime aqueous humor formation, tonographic outflow facility and the flow and IOP response to timolol are similar in both eyes.¹⁸¹ However, eyes with Horner's syndrome show a decrease in aqueous humor formation in response to epinephrine instead of the normal increase. Isoproterenol, on the other hand, increases flow during sleep in both normal and Horner's syndrome eyes but has no significant effect on flow in either during the day.¹⁸² Chemical sympathectomy with guanethidine sulfate in glaucomatous humans lowers IOP, presumably by reducing aqueous humor production measured indirectly by tonography.¹⁸³ VIP stimulated aqueous formation following intravenous administration in monkeys is secondary to activation of the sympathetic nervous system while the effect of intracameral administration of VIP is a direct effect on the ciliary epithelium.¹⁸⁴ PACAP appear to be slightly more potent than VIP as a stimulator of aqueous humor flow in the monkey.¹⁷⁷ The role of sympathetic innervation in mediating aqueous inflow and outflow responses to pharmacologic agents remains largely uncertain. Also the role of sympathetic innervation in mediating inflow responses can vary depending on the species used, i.e. rabbits vs monkeys, as is found, for example, with opioid agonists.^{185,186}

Cholinergic mechanisms

The effects of cholinergic drugs on aqueous humor formation and composition and on the blood-aqueous barrier are unclear. Overall, cholinomimetics have little effect on the volumetric rate of aqueous humor formation. In general, cholinergic drugs cause vasodilation in the anterior segment resulting in increased blood flow to the choroid, iris, ciliary processes, and ciliary muscle (see Chapter 10). However cholinergic drugs may also promote vasoconstriction in the rabbit eye.¹⁸⁷ Congestion in the iris and ciliary body is a well-recognized clinical side-effect of topical cholinomimetics, especially the anticholinesterases.¹⁸⁸ The presence of flare and cells in the aqueous humor by biomicroscopy indicates that these agents can cause breakdown of the blood-aqueous barrier and perhaps frank inflammation.¹⁸⁸ Pilocarpine increases blood-aqueous barrier permeability to iodide¹⁸⁹ and inulin.¹⁹⁰ Cholinergic drugs may alter the aqueous humor concentration of inorganic ions¹⁹¹ and the movement of certain amino acids from the blood into the aqueous humor and may also influence the outward-directed transport systems of the ciliary processes.^{192,193} Cholinergic agents can disrupt the coupling and Na⁺ currents between pigmented and non-pigmented epithelial cells in vitro, suggesting a possible inhibitory effect on aqueous secretion^{194,195} although this is likely to be minimal as stated below.

Under certain conditions, pilocarpine may increase pseudofacility.^{59,196} Using a variety of species, conditions, and experimental techniques, cholinergic agents or parasympathetic nerve stimulation is reported to increase, decrease, or

Box 11.1 Aqueous Humor Formation

- β-adrenergic antagonists such as timolol, that lower IOP by decreasing aqueous humor formation, continue to be a mainstay in clinical glaucoma therapy
- Nocturnal IOP elevation in glaucomatous eyes may not be effectively eliminated with adrenergic-based glaucoma therapies
- α2-adrenergic agonists such as apraclonidine and brimonidine, are powerful ocular hypotensive agents, lowering IOP primarily by decreasing aqueous humor formation
- Long-term suppression of aqueous humor formation and redirection of aqueous drainage from the trabecular to the uveoscleral pathway could lead to underperfusion of the trabecular meshwork with detrimental morphologic and functional effects
- Brinzolamide or timolol added to latanoprost have similar ocular hypotensive effects and safety in POAG, NTG, or OHT.⁶⁷⁸ The small difference in efficacy between the secretory suppressants is buried beneath the bigger IOP effect of latanoprost. This has to do with the physics of IOP; at a lower pressure, it is harder to get the same magnitude of effect

not alter the aqueous humor formation rate and to increase slightly the episcleral venous pressure.^{197–208} These apparently confusing results may indicate that cholinergic drug effects on these parameters are extremely dependent on species and technique-related factors and on the ambient neurovascular milieu. In any event, the effects on the rate of aqueous humor formation and episcleral venous pressure are surely minor in most instances, and not responsible for the drug-induced decrease in IOP that forms the basis of the therapeutic efficacy of pilocarpine in chronic glaucoma; the latter resides in its ability to decrease outflow resistance via its effect on the ciliary muscle and perhaps, to a much lesser extent, directly on the TM²⁰⁹ (see [Aqueous Humor Drainage](#)).

Adrenergic mechanisms

The precise role and receptor specificity of adrenergic mechanisms in regulating the rate of aqueous humor formation are unclear. At one time it was generally believed that long-term topical administration of epinephrine, a combined α_1 , α_2 , β_1 , β_2 -adrenergic agonist, would decrease the rate of aqueous humor formation.¹⁰⁷ This effect was thought to be mediated by β -adrenergic receptors in the non-pigmented ciliary epithelium, via activation of a membrane adenylate cyclase.^{68,210,211} Further, forskolin, which directly and irreversibly activates intracellular adenylate cyclase, in some,^{212,213} albeit not all,²¹⁴ studies decreases the rate of aqueous humor formation when given topically or intravitreally.

Fluorophotometric studies show that short-term topical administration of epinephrine increases aqueous humor formation;^{10,180,215} studies with other adrenergic agonists, including salbutamol,²¹⁶ isoproterenol (isoprenaline),¹⁸² and terbutaline,²¹⁷ support this finding and are consistent with many studies showing that β -adrenergic antagonists unequivocally decrease aqueous humor formation.^{15,218,219}

The ocular hypotensive action of β -antagonists led to their becoming mainstays of clinical glaucoma therapy: the non-selective β_1 , β_2 antagonists timolol,^{215,220–222} levobunolol,²²³ and metipranolol,²²⁴ the non-selective β_1 , β_2 partial agonist carteolol,^{225,226} and the relatively β_1 selective antagonist betaxolol.²²⁷ Adrenergic receptors in the ciliary epithelium are of the β_2 subtype,^{228–230} but antagonists that are relatively selective for β_1 receptors (e.g. betaxolol) are effective (although less potent) in suppressing aqueous humor formation.^{58,227,231–233} However, the apparent β_1 efficacy may be related to a sufficiently high concentration reaching the ciliary epithelium so that non-selective blockade of β_2 receptors may occur.²³⁴

It is questioned whether β -adrenergic antagonists suppress aqueous humor formation via their effect on ciliary epithelial β -adrenergic receptors.^{77,181,211,214,235–237} There is evidence that classical β -adrenergic receptor blockade may not be involved, and that other receptor types such as 5HT_{1A} may be relevant (see [Other Agents](#)).²³⁸ Furthermore, Na/K/2Cl cotransport stimulated by epinephrine and isoproterenol can be inhibited by β_2 -adrenergic receptor antagonists in human fetal non-pigmented ciliary epithelial cells.²³⁹

Aqueous humor formation is reduced by nearly 50 percent during sleep,^{58,240,241} due to the β -arrestin/cAMP cascade regulation of signal transduction from the β -adrenergic receptor

to the ciliary epithelium. This results in a circadian fluctuation of IOP.²⁴² However it is suggested that IOP may actually increase in humans at night and that technical limitations may be responsible for previously reported IOP decreases.^{243,244} Nocturnal IOP elevation may play a more important role in glaucomatous progression than previously appreciated.²⁴¹ β -Antagonists produce little additional reduction in aqueous humor formation during sleep²⁴⁵ or in pentobarbital-anesthetized monkeys.²⁴⁶ Therefore adrenergic-based glaucoma therapies which target aqueous humor formation reduction may be less efficacious for combating the progression of glaucomatous damage than therapies targeting other mechanisms.

Sympathetic fibers synapse in the superior cervical ganglion and distribute to the muscles and blood vessels of the ciliary body, regulating blood flow to the ciliary process vasculature (see Chapter 10). Catecholaminergic and NPY-ergic nerve fibers preferentially supply the vasculature and epithelium of the monkey anterior ciliary processes, suggesting that they assist in the precise regulation of aqueous humor formation.²⁴⁷ Stimulation of the cervical sympathetic nerves in rhesus monkeys significantly increases the rate of aqueous humor formation.¹⁷⁹ However adrenergic tone to the ciliary epithelium may be humoral catecholaminergic rather than sympathetic innervation. Two major hormones of the adrenal gland, epinephrine and cortisol can regulate aqueous formation.²⁴⁸ Aqueous flow in human subjects correlates with circulating catecholamine levels during sleep and wakefulness.²⁴⁹ Adrenergic drugs may exert their effect by causing localized constriction in the arterioles that supply the ciliary processes.²⁵⁰

Topically applied α_1 -adrenergic agonists and antagonists appear to have little effect on fluorophotometrically determined aqueous humor formation in the normal intact human eye.^{251,252} Clonidine, which has both α_1 -antagonist and α_2 -agonist properties, decreases aqueous humor formation and ocular blood flow.^{217,253–255} Therefore epinephrine may have a dual effect on aqueous humor formation: stimulation via β -adrenoceptors, and inhibition via α_2 -adrenoceptors.^{256–258} α_2 -Adrenergic agonists, such as apraclonidine and brimonidine, are powerful ocular hypotensive agents when applied topically, and lower IOP primarily by decreasing aqueous humor formation.^{16,259} However, one study in humans suggests that brimonidine suppresses aqueous humor formation early on, but after 8–29 days of treatment the predominant effect is on uveoscleral outflow.²⁶⁰

Other agents

There are many other ways in which aqueous humor formation can be reduced pharmacologically (Table 11.2). Effective compounds include: the guanylate cyclase activators atrial natriuretic factor^{261,262} and the nitrovasodilators sodium nitroprusside,^{263,264} sodium azide,²⁶⁵ and nitroglycerin.²⁶³ 8-Bromo cyclic GMP also reduces the aqueous humor formation rate by 15–20 percent in the monkey.²⁶⁶ Atrial natriuretic factor injected intravitreally reduces IOP and aqueous humor formation in rabbits and monkeys.²⁶² However, intracameral and intravenous administration of atrial natriuretic factor to monkeys increases aqueous humor formation.²⁶⁷ Atrial natriuretic factor levels are elevated in aqueous humor of rabbits following topical treatment with kappa

Table 11.2 Factors causing reduced aqueous humor secretion

I. General	II. Systemic	III. Local	IV. Pharmacologic	V. Surgical
A. Age	A. Artificial reduction in internal carotid arterial blood flow	A. Increased IOP (pseudofacility)	A. β -Adrenoceptor antagonists (e.g. timolol, betaxolol, levobunolol, carteolol, metipranolol)	A. Cyclodialysis
B. Diurnal cycle	B. Diencephalic stimulation	B. Uveitis (especially iridocyclitis)	B. Carbonic anhydrase inhibitors	B. Cyclocryotherapy
C. Exercise	C. Hypothermia	C. Retinal detachment	C. Nitrovasodilators; atrial natriuretic factor (route and species dependent)	C. Cyclodiathermy
	D. Acidosis	D. Retrobulbar anesthesia	D. 5-HT _{1A} antagonists (e.g. ketanserin)	D. Cyclophotocoagulation
	E. General anesthesia	E. Choroidal detachment	E. DA ₂ agonists (e.g. pergolide, ergotriptane, bromocriptine)	
			F. α_2 -Adrenoceptor agonists (e.g. apraclonidine, brimonidine)	
			G. Opioid agonists	
			H. Δ^9 -Tetrahydrocannabinol (Δ^9 - THC)	
			I. Metabolic inhibitors (e.g. DNP, fluorocetamide)

opioid agonists, which results in IOP reduction and aqueous humor formation suppression.²⁶⁸ However, non-kappa opioid mechanisms are responsible for aqueous humor formation and IOP reductions in monkeys.¹⁸⁵ Nitric oxide may be involved in mediating the IOP lowering response to mu3 opioid agonists in rabbits.^{269–271}

The serotonergic antagonist ketanserin reduces the aqueous humor formation rate in rabbits, cats, and monkeys.²⁷² Serotonergic receptors of a 5-HT_{1A}-like subtype are reported to exist in the iris-ciliary body of rabbits and humans.^{238,273,274} These receptors may be antagonized by timolol and other β -blockers.²³⁸ The 5-HT_{1A} agonist 8-OH-DPAT dose-dependently decreases IOP in normotensive rabbits during light and dark cycles.^{275,276} The more selective 5-HT_{1A} agonist flesinoxan also decreases IOP in rabbits.²⁷⁷ However, the precise nature of the putative 5-HT_{1A}-like receptor subtype in the ciliary epithelium is still in question. Also, IOP and aqueous flow suppression of 5-HT_{1A} receptor agonists in non-human primates is variable.²⁷⁸ A selective 5-HT₂ agonist increases aqueous humor formation following topical treatment in monkeys but lowers IOP by increasing uveoscleral outflow.²⁷⁹

Metabolic inhibitors such as dinitrophenol decrease aqueous humor formation²⁸⁰ as do the cardiac glycosides ouabain and digoxin, which inhibit the ciliary epithelial Na⁺-K⁺-ATPase enzyme.^{88,281} None of these has yet been shown to be useful clinically as glaucoma therapeutics agents. Ibopamine exhibits activity at dopaminergic and adrenergic receptors. In humans, it can increase aqueous humor formation but can decrease²⁸² or increase IOP.^{283,284}

A component of marijuana (cannabis), Δ^9 -tetrahydrocannabinol, reduces secretion of aqueous in human volunteers²⁸⁵ when injected intravenously or when inhaled via marijuana smoking. In contrast, topical Δ^9 -tetrahydrocannabinol has no effect on the human eye.^{286,287} Studies demonstrate the presence of functional CB1 receptors in the ciliary processes and TM of human and animal tissue.^{288–290} Topical application of the cannabinoid receptor agonist, WIN-55-212-2, significantly reduces aqueous humor formation in normal and glaucomatous cynomolgus monkeys, but without increasing outflow facility. The decrease in aqueous humor formation after a single application is insufficient to explain the reduction in IOP, suggesting that other mechanisms are involved.³² The endocannabinoid, 2-arachidonoylglycerol, increases outflow facility in a porcine organ culture system by an effect mediated through both CB1 and CB2 cannabinoid receptors and changes in the actin cytoskeleton in porcine TM cells.²⁹¹

Other local, systemic, and surgical factors can reduce aqueous humor formation rate, as can age and exercise (Table 11.2). In a study of 300 normal volunteers, ages 5–83 years, there is an average decline in aqueous flow of 25 percent between the ages of 10–80 years.⁵⁸ A smaller decline occurs in humans over 65 years of age.¹¹ There is no age-related decline in aqueous humor formation in rhesus monkeys 25–29 years of age (human equivalent 62–73 years) compared to those 3–10 years or 19–23 years of age.⁸

Long-term use of drugs that decrease IOP by decreasing aqueous humor formation could adversely affect the eye.²⁹² During the course of several weeks of oral acetazolamide

therapy in humans, IOP gradually reverts toward pretreatment values but tonographic outflow facility is reduced.²⁹² Similarly, monkeys receiving prolonged treatment with timolol show a reduction in outflow facility.²¹⁹ Underperfusion of the TM can lead to detrimental morphologic effects.²⁹³

Aqueous humor drainage

Fluid mechanics

The tissues of the anterior chamber angle normally offer a certain resistance to fluid outflow. IOP builds up, in response to the inflow of aqueous humor, to the level sufficient to drive fluid across that resistance at the same rate it is produced by the ciliary body; this is the steady-state IOP. In the glaucomatous eye, this resistance is often unusually high, causing elevated IOP. Results from three major clinical trials confirm the value of reducing IOP in patients with ocular hypertension or glaucoma to prevent the onset of glaucoma in the former case and the progression of disease in the latter.^{294–297} Understanding the factors governing normal and abnormal aqueous humor formation, aqueous humor outflow, IOP, and their interrelationships and manipulation is vital in understanding and treating glaucoma.

Briefly, let:

- F = flow ($\mu\text{l}/\text{min}$)
- F_{in} = total aqueous humor inflow: human = $\sim 2.5 \mu\text{l} \times \text{min}^{-1}$.^{11,58,221,298}
- F_s = inflow from active secretion
- F_f = inflow from ultrafiltration
- F_{out} = total aqueous humor outflow
- F_{trab} = outflow via trabecular pathway
- F_u = outflow via uveoscleral pathway, $0.3 \mu\text{l}/\text{min}$, measured invasively by radioactive tracer, in primarily elderly human eyes with malignant melanoma, tumor or glaucoma;⁹ $1.64 \mu\text{l}/\text{min}$ in normal subjects age 20–30 yrs and $1.16 \mu\text{l}/\text{min}$ in subjects >60 years, measured by non-invasive fluorophotometry¹¹
- P = pressure (mmHg)
- P_i = IOP: humans = 16 mmHg ²⁹⁹
- P_e = episcleral venous pressure: human = 9 mmHg ^{300,301}
- R = resistance to flow ($\text{mmHg} \times \text{min}/\mu\text{l}$)
- C = facility or conductance of flow ($\mu\text{l}/\text{min}/\text{mmHg}$) = $1/R$
- C_{tot} = total aqueous humor outflow facility (OF): humans age 20–30 years, $0.25 \mu\text{l}/\text{min}/\text{mmHg}$; >60 years, $0.19 \mu\text{l}/\text{min}/\text{mmHg}$.¹¹ OF = $0.54 - (0.0042 \times \text{age in years}) \mu\text{l}/\text{min}/\text{mmHg}$.³⁰² $0.24 \mu\text{l}/\text{min}/\text{mmHg}$.³⁰³ <40 years, 0.33 ; >60 years, $0.23 \mu\text{l}/\text{min}/\text{mmHg}$.³⁰⁴ $0.28 \mu\text{l}/\text{min}/\text{mmHg}$.³⁰⁵ all measured by indentation tonography
- C_{trab} = facility of outflow via trabecular pathway: humans 20–30 years, $0.21 \mu\text{l}/\text{min}/\text{mmHg}$; >60 years, $0.25 \mu\text{l}/\text{min}/\text{mmHg}$ (fluorophotometry);³⁰⁶ $0.22 \mu\text{l}/\text{min}/\text{mmHg}$ (tonography)³⁰⁵
- C_u = facility of outflow via uveoscleral pathway: humans = $0.02 \mu\text{l}/\text{min}/\text{mmHg}$.³⁰⁷ this was probably based on reported monkey values^{152,308}

- C_{ps} = facility of inflow: human = $0.06 \mu\text{l}/\text{min}/\text{mmHg}$,³⁰⁵ $0.08 \mu\text{l}/\text{min}/\text{mmHg}$.⁵³ These values for C_{ps} are most likely overestimates: under normal circumstances in a non-inflamed eye the phenomenon is negligible;⁵⁴ values for the normal monkey measured by a more precise tracer technique are $<0.02 \mu\text{l}/\text{min}/\text{mmHg}$.^{152,308}

Then:

$$F_{\text{in}} = F_s + F_t$$

$$F_{\text{out}} = F_{\text{trab}} + F_u$$

$$C_{\text{tot}} = C_{\text{trab}} + C_u + C_{\text{ps}}$$

At steady-state:

$$F = F_{\text{in}} = F_{\text{out}}$$

The simplest hydraulic model, represented by the classic Goldmann equation, views aqueous flow as passive non-energy-dependent bulk fluid movement down a pressure gradient, with aqueous leaving the eye only via the trabecular route, where $\Delta P = P_i - P_e$, so that $F = C_{\text{trab}}(P_i - P_e)$. This relationship is correct as far as it goes, but it is vastly oversimplified. Since there is no complete endothelial layer covering the anterior surface of the ciliary body and no delimitation of the spaces between the trabecular beams and the spaces between the ciliary muscle bundles,¹⁴⁰ fluid can pass from the chamber angle into the tissue spaces within the ciliary muscle. These spaces in turn open into the suprachoroid, from which fluid can pass through the scleral substance or the perivascular/perineural scleral spaces into the episcleral tissues. Some investigators believe that some fluid may also be drawn osmotically into the vortex veins by the high protein content in the blood of these vessels.² Along these uveal routes, the fluid mixes with tissue fluid from the ciliary muscle, ciliary processes, and choroid. Thus, this flow pathway may be analogous to lymphatic drainage (also see [Prostaglandin Mechanisms](#)) of tissue fluid in other organs and provide an important means of ridding the eye of potentially toxic tissue metabolites.^{153,154} The eye has long been considered to be devoid of lymphatics, but expression of lymphatic markers in the ciliary body and muscle have recently been reported.^{308a–308d} Whether there is a true lymphatic flow system in the eye remains to be established, however.

Flow from the anterior chamber across the TM into Schlemm's canal is pressure-dependent, but drainage via the uveoscleral pathway is virtually independent of pressure at IOP levels greater than 7–10 mmHg.^{12,48,309} While the actual drainage rates ($\mu\text{l}/\text{min}$) via the trabecular and uveoscleral routes in the monkey may be approximately equal, measured facility of uveoscleral outflow (C_u , determined by measuring uveoscleral outflow at two different IOP levels) is only about $0.02 \mu\text{l}/\text{min}/\text{mmHg}$, or less than one-twentieth the facility of trabecular outflow.³⁰⁹ The reasons for the pressure-independence of the uveoscleral pathway are not entirely clear but might be consequent to the complex nature of the pressure and resistance relationships between the various fluid compartments within the soft intraocular tissues along the route.¹² For instance, pressure in the potential suprachoroidal space (P_s) is directly dependent on IOP, such that at any IOP level, P_s is considerably but constantly less than IOP.¹² Since the pressure gradient between the anterior

chamber and suprachoroid is independent of IOP, bulk fluid flow between these compartments will also be IOP-independent. Intraorbital pressure is such that under normal circumstances there is always a positive pressure gradient between the suprachoroidal and intraorbital spaces.¹² Fluid and solutes, including large protein molecules, can thus easily exit the eye by passing through the spaces surrounding the neural or vascular scleral emissaria or through the scleral substance itself.^{4,50,310,311} At very low IOP levels, the net pressure gradient across the uveoscleral pathways is apparently so low that uveoscleral drainage decreases.⁴⁸

The absence of an outflow gradient from the suprachoroid may contribute to the development of choroidal detachments seen during the ocular hypotony that sometimes follows intraocular surgery.¹² However, other investigators find unconventional outflow to be more pressure-sensitive than described by Bill.^{3,312,313} Uveoscleral outflow may become more sensitive to pressure following prostaglandin treatment.³¹⁴ There is no need for fluid flow to carry tracer across the sclera since it can diffuse across on its own, based on calculations of diffusional transport properties.² Direct evidence for a uveovortex pathway³ is demonstrated after perfusion of the anterior chamber with fluorescein, and finding the fluorescein concentration in the vortex veins is higher than in the general circulation. Also, flow across the sclera is pressure-dependent.³¹³ Uveovortex flow explains the relative insensitivity of the flow to pressure because most of the driving force is the colloidal osmotic pressure of the blood that draws the fluid into these vessels.² Clearly, more needs to be learned about this flow pathway. Since, under normal steady-state conditions, C_{ps} and C_u are so low compared with C_{trab} , the hydraulics of aqueous dynamics may be reasonably approximated for clinical purposes by:

$$F_{in} = F_{out} = C_{trab}(P_i - P_e) + F_u$$

or rearranged:

$$P_i = P_e + (F_{in} - F_u)/C_{trab}$$

Clinically significant increases in inflow occur only in situations involving breakdown of the blood-aqueous barrier. The pressure sensitivity of the ultrafiltration component of aqueous secretion blunts the tendency for IOP to rise under such conditions, that is, C_{ps} is increased. Elevated episcleral venous pressure, such as may occur with arteriovenous communications resulting from congenital malformations or trauma³¹⁵ and perhaps, as shown for the first time in one study, in POAG and normal tension glaucoma,³⁰⁰ causes a nearly mmHg for mmHg increase in IOP. Clinically relevant reductions in IOP are produced by decreasing F_{in} or by increasing C_{trab} and F_u . Pharmacologic agents may exert small and probably clinically insignificant effects on P_e .^{59,179,196,197,316-321}

Structural components

Approximately one-half to three-quarters of the aqueous leaves the eye through the TM and Schlemm's canal.^{11,306} This outflow is pressure dependent. Schlemm's canal and the TM lie within the internal scleral groove between the scleral spur and the ring of Schwalbe's line at the termination of Descemet's membrane. An anterior non-filtering portion, which presents minimal resistance to fluid outflow, can be

distinguished from a posterior filtering portion of the meshwork. The TM itself consists of three functionally and structurally different parts: the iridic and uveal part, which represents the innermost portion of the meshwork; the corneoscleral part, which extends between the scleral spur and the cornea; and the juxtaganicular part or cribriform layer, which lies adjacent to the inner wall of Schlemm's canal (Fig. 11.4).³²²⁻³²⁶

The major resistance site within the trabecular structures likely resides in the cribriform portion of the meshwork,^{322-324,326-328} the outermost part of the mesh consisting of several layers of endothelial cells embedded in a ground substance comprising a wide variety of macromolecules, including hyaluronic acid, other glycosaminoglycans, collagen, fibronectin, and other glycoproteins presumably produced by meshwork endothelial cells.³²⁹⁻³³¹ The cribriform layer is supported by an elastic-like fiber network and fine collagen fiber bundles (Fig. 11.5),³³² having the same orientation as the elastic-like network in the central core of the trabecular lamellae. This network is connected to the inner wall endothelium of Schlemm's canal by fine, bent, connecting fibrils. This cribriform plexus is far more extensive in the juxtaganicular tissue of human eyes as compared to other species, perhaps contributing to the lack of washout in human eyes *in vitro*.³³³ The washout-associated increase in outflow facility in nonhuman species³³⁴⁻³³⁷ correlates with the extent of physical separation between the juxtaganicular tissue and the inner wall endothelium lining Schlemm's canal or, in some species, the aqueous plexus.³³⁸

However some investigators consider the main resistance to lie slightly proximal to the cribriform meshwork tissue,³³⁹⁻³⁴¹ i.e. in the inner wall itself and the very flimsy basement membrane of the inner wall endothelial cells. Separation of the basal lamina cells lining of the inner wall of Schlemm's canal from the underlying juxtaganicular tissue as seen using quick-freeze/deep-etch electron microscopy may represent flow pathways.³⁴² Under normal conditions, the inner wall of Schlemm's canal and juxtaganicular cells may be in a contracted state, limiting the routes available for fluid flow as demonstrated with gold particle infusion studies in non-human primates (Fig. 11.6).^{343,344} Expansion of the area available for fluid drainage can increase the rate of fluid outflow.^{343,344} The accompanying loss of extracellular material may not be responsible for the decrease in resistance to fluid outflow.³⁴²⁻³⁴⁵

Fluid movement across the inner canal wall endothelium itself appears to be predominantly via passive pressure-dependent transcellular pathways,³²³ including giant vacuole formation (Fig. 11.7) especially near collector channels.³⁴⁶⁻³⁵⁰ Pore formation is often associated with the giant vacuoles, but may also be found in thin, flat regions in the inner wall.³²³ Calculations of the number and size of pores and openings in the inner wall endothelium of Schlemm's canal are too large to account for most of the outflow resistance.^{351,352} These and other findings lead to the assumption that the main resistance to aqueous outflow is located internal to the endothelial lining, i.e. within the subendothelial or cribriform layer.³⁵³

Although the pores themselves contribute negligible flow resistance, because they force the fluid to "funnel" through those regions of the cribriform meshwork tissue nearest the pores, their number and size can greatly influence the

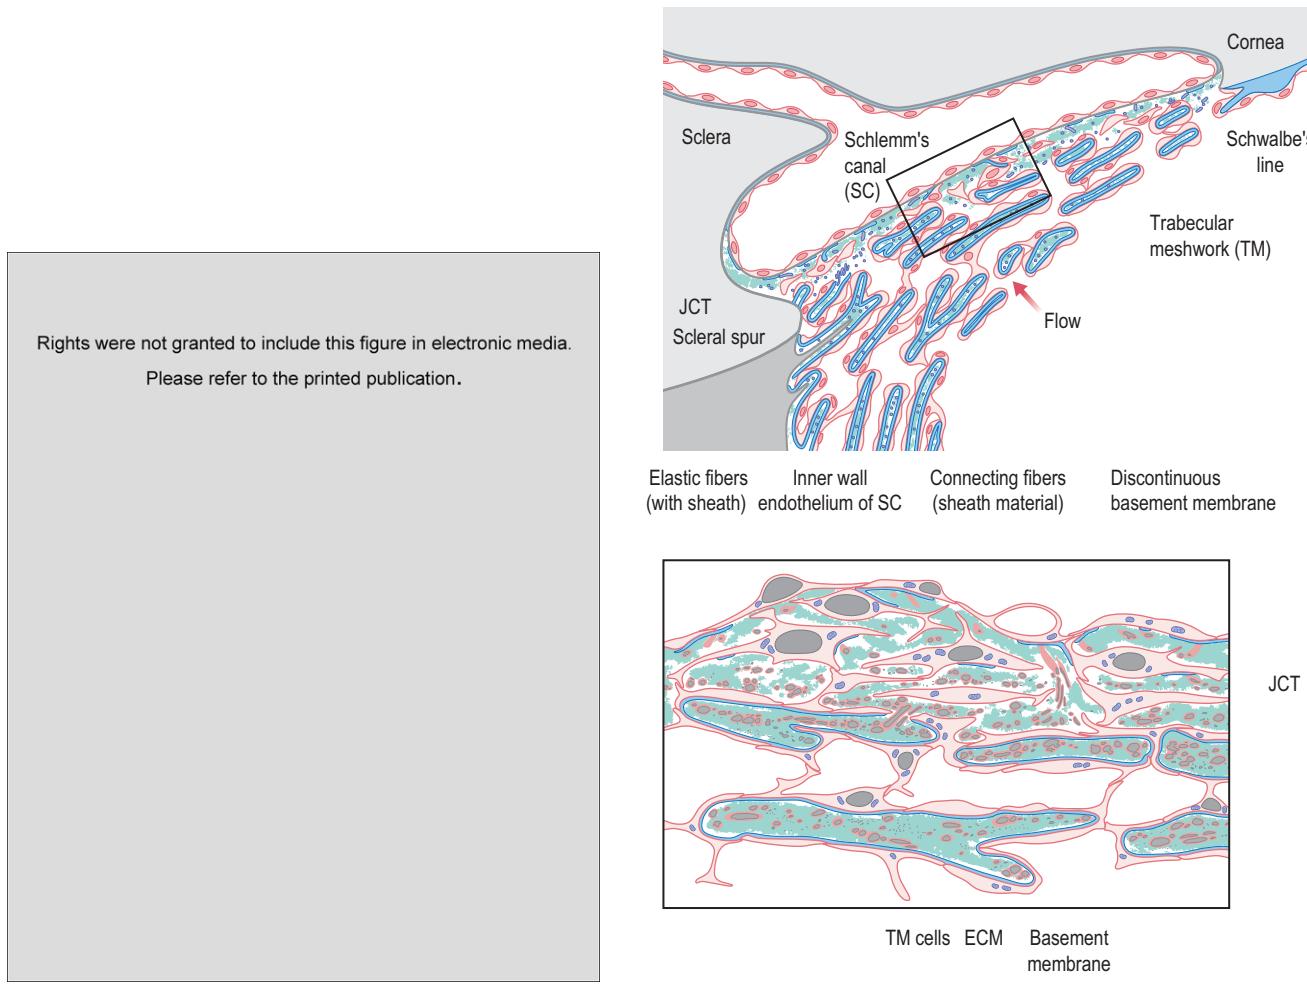

Figure 11.4 (A) Three layers of trabecular meshwork (shown in cutaway view): uveal, corneoscleral, and juxtapacanalicular. (From Acott TS, Kelley MJ. *Exp Eye Res* 86:543, 2008. Copyright Elsevier 2008.) (B) Diagram of the outflow pathway and juxtapacanalicular (JCT) or cribriform region. The lower portion of the figure shows a stylized view of the TM and the upper inset shows an expanded view of the JCT region.

effective outflow resistance of the cribriform meshwork tissue.³⁵⁴ However, two studies^{351,352} failed to find a correlation between outflow facility and inner wall pore density as would be expected if the funneling effect contributed to aqueous outflow resistance.² Studies with gold particles suggest that exclusion of large segments of the trabecular outflow pathway may help maintain high resistance to flow. Expanding the areas available for fluid drainage, by relaxation of the inner wall cells and the adjacent cribriform meshwork region may be a possible approach to glaucoma therapy (Fig. 11.6).³⁴³

Experimental studies of the transendothelial passage of ferritin particles in monkeys indicate that ferritin also traverses tortuous paracellular routes that lie between the endothelial cells of Schlemm's canal.³⁵⁵ The functional significance of these paracellular routes for aqueous outflow is not known. Tight junctions between endothelial cells of Schlemm's canal become less complex with increasing pressure, suggesting that the paracellular pathway into Schlemm's canal in the normal eye may be sensitive to modulation within a range of physiologically relevant pressures.³⁵⁶ However, gold tracer does not pass across junctions

between the cells at a pressure of 25 mmHg; perhaps a higher pressure gradient is required to disrupt normal cellular junctions.³⁴³

Arguments about trans- vs paracellular routes and inner wall vs juxtapacanalicular resistance seem to be relatively minor questions from a clinical/translational viewpoint.

Pumping model for trabecular outflow

An alternative to the bulk flow model of aqueous outflow is one that characterizes it as a pumping phenomenon that depends on tissue compliance rather than static resistance (see reviews^{357,358}). Research supports the hypothesis that the aqueous outflow pump receives power from transient increases in IOP such as occur in systole of the cardiac cycle, during blinking and during eye movement. In the aqueous outflow pump model, all aqueous flow is through Schlemm's canal valves spanning the inner and outer walls of Schlemm's canal (Fig. 11.8). Clinical evidence of pulsatile flow into Schlemm's canal, from Schlemm's canal into the collector channels, and from aqueous veins into episcleral veins supports the model (visit [youtube.com/majohnstone](https://www.youtube.com/majohnstone) to see a video of this courtesy of Robert Stegmann). Tissue

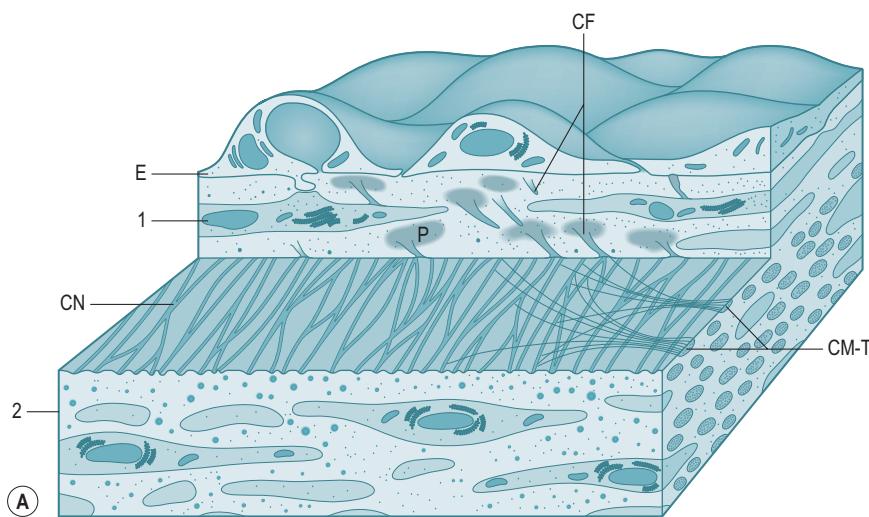

Figure 11.5 (A) Schematic drawing of the cribriform meshwork and the endothelial lining of Schlemm's canal (E). Note the connection between the ciliary muscle tendons (CM-T) and the elastic-like fiber plexus, or "cribriform plexus" (CN), located mainly in the region between the first and second subendothelial cell layers (1. and 2.). The cribriform plexus is connected to the inner wall endothelium and the plaque material (P) by a system of fine fibrils or "connecting fibrils" (CF). (B) Electron micrograph of a tangential section through the cribriform region almost at the level between the second subendothelial cell layer and the first corneoscleral trabecular lamellas (normal eye). The cells seen in the upper left are subendothelial. The elastic-like fibers of the cribriform region (arrows) form a plexus that shows the same equatorial orientation as the network of the elastic-like fibers of the trabecular lamellas. (From Rohen JW, Futa R, Lütjen-Drecoll E: Invest Ophthalmol Vis Sci 21:574, 1981, reproduced with permission from the Association for Research in Vision and Ophthalmology.)

Schematic drawings depicting 15-cell stretches (cell-cell junctions marked by arrows) along the Schlemm's canal (SC) of control and H-7-treated eyes. The location of individual gold particles is represented by red dots. (Bars = 4 μm.) (From Sabany I et al: Arch Ophthalmol 118:955, 2000. Copyright 2000 American Medical Association. All rights reserved.)

biomechanics allows the aqueous outflow pump to undergo short-term pressure-dependent stroke volume changes to maintain short-term homeostasis. Failure of the pumping mechanism occurs in glaucoma as a result of TM stiffening and reduced trabecular movement and persistent closure of Schlemm's canal.

Active involvement of the TM in regulating outflow

Another emerging concept portrays the TM as a living, active and reactive organ, rather than just a passive mélange of tissue components. Long-term homeostasis in response to physical stress requires modulation by cellular constituents

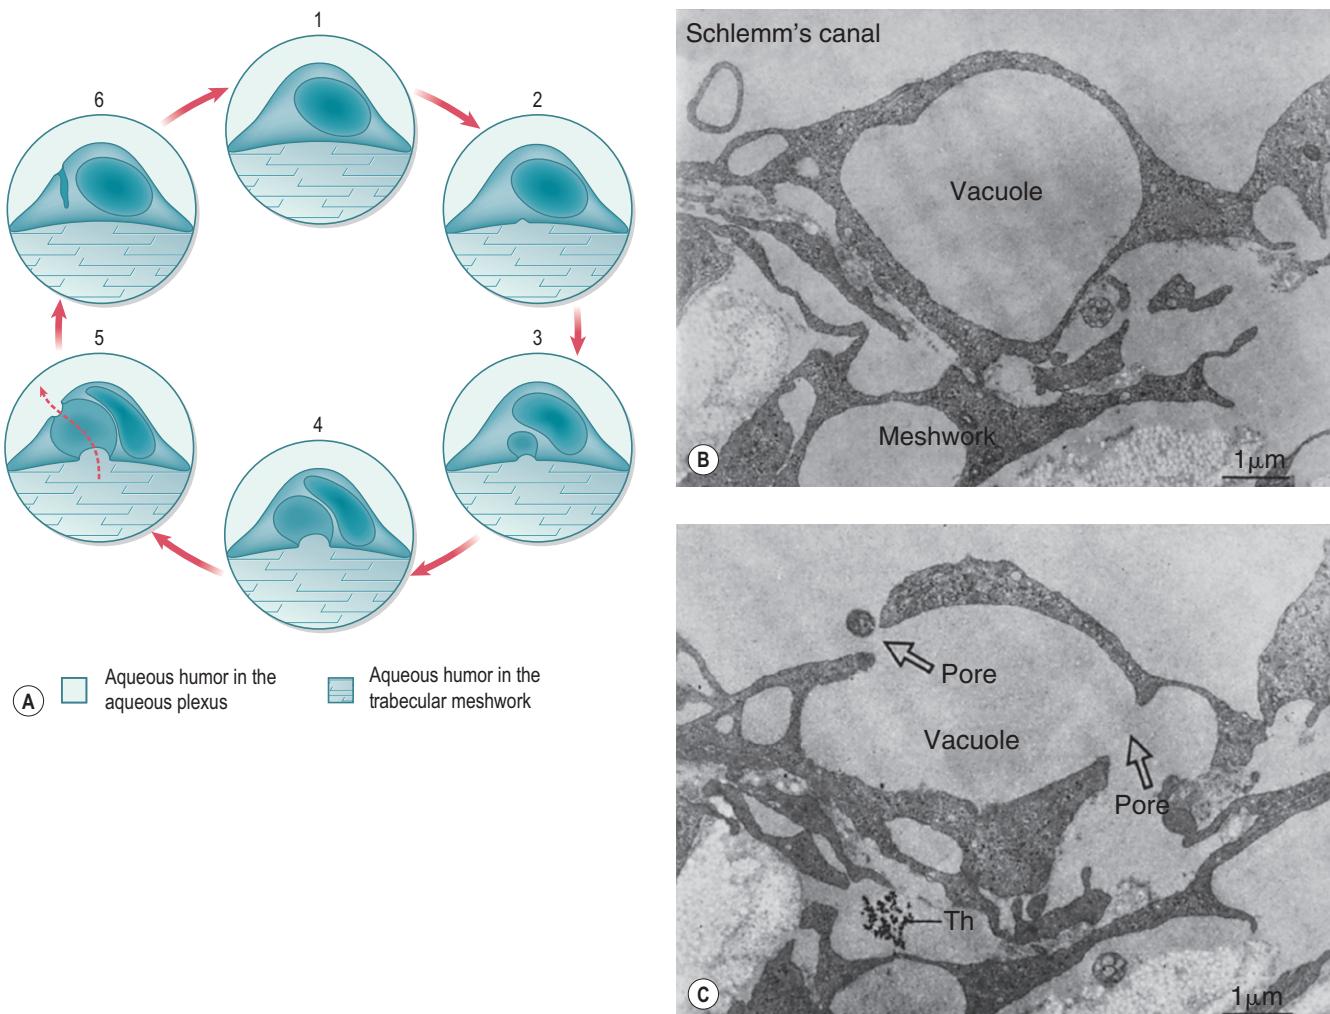

Figure 11.7 **(A)** Theory of transcellular aqueous transport in which a series of pores and giant vacuoles opens (probably in response to transendothelial hydrostatic pressure) on the connective tissue side of the juxtaganicular meshwork (2–4). Fusion of basal and apical cell plasmalemma creates a temporary transcellular channel (5) that allows bulk flow of aqueous into Schlemm's canal. (From Tripathi RC: Exp Eye Res 11:116, 1971. Copyright Elsevier 1971.) **(B)** Transmission electron micrograph of the inner wall of Schlemm's canal and the adjacent subendothelial tissue showing empty spaces or "giant vacuoles" within the endothelial cells. (From Inomata H et al: Am J Ophthalmol 73:760, 1972. Copyright Elsevier 1972.) **(C)** Serial sections of the inner wall of Schlemm's canal indicate that the "giant vacuoles" of the endothelial cells have openings toward the trabecular side, indicating that they are invaginations from the trabecular side. Some of the invaginations also have openings (pores) into Schlemm's canal. Aqueous humor can pass through the cells via the invaginations and the pores. Th = thorotrust. (From Inomata H et al: Am J Ophthalmol 73:760, 1972. Copyright Elsevier 1972.)

of the conventional outflow pathway: Schlemm's canal endothelia, juxtaganicular cells, endothelium lining the lumen of Schlemm's canal valves, and endothelium lining trabecular lamellae. Extracellular load-bearing constituents include the ECM of the trabecular lamellae and the juxtaganicular meshwork. How might all this work? The TM is in essence suspended between two fluid compartments (anterior chamber and Schlemm's canal) at different pressures. The TM can likely "sense" this pressure differential by "monitoring" stretch, deformation, shear stress, etc. and strives to maintain these parameters within a homeostatic range. Schlemm's canal endothelial cells may transmit sheer stress or other deformational stimuli through cell processes to the endothelium of the juxtaganicular region and the trabecular lamellae and to their corresponding basement membrane via integrins which in turn mediate regulation of ECM deposition and relaxation/contractility of the cells themselves. ECM rigidity in turn, modulates cytoskeletal

structures, protein expression patterns, signal transduction, and fibronectin deposition in HTM cells.³⁵⁹ Thus the tissue senses the physical as well as the biochemical environment in which it resides, and makes modifications to its physical and conformational properties to affect its overall hydraulic conductivity and thereby allow the eye to reach a specific target pressure (see also [Cytoskeletal and Cell-Junctional Mechanisms](#)). One possibility for derangement in glaucoma is that the set points become altered.

Outflow obstruction

Extracellular matrix accumulation and POAG

In glaucomatous eyes there is an increase in ECM beneath the inner wall of Schlemm's canal and in the cribriform region of the TM and thickening of the trabecular lamellae compared with age-matched normal controls.^{40,360} In advanced cases of primary open-angle glaucoma (POAG) there is

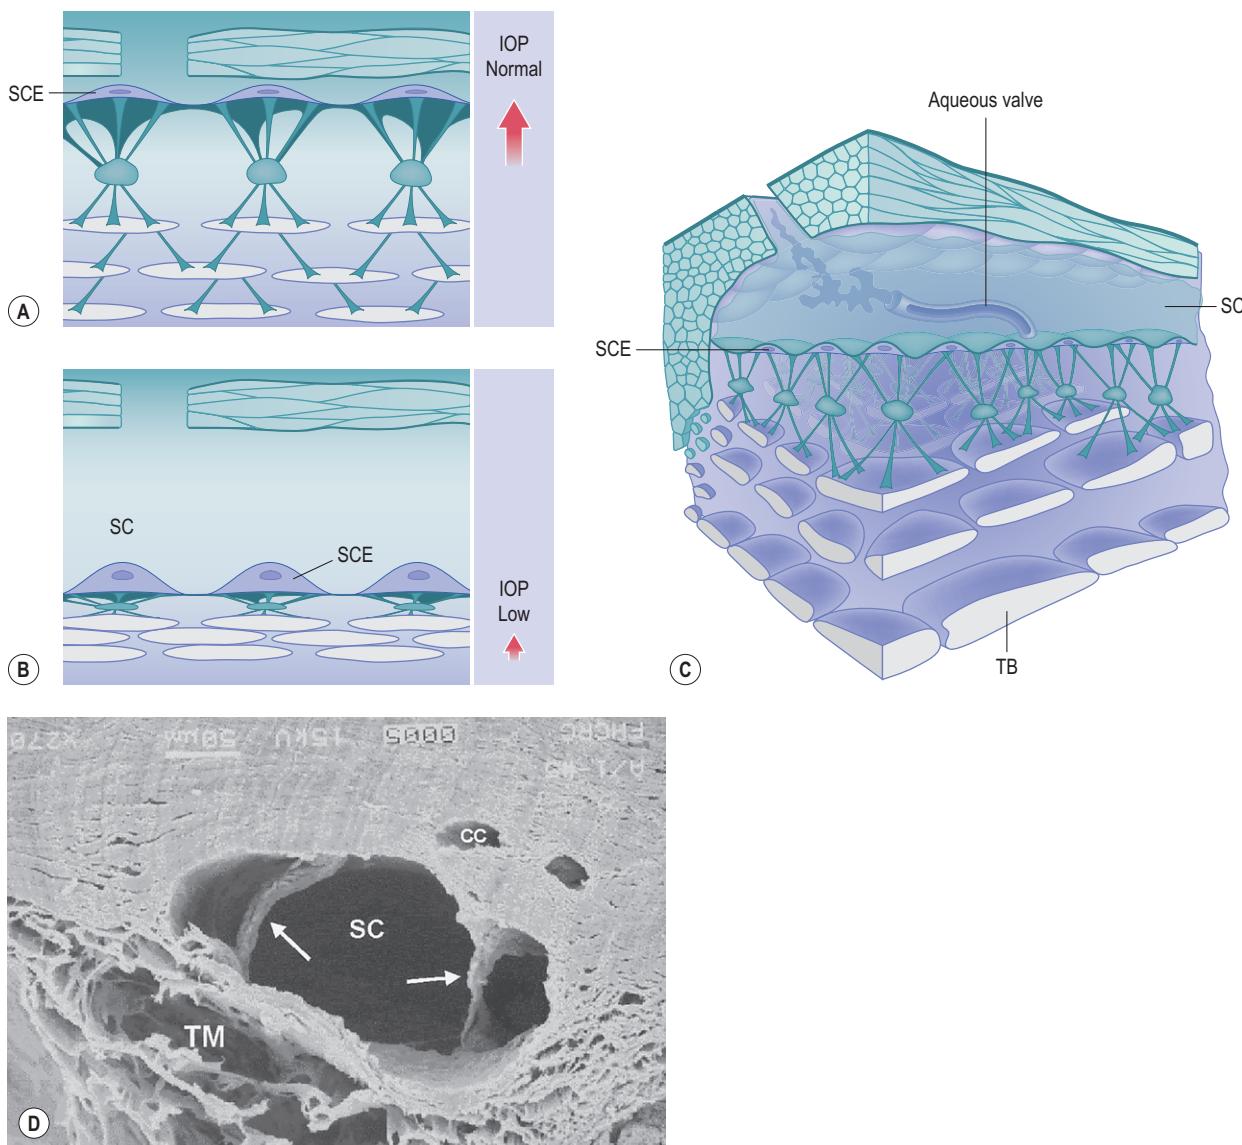

Figure 11.8 (A), (B), (C) Schematic representation of the biomechanical pump model. The pump is powered by transient increases in IOP, primarily caused by the cardiac cycle, blinking and eye movements. As the pressure increases, fluid is forced into one-way collector valves (C) that span across Schlemm's canal. At the same time, the increase in IOP pushes the endothelium of the inner wall of Schlemm's canal (A, B) outward and forces aqueous in the canal to move circumferentially into collector channels and aqueous veins. As the pressure drops, the tissues rebound, causing a pressure drop inside Schlemm's canal, moving fluid from the one-way valves (C) into the canal. SC, Schlemm's canal; SCE, Schlemm's canal endothelium; TB, trabecular beams. (From Johnstone MA: Rev Ophthalmol 14:9, 2007. Reproduced with permission from Jobson Publishing LLC and Murray A. Johnstone, MD.) (D) Valve-like structures in Schlemm's canal shown by scanning electron microscopy. Monkey eye – *Macaca nemestrina*. Viscoelastic dilation of Schlemm's canal (SC). Two valve-like structures (white arrows) span between trabecular meshwork (TM) and corneoscleral wall of SC. (cc) collector channel ostia. (From Smit BA, Johnstone MA: Ophthalmology 109:786, 2002. Copyright Elsevier 2002.)

additional loss of trabecular cells beyond that associated with normal aging.^{132,361} In this condition, the inner uveal and corneoscleral lamellae can be “glued” together,³⁶¹ and Schlemm's canal can be partly obliterated. Areas with more ECM are less perfused, presumably because of the higher resistance of the area.³⁶² The origin of the increased amounts of ECM in glaucomatous eyes is still unknown. Additionally, most specimens of glaucomatous eyes investigated morphologically are derived from patients who have been treated for many years with antiglaucoma drugs which can themselves induce changes in the biology of the trabecular cells.³⁶³

Transforming growth factor (TGF) β 2, a component of normal aqueous humor in many mammalian eyes,^{364–367} influences ECM production in the TM and has been

implicated in IOP elevation.^{368,369} Increased levels of total and active TGF β 2 are found in the aqueous humor of POAG patients compared to age-matched controls.^{367,370} TGF β 2 decreases the activity of matrix metalloproteinases (MMP), and thus possibly contributes to increased ECM in the TM of glaucomatous eyes.³⁷¹ TGF β s have an inhibitory effect on the rate of cell proliferation and motility of TM cells in vitro, which could contribute to the decreased cellularity of the TM.³⁷² Perfusion of human anterior segments in vitro with TGF β 2 results in decreased outflow facility and increased focal accumulation of ECM under the inner wall of Schlemm's canal.³⁶⁹ Similarly, TGF β 2 also enhances production of cochlins (an ECM protein found only in the TM of POAG eyes³⁷³), increases IOP and decreases outflow facility in

monkey and pig organ-cultured anterior segments.³⁷⁴ Over-expression of cochlin alone can also increase IOP in monkey organ-cultured anterior segments.⁶⁸² In vitro treatment of cultured TM cells with TGF β 2 results in elevated production of ECM proteins such as fibronectin and plasminogen activator inhibitor (PAI-1).³⁶⁸ In addition, interactions between bone morphogenic protein (BMP) and Wnt signaling, together with those between BMP and TGF- β , as well as TGF- β and Wnt, represent potential checkpoints to regulate TM cell function, IOP, and glaucoma pathogenesis. Increased expression of secreted frizzled-related protein-1 (sFRP-1) in glaucomatous TM may be responsible for the glaucoma phenotype of elevated IOP in humans. Studies are being conducted to determine the prevalence of defects in the Wnt pathway in the glaucoma population, the primary cause of altered sFRP-1 expression, and the potential deficiency of other members of the WNT pathway involved in glaucoma.⁶⁸³

How important "extra" ECM is in increasing resistance to aqueous outflow (and thus increasing IOP) in open-angle glaucoma is uncertain. The endothelial cells of the TM have phagocytic capabilities.³⁷⁵⁻³⁷⁷ It has been proposed that the TM is in effect a self-cleaning filter, and that in most of the open-angle glaucomas, the self-cleaning (i.e. phagocytic) function is deficient or at least inadequate to cope with the amount of material present.^{12,378} Phagocytosis, especially of particulate matter and red blood cells, is also carried out by trabecular macrophages. Although this process may be important in clearing the anterior chamber of some inflammatory debris or as a normal housekeeping function, it is probably not significant for bulk outflow of aqueous. However, this is another example of the TM as a reactive rather than a passive tissue, sensing its environment and modifying it. Artificial perfusion of the anterior chamber in non-human primates is associated with a progressive time-dependent decrease in outflow resistance as described above (Structural components – washout). Resistance washout does not change with age in monkeys.³⁷⁹

Combining the clogged-filter concept of glaucoma and the washout concept of perfusion-induced resistance decrease inevitably led to interest in compounds that might disrupt or remodel the structure of the meshwork and canal inner wall so as to enhance flow through the tissue and/or promote washout of normal and pathologic resistance-producing ECM (see Cytoskeletal Mechanisms). Such compounds might provide insights into cellular and extracellular mechanisms governing outflow resistance in normal and glaucomatous states. Additionally, if normal or pathologic ECM required many years to accumulate to the extent that IOP became elevated, perhaps a one-time washout would provide years of normalized outflow resistance and IOP.^{380,381}

Cell and other particulates

Normal erythrocytes are deformable and pass easily from the anterior chamber through the tortuous pathways of the TM and the inner wall of Schlemm's canal.³²³ However, non-deformable erythrocytes such as sickled or clastic (ghost) cells may become trapped within and obstruct the TM, elevating outflow resistance and IOP.³⁸²⁻³⁸⁴ Similarly, macrophages that are swollen after ingesting lens proteins leaking from a hypermature cataract³⁸⁵ or breakdown products from intraocular erythrocytes³⁸⁶ or pigmented tumors (or the tumor cells themselves)³⁸⁷ may produce meshwork obstruction. Pigment liberated from the iris spontaneously

(pigmentary dispersion syndrome) or iatrogenically (following laser iridotomy) may clog or otherwise alter the meshwork function, presumably without prior ingestion by wandering macrophages,^{388,389} as may zonular fragments following iatrogenic enzymatic zonulolysis^{390,391} or lens capsular fragments following laser posterior capsulotomy.^{392,393} Ocular amyloidosis can lead to elevated IOP as a result of blockage of the TM with amyloid particles.³⁹⁴

Protein and other macromolecules

Glaucoma secondary to hypermature cataract (phacolytic glaucoma) or uveitis has long been ascribed to trabecular obstruction. In the former entity, the presence of protein-laden macrophages lining the chamber angle seems adequate to account for increased outflow resistance.³⁸⁵ The uveitis-related glaucomas comprise many different entities, and the etiology of the increased outflow resistance seems less clear; postulated mechanisms include trabecular involvement by the primary inflammatory process, trabecular obstruction by inflammatory cells, or secondary alteration of trabecular cellular physiology by inflammatory mediators or by-products released elsewhere in the eye.

Small amounts of purified high-molecular-weight, soluble lens proteins^{395,396} or serum itself,³⁹⁷ when perfused through the anterior chamber of freshly enucleated human eyes, causes an acute and marked increase in outflow resistance. Thus, it may be that specific proteins, protein subfragments, or other macromolecules are themselves capable of obstructing or altering the meshwork so as to increase outflow resistance, perhaps contributing to the elevated IOP in entities such as the phacolytic, uveitic, exfoliation,³⁹⁸ and hemolytic³⁸⁶ glaucomas. Experimental perfusion of the enucleated calf eye^{399,400} or monkey eye in vivo⁴⁰¹ with medium containing higher protein concentrations than found in normal aqueous humor indeed reduces or eliminates resistance washout. Perhaps protein in the TM is essential for maintenance of normal resistance either by providing resistance itself, or by signaling or modifying some property of the meshwork such as stimulation of focal adhesion and stress fiber formation, to enhance adhesion of TM cells to the ECM.⁴⁰¹⁻⁴⁰³

Hyaluronate- and chondroitin sulfate-based agents used as tissue spacers during intraocular surgery ("viscoelastic agents") may raise IOP in human eyes if not completely removed from the eye by irrigation/aspiration at the conclusion of a procedure, presumably by obstructing trabecular outflow.^{404,405}

Pharmacology and regulation of outflow

Cholinergic mechanisms

Conventional (trabecular) outflow

In primates the iris root inserts into the ciliary muscle and the uveal meshwork just posterior to the scleral spur, while the ciliary muscle inserts at the scleral spur and the posterior inner aspect of the TM.⁴⁰⁶ The anterior tendons of the longitudinal portion of the ciliary muscle insert into the outer lamellated portion of the TM and into the cribriform meshwork, and via elastic elements into specialized cell surface

adaptations on the inner wall endothelial cells (see Fig. 11.5). Ciliary muscle contraction results not only in spreading of the lamellated portion of the meshwork but also in an inward pulling of the cribriform elastic fiber plexus and straightening of the connecting fibrils and perhaps dilation of Schlemm's canal. Movement of the inner wall region might affect the area and configuration of the outflow pathways and thereby outflow resistance.⁴⁰⁷ Voluntary accommodation (human),⁴⁰⁸ electrical stimulation of the third cranial nerve (cat),⁴⁰⁹ topical, intracameral, or systemically administered cholinergic agonists (monkey and human),^{410,411} and, in enucleated eyes (monkey and human), pushing the lens posteriorly with a plunger through a corneal fitting⁴¹² all decrease outflow resistance, while ganglionic blocking agents and cholinergic antagonists increase resistance.^{410,413-415}

Furthermore, the resistance-decreasing effect of intravenous pilocarpine in monkeys is virtually instantaneous, implying that the effect is mediated by an arterially perfused structure or structures.⁴¹⁶ However, not all the experimental evidence supports this strictly mechanical view of cholinergic and anticholinergic effects on meshwork function. For example, in monkeys, intravenous atropine rapidly reverses some but not all of the pilocarpine-induced resistance decrease,^{417,418} and topical pilocarpine causes a much greater resistance decrease per diopter of induced accommodation than does systemic pilocarpine (monkey)⁴¹⁸ or voluntary accommodation (human).⁴¹⁹ The inability of atropine to rapidly and completely reverse the pilocarpine-induced facility increase in normal eyes could be due to mechanical hysteresis of the meshwork.⁴²⁰ The variation in the relative magnitude of pilocarpine-induced accommodation and resistance decrease when the drug is administered by different routes might reflect differences in bioavailability of the drug to different regions of the muscle.⁴¹⁸

However, following ciliary muscle disinsertion and total iris removal (but not iris removal alone), there is virtually no acute resistance response to intravenous or intracameral pilocarpine and no response to topical pilocarpine.⁴²¹ Thus it seems virtually certain that the acute resistance-decreasing action of pilocarpine, and presumably other cholinomimetics, is mediated entirely by drug-induced ciliary muscle contraction, with no direct pharmacologic effect on the meshwork itself.

Cholinergic and norenergic nerve terminals that could induce contraction and relaxation of TM and scleral spur cells are present in primate TM and scleral spur. Terminals in contact with the elastic-like network of the TM and containing substance P immunoreactive fibers resemble afferent mechanoreceptor-like terminals.⁴²² Afferent mechanoreceptors that measure stress or strain in the connective tissue elements of the scleral spur have also been identified.⁴²³ These findings raise the possibility that the TM may have some ability to self-regulate aqueous humor outflow.

Muscarinic receptors and contractile elements are present in the TM. The m3 mRNA muscarinic receptor transcript is detected in human TM of cadaver eyes.⁴²⁴ Carbachol (CARB)-induced mobilization of Ca^{2+} and phosphoinositide production in human TM cells in culture is associated with the M3 muscarinic receptor.⁴²⁵ Smooth muscle specific contractile proteins are present in cells within the human TM and adjacent to the outer wall of Schlemm's canal and the collector channels.⁴²⁶⁻⁴²⁸ Isolated bovine TM strips contract

isometrically in response to CARB, pilocarpine, aceclidine (ACEC) and acetylcholine and endothelin-1.⁴²⁹⁻⁴³¹ However, in the organ cultured perfused bovine anterior segment, endothelin-1 and CARB-induced contractions result in an increase in resistance and a reduction of the outflow rate.⁴³² Also, low (10^{-8} to 10^{-6}M) but not high (10^{-4} to 10^{-2}M) doses of pilocarpine, ACEC, or CARB induce increased outflow facility in human perfused anterior ocular segments, devoid of ciliary muscle.^{433,434} However, low doses of pilocarpine have no effect on outflow facility in living monkeys, eyes;⁴³⁵ facility increases occur only at doses which also produced miosis and accommodation.

Direct effects of cholinergics on the TM and outflow facility could be mediated by cAMP⁴³⁶ and/or increased intracellular calcium and phospholipase C activity.⁴²⁵ Since receptor subtype specificity is concentration-dependent, low pilocarpine doses theoretically could stimulate M2 receptor-mediated cAMP elevation in the TM, and consequent relaxation of the meshwork.²⁰⁹ These potential direct actions of cholinomimetics notwithstanding, the major effect of cholinomimetics on outflow facility is almost surely related to ciliary muscle contraction.

Pilocarpine-induced ciliary muscle contraction spreads the TM, perhaps with the same physiological consequences as direct relaxation of the meshwork – decreased tissue density and thus decreased flow resistance due to opening of new flow pathways. Combination of threshold facility-effective doses of pilocarpine with maximal outflow facility-effective doses of H-7 (see Cytoskeletal Mechanisms) can further enhance the outflow facility response with minimal effects on accommodation.⁴³⁷

At least two different subtypes of muscarinic receptors, M2 and M3, are present in the ciliary muscle.^{424,438,439} The M2 receptor shows preferential localization to the longitudinal,⁴³⁸ putatively more facility relevant portion of the ciliary muscle, but to date no functional role for this subtype has been elucidated. mRNA from the M2, M3, and M5 subtypes is strongly expressed in the longitudinal and circular portions of human ciliary muscle cells and tissue.⁴³⁹ The M3 subtype appears to mediate the outflow facility and accommodative responses to pilocarpine and aceclidine in monkeys.^{440,441} In monkeys, the outer longitudinal region of the ciliary muscle differs ultrastructurally and histochemically from the inner reticular and circular portions.⁴⁴² Although differential distribution of muscarinic subtypes is probably not responsible for the outflow facility/accommodation dissociation occurring under certain conditions, functional dissociation might be produced by combinations of drugs from different classes.

Alterations in cholinergic sensitivity of the outflow apparatus

Given the long-term use of cholinergic agonists in glaucoma therapy and the vital role of ciliary muscle tone in regulating outflow resistance, it is important to note that in the monkey, topical administration of the cholinesterase inhibitor echothiophate or the direct-acting agonist pilocarpine can induce subsensitivity of the outflow facility and accommodative responses to pilocarpine, accompanied by decreased numbers of muscarinic receptors in the ciliary muscle.⁴⁴³⁻⁴⁴⁹ Even a single dose of pilocarpine or carbachol reduces receptor number.⁴⁴⁸ Since cholinergic drug therapy is not the

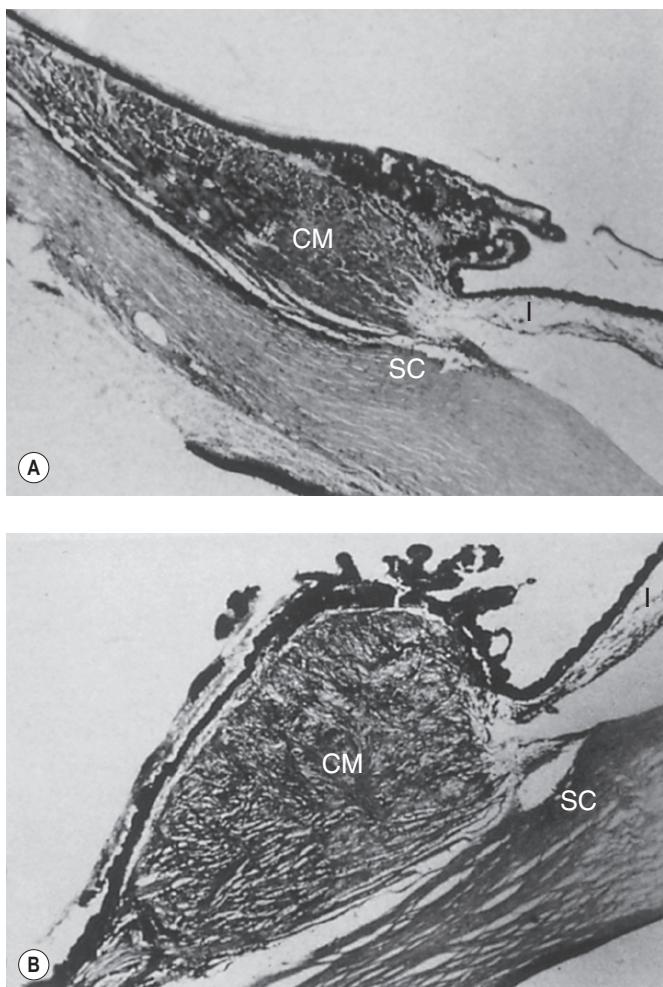

Figure 11.9 Histologic sagittal sections through the chamber angle region of monkey eyes treated acutely with atropine (**A**) or pilocarpine (**B**) topically. After treatment with pilocarpine, the muscle moves anteriorly and inwardly, thereby expanding the trabecular lamellas and widening Schlemm's canal. This contraction also obliterates the spaces between the ciliary muscle bundles, obstructing uveoscleral outflow. Conversely, atropine relaxes the ciliary muscle bundles. CM, Ciliary muscle; I, iris; SC, Schlemm's canal (Vervet monkey, Azan stain; original magnification $\times 25$). (From Lütjen-Drecoll E, Kaufman PL: J Glaucoma 2:316, 1993.)

mainstay of glaucoma therapy that it once was, the issues related to refractoriness to long-term therapy versus disease progression are no longer prominent areas of research.

Unconventional (uveoscleral) outflow

When the ciliary muscle contracts in response to exogenous pilocarpine (Fig. 11.9), the spaces between the muscle bundles are essentially obliterated.^{363,406,410} Conversely, during atropine-induced muscle relaxation, the spaces are widened.⁴¹⁰ If mock aqueous humor containing albumin labeled with iodine-125 or iodine-131 (which under resting conditions leave the anterior chamber essentially by bulk flow via the trabecular and uveoscleral drainage routes) is perfused through the anterior chamber, autoradiographs may be made to show qualitatively the distribution of the flow.^{9,317} In the pilocarpinized eye, radioactivity is present in the iris stroma, the iris root, the region of Schlemm's canal and the surrounding sclera, and the most anterior portion

of the ciliary muscle. In the atropinized eye, radioactivity is found in all these tissues, as well as throughout the entire ciliary muscle and even further posteriorly in the suprachoroid/sclera.^{9,317} In other perfusion experiments quantifying uveoscleral drainage, pilocarpinized eyes demonstrate but a fraction of the uveoscleral flow in atropinized eyes.^{197,317,318} Thus, to generalize in the primate eye, the magnitude of the pilocarpine (and presumably all cholinergic agonists) enhancement of aqueous humor drainage via the trabecular route is greater than the reduction of drainage via the uveoscleral route thus resulting in a reduction in IOP.

Adrenergic mechanisms

Conventional (trabecular) outflow

Topical and intracameral epinephrine increase outflow facility in primate eyes.^{179,316,450–453} Much work has been done attempting to define the time course, type of receptors (e.g. α , β , adenosine), and biochemical pathways (e.g., prostaglandins, cyclic adenosine monophosphate⁴⁵⁴) involved in these responses. Adrenergic receptor stimulation could alter intraocular, intrascleral, and extrascleral vascular tone, as well as have possible direct effects on the outflow pathways, all of which might alter IOP. These potential sites of action are not mutually exclusive, and indeed that might account for much of the variability and confusion in the literature.

In surgically untouched, aniridic, and ciliary muscle disinserted monkey eyes with widely varying starting facilities, epinephrine and norepinephrine increase facility by a constant percentage of the starting facility, indicating that neither the iris nor the ciliary muscle is involved in the responses and that the drugs exert their effects on whatever is responsible for the major part of the variation in starting facility (see Cytoskeletal Mechanisms). One possibility is an increase in the hydraulic conductivity per unit filtering area.^{455,456} Trabecular outflow facility increases in response to β -adrenergic agonists.^{10,179,457} Human TM or Schlemm's canal endothelial cells grown on porous filter supports separate and shrink when exposed to isoproterenol or epinephrine, resulting in increased transendothelial fluid flow.⁴⁵⁸ Biochemical evidence also points to the meshwork as the target tissue. It appears that the facility-increasing effect of epinephrine and norepinephrine is mediated by β_2 -adrenergic receptors on the trabecular endothelial cells, and the subsequent G-protein adenylate cyclase-cyclic AMP cascade.^{61,459} The facility-increasing effect of epinephrine is blocked by timolol^{460,461} but not betaxolol,^{462–464} in both humans and monkeys, consistent with the hypothesis that there are no β_1 receptors present in the primate TM.

Trabecular cells synthesize cAMP in response to stimulation with β -adrenoceptor-selective agonists.¹⁴ The increase in cAMP synthesis by TM cells in response to epinephrine can be blocked by timolol,¹⁴ although not by betaxolol (a β_1 -receptor antagonist), consistent with the hypothesis that there are only β_2 -receptors present in the TM. Topically applied adrenergic agonists (epinephrine, norepinephrine, isoproterenol) elevate aqueous humor cAMP levels, and intracameral injection of cAMP or its analogs, but not the inactive metabolite 5'AMP, lowers IOP and increases outflow facility.^{465–467} The cAMP-induced facility increase is not additive to that induced by adrenergic agonists, and vice-versa.⁴⁶⁸ Epinephrine increases facility and perfusate cAMP levels in

the organ-cultured perfused human anterior segment, effects that are blocked by timolol and the selective β_2 -antagonist ICI 118,551.⁴⁶⁹

In monkey ciliary muscle, ciliary processes, TM and iris tissue *in vitro*, epinephrine stimulates cAMP production. Part of the facility response *in vivo* and cAMP production *in vitro* is inhibited by indometacin, suggesting that part of the mechanism of action of epinephrine may be via prostanoid production or release.⁴⁷⁰ However, the epinephrine-induced facility increase in human anterior segments *in vitro* is attributed to protein synthesis and not to prostaglandin production.⁴⁷¹ Topical pretreatment of rabbits with an adenosine A1 antagonist inhibits both the epinephrine induced hypotensive response and the epinephrine-induced outflow facility increase, suggesting activation of ocular adenosine receptors as part of the ocular hypotensive action of epinephrine (see Other Mechanisms).⁴⁷²

Adrenergic innervation of the primate TM is sparse and concentrated mainly in the region of the meshwork near the ciliary muscle tendons. No functional significance can as yet be ascribed to these terminals.^{473–475} Studies suggest an epinephrine-induced disruption of actin filaments within the TM cells, consequent alteration in cell shape and cell-cell and cell-extracellular matrix (C-ECM) adhesions within the meshwork, resulting in altered meshwork geometry, and increased hydraulic conductivity across the meshwork. Relaxation of the TM also could play a role in the outflow facility response to epinephrine.⁴⁷⁶ Thus cytochalasin B (a disruptor of actin filament formation) potentiates the facility-increasing effect of epinephrine,⁴⁷⁷ while phalloidin (a stabilizer of actin filaments) inhibits it.⁴⁷⁸ Continuous exposure to epinephrine at a concentration of 10 μM produces arrest of normal cytokinetic cell movements, inhibits mitotic and phagocytic activity, marked cell retraction, and separation from the substrate and cellular degeneration after 4–5 days in cultured human trabecular cells.⁴⁷⁹ Similarly, the hydraulic conductivity of trabecular cell monolayer cultures grown on filters increases in response to epinephrine and is associated with changes in cell shape and with separation between cells.⁴⁸⁰ These actions of epinephrine were all partially blocked by pretreatment with timolol. β -Adrenergic agonists (epinephrine or isoproterenol) and analogs of cAMP increase phosphorylation of intermediate filaments of vimentin-type in human or rabbit ciliary processes or cultured ciliary epithelial-derived cells. Phosphorylation of vimentin increased by β -adrenergic agonists can be blocked by the β -adrenergic antagonist timolol⁴⁸¹ (see Cytoskeletal Mechanisms).

Unconventional (uveoscleral) outflow

β -Adrenergic receptors are present in the primate ciliary muscle, and their physiological or pharmacological stimulation relaxes the muscle.^{482–485} Epinephrine, in addition to increasing trabecular outflow, also increases uveoscleral outflow in monkeys⁴⁵³ and humans.^{10,215} The mechanism is unknown, but may be in part due to the mildly relaxant effect of epinephrine on the ciliary muscle, presumably acting via its β -adrenergic receptors.^{172,482–484} Pretreatment with the cyclo-oxygenase inhibitor indometacin inhibits the ocular hypotensive effect of topically applied epinephrine in humans⁴⁸⁶ suggesting that the IOP-lowering action of epinephrine may be mediated at least in part by prostaglandins or other cyclo-oxygenase products.^{457,486}

Numerous clinical studies in humans claim that topical application of timolol, a non-selective $\beta 1$ -, $\beta 2$ -adrenergic receptor antagonist, induces no change in distance refraction.⁴⁸⁷ However, a single topical application of 0.5 percent timolol may increase myopia by nearly 1 diopter, presumably by blocking the effect of endogenous ciliary muscle-relaxing sympathetic neuronal tone.⁴⁸⁸ Indirect fluorophotometric estimates fail to demonstrate any effect of timolol on uveoscleral outflow per se.²¹⁵ However, timolol may reduce epinephrine-induced increases in uveoscleral outflow when the two drugs are applied concurrently.²¹⁵ These findings are consistent with the data concerning adrenergic influences on ciliary muscle contractile tone and also illustrate the importance of the ambient neuronal and pharmacologic adrenergic tone in determining the response of a target tissue to an exogenous adrenergic agent.

In addition to suppressing aqueous formation (see above), α_2 -adrenergic agonists may enhance uveoscleral outflow. In humans apraclonidine- and brimonidine-induced IOP reductions are associated with decreased aqueous humor formation and decreased (apraclonidine) or increased (brimonidine) uveoscleral outflow.^{489,490} Treatment of ocular hypertensive patients with brimonidine for one month results in a suppression of aqueous formation early on with a later increase in uveoscleral outflow.²⁶⁰ A single topical application of either brimonidine or apraclonidine decreases IOP and aqueous flow by similar amounts in timolol-treated normal human eyes,²⁵⁹ suggesting that both α_2 -agonists act by a similar mechanism.

Bunazosin, a selective α_1 -adrenoceptor antagonist, can further enhance IOP lowering when used as an adjunctive therapy with latanoprost in monkeys (normotensive)⁴⁹¹ and humans (glaucoma)⁴⁹² or with timolol⁴⁹¹ by a mechanism partly due to ciliary muscle (bovine) relaxation but independent of an effect on matrix metalloproteinase activities (cultured monkey ciliary muscle cells).⁴⁹²

Cytoskeletal and cell junctional mechanisms (Box 11.2)

Agents that alter the cytoskeleton, cell junctions, contractile proteins, or ECM are capable of producing a “pharmacologic trabeculotomy”. The adhesion of cells to their neighbors or to the ECM has multiple effects on cell shape and dynamics. Cell-cell and cell-extracellular matrix adherens junctions are complex and dynamic in nature, comprising a myriad of proteins, and are modulated by the ambient physical

Box 11.2 Cytoskeletal, cell contractility/relaxation and cell junctional mechanisms

- Agents that alter the actin cytoskeleton and cellular contractility are in development to lower IOP by directly targeting the trabecular meshwork
- Relaxation of the trabecular meshwork and Schlemm's canal increases the area available for fluid drainage
- The first clinical trial using a selective ROCK inhibitor SNJ-1656 in healthy human eyes shows a dose-dependent decrease in IOP after single and multiple topical applications, but with some ocular surface toxicity⁵²³

(pressure, shear stress) and chemical (endogenous hormonal and biochemical, exogenous pharmacological) milieu. They play a role in signaling to the cell the state of its external environment. Actin filaments play a central role as the "backbone" of the submembrane plaque in both types of junctions (Fig. 11.10), with the coupling of actin and myosin being essential for cell contractility.^{493,494}

Changes in TM and/or Schlemm's canal cells, which could affect trabecular outflow resistance by altering the dimensions or direction of flow pathways and the amount and composition of the ECM, can be modulated directly by actin-disrupting agents or indirectly by inhibition of specific protein kinase(s) or cellular contractility through administration of protein kinase inhibitors or gene therapy.^{38,495}

Early studies involving anterior chamber perfusions of living monkey eyes with cytochalasins, fungal metabolites that block actin filament assembly, resulted in marked increases in total outflow facility within minutes.^{477,496,497} Tracer studies demonstrate that the increase in total outflow facility represents increased facility across the meshwork and inner canal wall⁴⁹⁸ and is not related to contraction of the ciliary muscle since the effect is similar in eyes with and without surgically disinserted ciliary muscles.^{308,496} More recently, studies show that potent actin-disrupting agents such as marine macrolides like latrunculins, which sequester monomeric G-actin, lead to massive disassembly of filamentous actin (Fig. 11.10). Treatment of HTM cells with latrunculin A or B (LAT-A, LAT-B) results in cell rounding and retraction of the lamellipodium, which is accompanied by an apparent "arborization" of the cells.^{499,500} LAT-A or -B administered intracamerally or topically to living monkey eyes induces 2–4-fold increases in outflow facility.^{501,502} In organ-cultured postmortem porcine eyes or human eyes, LAT-B significantly increases outflow facility by 60–70 percent.^{500,503} Single or multiple topical treatments with LAT-A and/or -B also significantly decrease IOP in monkeys.^{501,502,504}

Morphologically, the LAT-B-induced decrease in outflow resistance in monkey eyes *in vivo* is associated with massive "ballooning" of the juxtapacanalicular region, leading to expansion of the space between the inner wall of Schlemm's canal and the trabecular collagen beams without observable separations between inner wall cells.⁵⁰⁵ However, in postmortem human eyes, the facility increase is accompanied by increased openings between inner wall cells with only very modest rarefaction of the juxtapacanalicular tissue and separation of the inner wall of Schlemm's canal from juxtapacanalicular tissue.⁵⁰³

Perturbation of the cellular actomyosin system by inhibition of myosin light chain kinase (MLCK) and/or Rho kinase is demonstrated with the nonselective serine-threonine kinase inhibitor H-7.^{500,506–509} H-7, administered intracamerally or topically to living monkey eyes, doubles outflow facility and decreases IOP⁵⁰⁸ by directly affecting the TM.⁵¹⁰ In porcine, human or monkey eye cultured anterior segments, H-7 also significantly increases outflow facility.^{500,511,512} The H-7-induced increase in outflow facility in the live monkey eye is associated with cellular relaxation and drainage-surface expansion of the TM and Schlemm's canal (see Fig. 11.6), accompanied by loss of ECM. The inner wall cells of Schlemm's canal become highly extended, yet cell-cell junctions are maintained.^{343,344} A specific Rho kinase inhibitor, Y-27632, induces reversible changes in

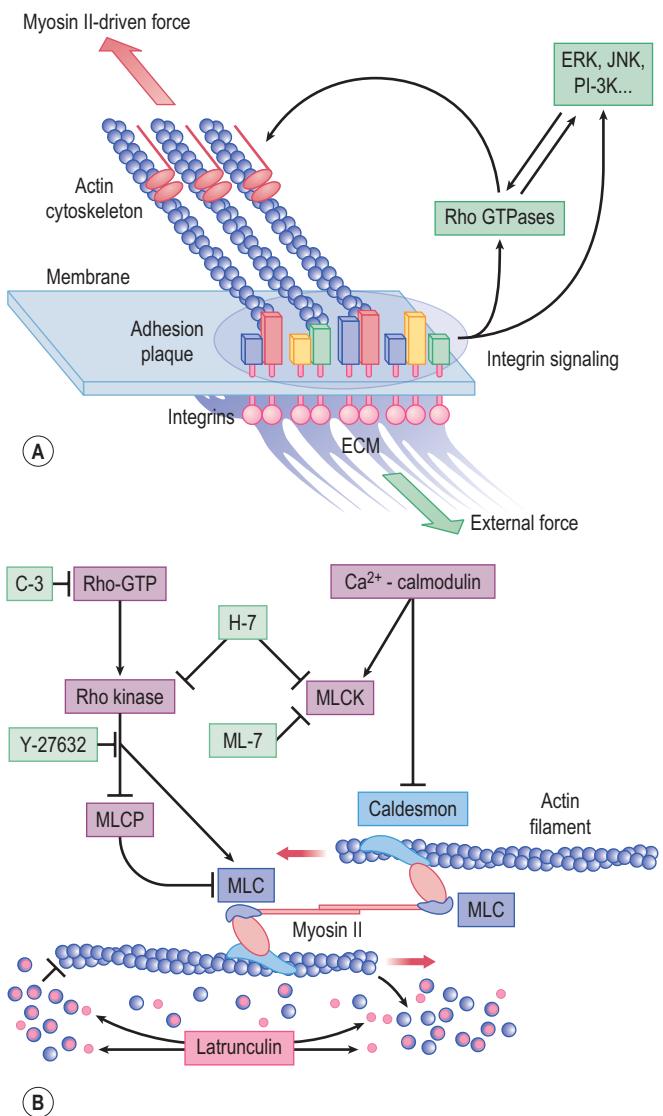

Figure 11.10 (A) Focal adhesion (FA) as a mechanosensor. Focal adhesions are multi-molecular complexes connecting the extracellular matrix with the actin cytoskeleton. Heterodimeric transmembrane integrin receptors (red) bind matrix proteins via their extracellular domains, while their cytoplasmic domains are associated with a dense submembrane plaque containing more than 50 different proteins ("boxes" enclosed in the oval area) including structural elements as well as signal transduction proteins such as FAK, Src, ILK, etc. The plaque, in turn, is connected to the termini of actin filament bundles. The assembly and maintenance of FA depend on local mechanical forces. This force may be generated by myosin II-driven isometric contraction of the actin cytoskeleton, or by extracellular perturbations such as matrix stretching or fluid shear stress. Force-induced assembly of the adhesion plaque leads to the activation of a variety of signaling pathways that control cell proliferation, differentiation, and survival (e.g., MAP kinase and PI 3-kinase pathways) as well as the organization of the cytoskeleton (e.g., Rho family GTPase pathways). Rho, in particular, is an indispensable regulator of FA assembly affecting, via its immediate targets Dia1 and ROCK, actin polymerization and myosin II-driven contractility. (From Geiger B, Bershadsky A: Cell 110:129, 2002. Copyright Elsevier 2002.) (B) Schematic drawing illustrating targets for agents known to disrupt the actin cytoskeleton to enhance outflow facility. C-3, Y-27632 and H-7 block the Rho cascade, inhibiting actomyosin contraction and disrupting actin stress fibers; H-7 and ML-7 block myosin light chain kinase phosphorylation of the myosin light chain to interfere with actin-myosin interactions; latrunculin sequesters monomeric G actin leading to microfilament disassembly; caldesmon negatively regulates actin-myosin interactions. (Modified with permission from the original by Alexander Bershadsky.)

cell shape and decreases in actin stress fibers, focal adhesions, and protein phosphotyrosine staining in human TM cells and Schlemm's canal cells.^{513,514} In isolated bovine TM strips, Y-27632 completely blocks Ca²⁺-independent phorbol myristate acetate or endothelin-1-induced contraction.⁵¹⁵⁻⁵¹⁷ Rho kinase inhibitors increase outflow facility and/or decrease IOP in enucleated porcine eyes and/or living monkeys.^{513,514,518-521} Morphological studies in bovine eyes indicate that, with Y-27632, the structural correlate to the increase in outflow facility is physical separation between the juxtaganular connective tissue and inner wall of Schlemm's canal.⁵²² A clinical study demonstrates that topical administration of a selective ROCK (Rho-associated coiled coil-forming) protein kinase inhibitor (SNJ-1656, an ophthalmic solution of Y-39983 which is 30 times more potent at ROCK than Y-27632⁵²⁰) can lower IOP in humans⁵²³ although ocular surface toxicity occurs.

TM relaxation is also induced by modulating proteins, such as caldesmon, that negatively regulate actin-myosin interactions. When caldesmon is overexpressed, actin becomes uncoupled from myosin. Additionally, the exoenzyme C3 transferase disrupts actin-myosin interactions by inhibiting Rho-GTP thereby blocking the whole Rho cascade (Fig. 11.10). Recently, adenovirus-delivered exoenzyme C3 transferase (C3-toxin) cDNA and non-muscle caldesmon cDNA were successfully expressed in cultured human TM cells.^{524,525} Outflow facility in organ-cultured human or monkey eyes is dramatically increased following overexpression of these genes.^{525,526} Specific inhibition of Rho-kinase activity in the TM by dominant negative Rho expression also increases outflow facility in organ-cultured human anterior segments.⁵²⁷

Uncoupling of cellular adhesions from the ECM is another approach to disrupt the actin cytoskeleton resulting in increased outflow facility. It is well established that signaling events mediated by the ECM play a critical role in maintaining tissue architecture by regulating the organization of the actin cytoskeleton and cell contacts. Hence, these signaling events could potentially regulate outflow facility. Recent studies support this idea and show that the Heparin II (HepII) domain of fibronectin, an extracellular matrix protein found in the TM, increases outflow facility when perfused through cultured human anterior segments.⁵²⁸ Presumably this domain increases outflow facility by mediating the disassembly of the actin cytoskeleton in TM cells.⁵²⁹ The HepII domain plays an important role in regulating the organization of the actin cytoskeleton by acting as a ligand for members of the syndecan and integrin family of receptors.⁵³⁰

Microtubules comprise 25-nm-diameter hollow polar fibers, densely packed near the nucleus, and extending toward the cell periphery. They are not intrinsically contractile but are important for directional cell motility and, driven by specific microtubule motor proteins such as kinesins and dyneins, for cytoplasmic trafficking of vesicles and organelles. Associated proteins bind to microtubules and can affect their stability and potentially attach them to other cellular structures, including other cytoskeletal filaments. Microtubule function could affect outflow pathway events through direct cellular mechanical effects, influences on extracellular or cell membrane turnover, or secondary signaling leading to activation of the actin cytoskeleton.⁵³¹ Microtubule disrupting

agents such as ethacrynic acid, colchicine, and vinblastine, increase outflow facility and cause cellular contraction in HTM cells if the actin cytoskeleton is intact.^{532,533}

Ethacrynic acid (ECA), a sulphydryl-reactive diuretic drug, inhibits microtubule assembly in vitro, and induces a rapid decrease in phosphotyrosine levels of focal adhesion kinase and a more subtle decrease in paxillin phosphorylation. Dephosphorylation of these proteins disrupts signaling pathways that normally maintain the stability of the actin microfilaments and cellular adhesions, indicating a close relationship between the microtubule system and the actomyosin system. This action leads both to cell shape change in culture^{533,534} and to facility changes in vivo.⁵³⁵⁻⁵³⁸ In enucleated human eyes, lower resistance-effective ethacrynic acid doses do not produce morphologic changes in the TM, whereas higher doses induce separations between TM and Schlemm's canal cells.^{538,539} Recent evidence shows that several new derivatives of ECA significantly decrease IOP in cats and monkeys.^{540,541} These ECA derivatives are more potent than ECA in terms of inducing cell shape alterations and decreasing actin stress fiber content in human TM cells,⁵⁴² suggesting that microtubule disruption may reduce outflow resistance at least partially through perturbation of the actomyosin system.

Perfusion of the monkey anterior chamber with calcium- and magnesium-free mock aqueous humor containing 4–6 mM Na₂EDTA or with calcium-free mock aqueous containing 4 mM ethylene glycol bis (aminoethylether) tetra-acetate (EGTA) also causes large facility increases, accompanied by ultrastructural changes in which the junctions are clearly fractured;⁵⁴³ the latter is not the case with H-7 (see above). Since EDTA chelates both calcium and magnesium, while EGTA is much more specific for calcium,⁵⁴⁴ calcium would appear to be a critical cation in maintaining the structural and functional integrity of the conventional outflow pathway. The calcium channel antagonist, verapamil, increases outflow facility in organ-cultured human eyes.⁵⁴⁵

Thus, agents that alter the cytoskeleton, cell junctions, contractile proteins, or ECM are capable of, in effect, producing a "pharmacologic trabeculotomy". Derivatives of some of these compounds (latrunculins, Rho kinase inhibitors) are currently in clinical trials to lower IOP in humans.

Corticosteroid mechanisms

Studies suggest that glucocorticoids may play a major role in the normal physiologic regulation of outflow facility and IOP. Glucocorticoid receptors are identified in the cells of the outflow pathways.⁵⁴⁶ Corticosteroid regulation of IOP is proposed to occur via 11β-hydroxysteroid dehydrogenase (HSD)-1 expression which are localized in the non-pigmented ciliary epithelium of human eyes.⁵⁴⁷⁻⁵⁴⁹ This enzyme catalyzes the conversion of cortisone to cortisol which, in turn, induces Na⁺-K⁺-ATPase,⁵⁵⁰ leading to sodium and concomitant water transport into the posterior chamber, through epithelial sodium channels, resulting in aqueous production. Levels of cortisol compared to cortisone in the aqueous humor are normally much greater than in the systemic circulation.^{548,551}

However, long-term interactions of cortisol in the aqueous with glucocorticoid receptors in the TM, could contribute to increasing outflow resistance in susceptible individuals.⁵⁵¹

In the normal population, approximately 40 percent of patients treated with topical or systemic corticosteroids are termed "steroid responders," and develop markedly elevated IOP after several weeks.^{552,553} This contrasts to patients with POAG, 90 percent of which are considered steroid responders.^{553,554} One hundred percent of cow eyes treated *in vivo* with prednisolone acetate develop elevated IOP after 3 weeks of treatment.⁵⁵⁵ Glaucoma patients also have increased plasma levels of cortisol compared to normal individuals^{556,557} and increased vascular sensitivity to glucocorticoids.⁵⁵⁸ Oral administration of the glucocorticoid biosynthesis inhibitor metyrapone to glaucoma patients⁵⁵⁹ or the 11 β -hydroxysteroid dehydrogenase inhibitor carbenoxolone to ocular hypertensive patients⁵⁴⁷ elicits a small, transient decline in IOP. A recent pilot study shows that a single anterior juxtascleral depot of anecortave acetate (an angiostatic cortisene used in age-related macular degeneration) is effective in lowering IOP in POAG eyes for up to 12 months.⁵⁶⁰ The mechanism of action is currently unknown. IOP elevation in a sheep model of steroid induced glaucoma could be reversed or prevented by a single dose of a gene therapy vector carrying an inducible metalloproteinase human gene.⁶⁸¹

The glucocorticoid dexamethasone (DEX) alters complex carbohydrate, hyaluronic acid, protein, and collagen synthesis and distribution in cells and tissues of human aqueous humor outflow systems.^{377,561–563} In TM cells, DEX inhibits prostaglandin synthesis (90 percent), reduces phagocytic^{564,565} and extracellular protease activity, and changes gene expression.^{566–568} Cortisol metabolism may be altered in cultured TM cells from patients with primary open-angle glaucoma. These cells accumulate 5 β -dihydrocortisol and, to a lesser extent, 5 α -dihydrocortisol, metabolites which potentiate the facility-decreasing and IOP-increasing effects of DEX; these cells produce relatively little 3 α ,5 β -tetrahydrocortisol from cortisol.⁵⁶⁹ Normal human TM cells show no accumulation of active dihydrocortisol intermediates; all cortisol is rapidly metabolized to the inactive tetrahydrocortisol. 3 α ,5 β -Tetrahydrocortisol applied topically decreases IOP and increases outflow facility in glaucomatous human eyes,⁵⁶⁹ and antagonizes DEX-induced cytoskeletal reorganization (see below) in normal HTM cells^{569,570} but has no effect on outflow facility in normotensive monkeys following intracameral injection or 10 days of topical administration.⁵⁷¹

Glucocorticoid glaucoma and POAG eyes both exhibit increased amounts of ECM in the meshwork.⁵⁷² However, the ECM that accumulates in eyes with corticosteroid-induced glaucoma differs from that seen in eyes with POAG.⁵⁷³ The human anterior segment in organ culture exposed to DEX exhibits morphological changes similar to those reported for corticosteroid glaucoma and a resulting increase in IOP and decrease in outflow facility.⁵⁷⁴ Studies of DEX effects in cultured human TM cells, combined with studies of changes in laminin and fibronectin and alterations in phagocytosis and surface binding properties, may provide clues to the changes in pressure-dependent outflow seen with corticosteroid use.⁵⁷⁵ Inhibition of DEX-induced overexpression of laminin or collagen using antisense oligonucleotides increases permeability of DEX-treated HTM cells.⁵⁷⁶ Prolonged treatment of HTM cells with DEX decreases hyaluronan synthesis. Hyaluronan is an inert molecule

which may be necessary to prevent adherence of larger molecules to the cribriform meshwork.⁵⁷⁷ These and other DEX-induced alterations in several other molecules involved in the regulation of the ECM have recently been reviewed.⁵⁷⁸ Some glucocorticoid effects on the TM could also be mediated by alterations in growth factor/receptor expression.⁵⁷⁸

Human TM and Schlemm's canal cell monolayers grown on filters exhibit enhanced tight junction formation and decreased hydraulic conductivity in the presence of DEX.^{579,580} There is a 2-fold increase in the number of tight junctions, a 10–30-fold reduction in the mean area occupied by interendothelial "gaps" or preferential flow channels, and a 3–5-fold increase in the expression of the junction-associated protein ZO-1. Inhibition of ZO-1 expression abolishes the DEX-induced increase in resistance and the accompanying alteration in cell junctions and gaps. These results support the hypothesis that intercellular junctions are necessary for the development and maintenance of transendothelial flow resistance in cultured TM and Schlemm's canal cells and may be involved in the mechanism of increased resistance associated with glucocorticoid exposure.

Glucocorticoids are shown to reorganize the TM cytoskeleton. Most intriguing in terms of outflow resistance, are the unusual geodesic dome-like cross-linked actin networks (CLANs) formed in response to DEX treatment of TM cells and perfusion cultured anterior segments (Fig. 11.11).^{581–583} Higher basal levels of CLANs are present in glaucomatous TM cells and tissues and a greater CLAN response to glucocorticoids occurs in glaucomatous TM cells.⁵⁸⁴ Recent studies have shown that CLANs exist within TM cells *in situ* in both normal and glaucoma donor eyes. There may be a CLAN in all cells in glaucomatous TM *in situ* and in two-thirds of cells in normal TM.⁵⁸⁵ CLAN formation can be regulated by beta1 and beta3 integrin signaling pathways.⁵⁸⁶

Cultured human TM cells exposed to DEX also exhibit increased cell and nuclear size, an unusual stacked arrangement of smooth and rough endoplasmic reticulum, proliferation of the Golgi apparatus, and pleomorphic nuclei.⁵⁸¹ TM cell volume can be altered by an early DEX-induced enhancement of Na-K-Cl cotransport.⁵⁸⁷

One of the first TM cell genes/proteins induced by glucocorticoids is myocilin (MYOC) whose progressive induction over time matches the time course of clinical steroid effects on IOP and outflow facility, and is hypothesized to play a role in glaucoma pathogenesis (see review⁵⁸⁸).

The MYOC gene is directly linked to patients with open-angle glaucoma.⁵⁸⁹ Mutations in the MYOC gene are present only in a minor percentage (~3–4 percent) of patients with adult forms of POAG⁵⁹⁰ but are prevalent in juvenile open-angle glaucoma (see reviews^{588,591}). Disease-causing MYOC mutants are misfolded, leading to accumulation in the endoplasmic reticulum which can result in cell death.⁵⁹² Recombinant MYOC increases outflow resistance in the organ-cultured human anterior segment.⁵⁹³ In contrast, overexpression of mutant MYOC *in vivo* in cats does not elevate IOP.⁵⁹⁴ It may be that IOP elevation is dependent on other factors in addition to a mutant MYOC protein or that longer duration of exposure may be required *in vivo*.

MYOC may play a role in maintaining normal outflow pathways. Maintaining elevated pressure in human anterior segment organ culture for 7 days causes a marked increase in MYOC mRNA that could be part of a protective response

Figure 11.11 Whole mount transmission electron micrographs of the cytoskeleton of control trabecular meshwork cells (**A**) and trabecular meshwork cells exposed to 10^{-7} M dexamethasone for 14 days (**B**). The stress fibers in the control cells are arranged in normal linear arrays, whereas dexamethasone-treated microfilaments are grouped into 90- to 120-nm bundles radiating from electron-dense vertices. (From Clark AF et al: Invest Ophthalmol Vis Sci 35:281, 1994, reproduced with permission from the Association for Research in Vision and Ophthalmology.)

mechanism.⁵⁹⁵ Over expression of the amino terminal domain or full-length MYOC protein in the human anterior segment organ culture produces an increase in outflow facility.⁵⁹⁶ The regulation of human trabecular cell MYOC mRNA appears to be distinct in HTM cells compared with other cell types.⁵⁹⁷ MYOC is localized both intracellularly and extracellularly (in a glycosylated form, 66 kDa) at multiple sites (associated with mitochondria, cytoplasmic filaments, elastic-like fibers in trabecular beams, extracellular matrices in the juxtaganicular region) where it may exert diverse biological functions.^{567,598,599} It may serve a structural function within the cytoplasm, or it may associate with other molecules within the cell, perhaps as a molecular chaperone. Extracellularly, it may be involved in creating resistance to aqueous outflow by binding to other extracellular molecules, such as the heparin II domain of fibronectin,⁶⁰⁰ or to the cell membrane of trabecular cells.⁶⁰¹ Dynamic mechanical stimuli maintain MYOC expression in TM *in situ*.⁶⁰² Thus, the role of normal MYOC in glaucoma has yet to be established.

Prostaglandin mechanisms (Box 11.3)

There is a 60 percent increase in aqueous outflow via the uveoscleral pathway in monkeys after a single submaximal dose of PGF_{2α}-1-isopropyl ester (PGF_{2α}-IE).⁷ Following multiple submaximal doses (Table 11.3), there is more than a 100 percent increase in uveoscleral outflow.³¹⁴ In both instances, aqueous outflow is substantially redirected from the trabecular to the uveoscleral pathway. *In vitro*, PGF_{2α} produces a weak dose-dependent relaxation of carbachol-precontracted rhesus monkey ciliary muscle strips.⁶⁰³ Such relaxation may contribute to widening the intermuscular spaces *in vivo*.⁶⁰⁴ However, the majority of the outflow effect resulting from PGF_{2α} treatment is likely due to ECM remodeling in the anterior segment characterized by an increase in MMP-1, -2, and -3 and reduction in collagen types I, II and IV, within the ciliary muscle, iris root and peri-ciliary body sclera^{605–607} possibly associated with activation of the proto-oncogene c-fos.⁶⁰⁸ PGF_{2α} and latanoprost

Box 11.3 Prostaglandin Mechanisms

- Prostaglandin analogs are currently the most effective IOP-lowering glaucoma therapies, exerting their ocular hypotensive effects primarily by increasing uveoscleral outflow
- Prostaglandin-induced increases in scleral permeability may be used to enhance trans-scleral delivery of agents to the posterior segment of the eye
- Combination of subtype selective prostaglandin analogs may be more efficacious in IOP lowering than single subtype therapy
- Bimatoprost, latanoprost, and travoprost have similar mechanisms of action, primarily increasing uveoscleral outflow of aqueous humor in healthy adult human subjects, but the magnitude of the flow through each pathway depends on the measurement technique⁶⁷⁹
- Trabeculectomy patients have a significantly lower average diurnal IOP compared to patients treated with latanoprost or undergoing deep sclerectomy with collagen implant. No wider variation in diurnal IOP occurs with latanoprost compared to surgical procedures. IOP increase during a water drinking test is most marked in patients under latanoprost therapy as compared to patients with trabeculectomy or deep sclerectomy with collagen implant⁶⁸⁰

(13,14-dihydro-17-phenyl-18,19,20-trinor-PGF_{2α}-isopropyl ester) cause reductions in collagen types I, III, and IV, fibronectin, laminin and hyaluronan immunoreactivity in the ciliary muscle and adjacent sclera, while MMP-2 and -3 are increased.

Plasmin generation, an activator of MMPs, is enhanced.^{605,609} PGF_{2α} can stimulate the formation of endogenous prostaglandins by stimulation of phospholipase A2 and release of arachidonic acid for prostaglandin synthesis.⁶¹⁰ Human ciliary muscle cells exposed to PGF₂ ethanolamide or latanoprost for 9 days show a downregulation of the FP receptor. In the same study, downregulation of the aquaporin-1 and versican genes are proposed to increase flow through the ciliary muscle and decrease IOP.⁶¹¹ Long-term treatment with various subtype selective prostaglandins

Table 11.3 Uveoscleral outflow on day 5 of twice-daily unilateral treatment with PGF_{2α}

Treated	Control	Treated/Control
(a) Spontaneous IOP; Approximately 235–325 min (n = 6)		
Albumin	0.78 ± 0.12*	0.46 ± 0.03
1.66 ± 0.20†		
(b) IOP = 17–18 mmHg; Approximately 240–335 min (n = 2)		
Albumin	1.45 ± 0.01§	0.62 ± 0.11
2.41 ± 0.42		
(c) IOP = 17–18 mmHg; Approximately 135–195 min (n = 1)		
Albumin	2.03	0.63
3.21		
(d) All IOP Time Group Combined (n = 9)		
Albumin	1.07 ± 0.17§	0.52 ± 0.04
2.00 ± 0.24‡		

IOP, intraocular pressure; PGF_{2α}, prostaglandin F_{2α}.

On day 5 anterior chambers were exchanged with 2 mL of either ¹²⁵I- or ¹³¹I-albumin. Infusion was continued at a lower rate for the balance of the indicated times. Pressures other than spontaneous were maintained by tracer flow from an elevated reservoir. Animals were then sacrificed and the equivalent anterior chamber fluid recovered in the ocular and periocular tissues was determined. Overall, PGF_{2α} increased uveoscleral outflow approximately two-fold compared with control eyes. Data are mean ± standard error of mean uveoscleral outflow (μL/min) for n animals, each contributing one treated and one control eye, following the ninth unilateral dose of PGF_{2α} on day 5; min indicates time window following PGF_{2α} encompassed by the measurement. Significantly different from 1.0 by the two-tailed paired t-test: *p < .05; †p < .01. Significantly different from contralateral control by the two-tailed two sample t-test: *p < .05; §p < .01.

(From Gabelt BT, Kaufman PL: Exp Eye Res 49:389, 1989, Copyright Elsevier 1989.)

results in intermuscular spaces became more organized and lined with an incomplete layer of endothelial cells resembling lymphatic pathways.⁶¹²

Prostaglandin-induced changes in the sclera also are important in the regulation of uveoscleral outflow and may be used to enhance trans-scleral delivery of peptides and other high-molecular-weight substances to the posterior segment of the eye. Five days of topical treatment with PGF_{2α}-isopropyl ester increases MMP-1, -2, and -3 in the sclera of monkeys.⁶¹³ Immunocytochemistry studies and mRNA analysis of human sclera and cultured human scleral fibroblasts shows the presence of EP₁, EP₂ and FP receptor subtypes but not EP₃ and EP₄ subtypes.⁶¹⁴ Human scleral permeability to dextran, measured in an Ussing chamber following exposure to PGF_{2α} and latanoprost acid for 1–3 days, increases in a dose- and time-dependent manner. This is accompanied by an increase in MMP concentration in the media with the greatest increases in MMP-2 and -3 compared to MMP-1.⁶¹⁵ PGF_{2α} and latanoprost acid also induce increases in mRNA for MMPs and tissue inhibitors of matrix metalloproteinases in human scleral organ cultures.⁶¹⁶ MMPs alone are shown to directly increase scleral permeability of mouse eyes.⁶¹⁷

Mice deficient in various prostaglandin receptors are used to determine the role of prostanoid receptor subtypes in mediating the IOP-lowering response to clinical prostaglandin analogs. Studies in FP receptor-deficient mice show that the FP receptor is essential for the early IOP-lowering response to topical latanoprost, travoprost, bimatoprost and unoprostone.⁶¹⁸ The involvement of the FP receptor in the IOP reduction with long-term dosing is unknown. Upregulation of MMP-2, -3, -9 and FP mRNA in the sclera following

7 days of topical treatment with latanoprost is also dependent on an intact FP receptor gene.^{618a,618b} EP receptor-deficient mice are studied in similar ways. When EP₁, EP₂, and EP₃ receptor-deficient mice and their wild-type background strain are treated topically with latanoprost, travoprost, bimatoprost, or unoprostone, EP₃ receptors are involved in the IOP – lowering response to latanoprost, travoprost, and bimatoprost at 3 hours after drug administration – but EP₁ and EP₂ receptors are not.⁶¹⁹ This is in contrast to what is expected from in vitro receptor binding^{620,621} and functional assays⁶²⁰ in which FP receptor binding and functional responses (phosphoinositide turnover) are at least two orders of magnitude greater than for EP3 receptors. Also, immunohistochemistry studies show that EP2 receptors are the most abundantly expressed EP subtype in human ocular tissues.⁶²² EP2 selective agonists are effective in lowering IOP in monkeys.^{623,624} Topical treatment with a combination of EP1, EP2, EP3 and FP receptor agonists increases the magnitude of the IOP-lowering response in monkeys when compared to FP agonist therapy alone.⁶²⁴

The uveoscleral outflow system likely evolved to protect the eye in several ways during inflammation. The TM becomes compromised by inflammation or obstructed by inflammatory debris, and the choroid is overloaded with debris and extravasated proteins that must be removed from the eye.¹⁵⁴ In this situation, prostaglandins are released and, as autacoids or hormones that are synthesized, released, and locally acting, induce the changes described. Since the eye has no true lymphatics, uveoscleral outflow may serve as an analog to an intraocular lymphatic drainage system.¹² However, as mentioned above, long-term exposure to prostaglandins, may lead to lymphatization of the uveoscleral pathway.⁶¹² The normal low flow rate that is sufficient to remove normal levels of extravascular protein may be inadequate when protein levels are increased as in uveitis. Redirection of aqueous outflow from the trabecular to the uveoscleral pathway would both rid the eye of excess proteins and maintain physiologic IOP. This could also explain the very low IOP that often accompanies uveitis; during experimental iridocyclitis in monkeys, uveoscleral outflow increases approximately four-fold (Table 11.4).¹⁵³

The increase in uveoscleral outflow in response to these compounds is so great that a larger reduction in IOP is possible than with any other known substance. PGF_{2α} analogs and metabolites are clinically useful ocular hypotensive agents, despite some undesirable side effects (conjunctival foreign body sensation, conjunctival hyperemia, stinging pain, photophobia),^{625,626} and increased iris pigmentation in some instances.⁶²⁷ In fact, they are the most commonly used glaucoma medications in the developed world. Gene therapy approaches to overexpress prostaglandin pathway genes in the anterior segment to lower IOP are being investigated so that problems patient compliance for drug administration may be reduced. Success has been demonstrated in a cat model where IOP was decreased for 5 months following lentiviral vector delivery of prostaglandin pathway genes.⁶²⁴

Cell volume related mechanisms

Na-K-Cl cotransporter is a plasma membrane protein that participates in vectorial transport of Na and Cl across epithelia and also regulates intracellular volume in a variety of epithelial and non-epithelial cell types.^{628–631} Changes in TM

Table 11.4 Distribution of dextran tracer, uveoscleral outflow, protein and intraocular pressure in control and inflamed cynomolgus monkey eyes

	Control Eye (μl)	Inflamed Eye (μl)	Probability *
Iris	1.2 \pm 0.3	2.4 \pm 0.3	0.07
Anterior uvea	8.5 \pm 2.4	18.6 \pm 4.3	0.43
Posterior uvea	0.3 \pm 0.2	4.2 \pm 0.8	0.006
Anterior sclera	8.4 \pm 1.6	28.4 \pm 4.4	0.01
Posterior sclera	1.9 \pm 0.9	21.5 \pm 3.9	0.006
Retina	0.1 \pm 0.1	2.1 \pm 0.9	0.08
Fluid [†]	0.7 \pm 0.4	11.2 \pm 3.4	0.03
Total	21.0 \pm 4.7	88.4 \pm 14.7	0.009
Uveoscleral outflow ($\mu\text{l}/\text{min}$)	0.7 \pm 0.2	2.9 \pm 0.5	0.009
AC protein (mg/ml)	0.20 \pm 0.02	7.8 \pm 4.0	0.006
Pre-IOP	16.7 \pm 0.8	15.2 \pm 1.3	0.43
Post IOP	14.2 \pm 1.6	3.0 \pm 1.1	<0.001

AC, Anterior chamber; IOP intraocular pressure.

Inflammation was induced by intravitreal injection of bovine serum albumin. Two days later, tracers were perfused through the anterior chamber and F_u was determined after 30 minutes at 15 mm Hg. Uveoscleral outflow was increased in inflamed eyes up to fourfold with the 70,000 molecular weight (MW) fluoresceinated dextran. Values are mean standard error of mean; $n = 6$.

*Paired t-test analysis value.

[†]Includes vitreous, posterior chamber fluid, suprachoroidal fluid.

cell volume by agents which modulate Na-K-Cl cotransport activity affect outflow facility in human and calf eyes *in vitro*.⁶³² However, no change in outflow facility is observed in monkeys *in vivo* following administration of the Na-K-Cl inhibitor bumetanide.⁹⁴ Although this was an intense area of interest for a time, no recent advances have been made.

Water channels (aquaporins), are also found in TM and Schlemm's canal cells.^{82,633,634} They may be involved in transcellular water movement in these tissues.⁶³⁵ However, no role in aquaporin 1 in regulating outflow facility is demonstrated after over-expression in human organ-cultured anterior segments.⁶³⁶

Nitric oxide donor-induced increases in outflow facility may be due partly to decreases in TM cell volume (also see *Other Agents*).

Although chloride channels are thought to be involved in the regulation of cellular volume and intracellular chloride concentration, they do not appear to contribute significantly to the regulation of outflow facility.⁶³⁷

Hyaluronidase and protease-induced facility increases

Glycosaminoglycans (GAGs) contribute to the filtration barrier of aqueous outflow through the TM. A quantitative biochemical profile of GAGs from normal and POAG TM

suggests that there is depletion of hyaluronic acid and an accumulation of chondroitin sulfates in the POAG TM.^{638,639} Substantial hyaluronan is present in the non-glaucomatous outflow pathway associated with the endothelial cells lining the trabecular beams. This finding supports potential roles for this glycosaminoglycan in the regulation of the physiological aqueous outflow resistance or in the maintenance of the outflow channels, or both.⁶⁴⁰ Hyaluronic acid covering the surfaces of the outflow pathways might prevent adherence of molecules to ECM components within the cribriform region and thereby prevent clogging of the outflow pathways.⁴⁰⁷ It is hypothesized that POAG is characterized by a decreased concentration of hyaluronic acid and increased turnover and downregulation of the hyaluronic acid receptor CD44 in the eye, which, in turn, may influence cell survival of TM and retinal ganglion cells.⁶⁴¹

Intracameral infusion of hyaluronidase markedly increases facility in the bovine eye, presumably as the result of washout of acid mucopolysaccharide-rich ECM in the chamber angle tissues.⁶⁴² Effects in primates are much more variable.⁶⁴³⁻⁶⁴⁷ The variations are attributed to interspecies differences, the type and source of hyaluronidase, and the conditions used for the enzymatic digestion that may have contributed to a variable and incomplete degradation of hyaluronic acid. In the enucleated human eye perfused at room temperature, α -chymotrypsin has little effect on facility.⁶⁴⁵ However, effects of trypsin may be masked at low temperatures⁶⁴⁸ and a combination of trypsin and ethylenediaminetetra-acetate (EDTA) may have a marked effect in dissociating cultured cells not easily dissociated by either agent alone.⁶⁴⁹ Perfusion of the anterior chamber of living monkeys with 50 U/mL α -chymotrypsin gives a large facility increase that persists for several hours even after the enzyme is removed from the infusate.⁶⁵⁰ The facility increase induced by intracameral 0.5 mM Na₂EDTA is augmented and prolonged by α -chymotrypsin.⁶⁵⁰

Exposure of porcine TM cells to growth factors such as TGF β induces increases in matrix metalloproteinases (MMPs) such as stromelysin, gelatinase B and collagenase, suggesting a role in the regulation of ECM turnover by TM cells.⁶⁵¹ However, prolonged elevation of TGF β 2, as occurs in POAG, can have the opposite effects and contribute to outflow obstruction (see *Outflow Obstruction*). Purified MMPs increase outflow facility in organ-cultured human anterior segments by 160 percent for at least 125 hours.⁶⁵²

The composition of the ECM in the TM has been recently reviewed.⁶⁵³ Presumably any of the enzymes involved in the biosynthesis or degradation of the ECM are potential targets to be manipulated for enhancing trabecular outflow.

Other agents

Nitric oxide mimicking nitrovasodilators can decrease IOP in monkeys by altering outflow resistance. In human eyes, the TM and ciliary muscle are enriched sites of nitric oxide synthesis.²⁸ One role for nitric oxide in the anterior segment may be to modulate outflow resistance either directly at the level of the TM, Schlemm's canal and collecting channels, or indirectly through alteration in the tone of the longitudinal ciliary muscle. Nitrovasodilators are shown to relax TM⁶⁵⁴ and ciliary muscle⁶⁵⁴ strips precontracted with

carbachol in vitro. Nitric oxide synthase-immunoreactive nerve fibers are abundant in the primate TM, especially in the cribriform region adjacent to the inner wall of Schlemm's canal.⁴²² Nitric oxide synthase released from nerve terminals could cause relaxation of TM cells and allow an increase in outflow facility independent from the ciliary muscle. In human glaucoma eyes there are dramatic reductions in staining indicative of nitric oxide synthase activity in ciliary muscle, TM and Schlemm's canal compared to control eyes,^{655,656} that are unrelated to the use of multiple glaucoma therapies, or the severity of the disease.⁶⁵⁵ Nitric oxide may also alter TM cell volume (see **Cell Volume Related Mechanisms**).

Purinergic P2 receptors are present in TM cells. Activation of these receptors in TM cells leads to intracellular calcium mobilization and/or extracellular signal-regulated kinase 1 and 2 (ERK1/2) pathway activation.⁶⁵⁷ IOP is decreased and outflow facility increased in monkeys following topical application of adenosine A1 agonists.²³ In bovine organ-cultured anterior segments, the outflow facility increase produced by adenosine A1 agonist cyclohexyladenosine is also associated with MMP activation.²⁵ Aqueous adenosine levels are positively correlated with IOP in ocular hypertensive individuals and could possibly serve as an endogenous modulator of IOP.⁶⁵⁸

There is evidence that the eye contains a renin-angiotensin system and that it may be involved in the regulation of IOP. The presence of angiotensin-converting enzyme activities, the concentration of angiotensinogen and angiotensin II, and the density of angiotensin-II AT1 receptors in ocular tissues and fluids are demonstrated in several species, including humans.⁶⁵⁹⁻⁶⁶³ Oral administration of an angiotensin II receptor type 1 antagonist^{664,665} or an angiotensin-converting enzyme inhibitor^{666,667} reduces IOP in normotensive and in POAG patients. Topical application of a renin inhibitor decreases IOP in rabbits and monkeys without affecting systemic blood pressure or heart rate.⁶⁶⁸

Multiple topical doses of an angiotensin AT1 receptor antagonist, CS-088, decreases IOP in monkey eyes with unilateral laser-induced glaucoma.⁶⁶⁹ In humans, the oral AT1 receptor antagonist, Losartan, increases outflow facility.⁶⁶⁵ The angiotensin-converting enzyme inhibitor, captopril⁶⁶⁶ decreases IOP and increases total outflow facility without affecting blood pressure, heart rate or pupil diameter. Another study suggests the IOP-lowering responses to ACE inhibition is due to prostaglandin biosynthesis and increased uveoscleral outflow.⁶⁷⁰ Angiotensin itself slightly decreases outflow facility in monkeys following intracameral injection.⁴⁵⁵

Physical enhancement of outflow

Aqueous outflow via the conventional drainage pathway is a physical process that can be altered pharmacologically as reviewed above. Ultimately, physical methods to alter trabecular outflow are accomplished by fistulation to allow fluid movement from one compartment to another.

Splicing ~50–100 small (50 µm), low-intensity argon, krypton or diode laser burns evenly around the circumference of the meshwork of the glaucomatous human eye can result in a significant and long-term increase in outflow facility and decrease in IOP, apparently without actually

producing a "hole" in the meshwork or inner canal wall.^{671,672} It may be that contracture of the laser-produced scars tightens and narrows the trabecular ring, and the distortion somehow expands the meshwork, opens aqueous channels, and improve hydraulic conductance.^{672,673} Other data suggest that laser energy-induced alterations in trabecular cell biosynthetic, biodegradative, or phagocytic functions result in less hydraulic resistance.^{674,675} Definitive proof of the facility-increasing mechanism of laser trabeculoplasty remains to be established.

Canaloplasty is a recently developed non-penetrating technique utilizing a flexible microcatheter to access the entire length of Schlemm's canal. The entire circumference of the canal or a portion of it can be dilated with viscoelastic. A trabecular tensioning suture can be inserted for applying additional tension. IOP can be effectively lowered with a relatively low surgical complication rate, although the pressure may not fall to the extent needed by some patients.^{676,677}

Metabolic Interactions between Neurons and Glial Cells

Carole Poityr-Yamate & Constantin J. Pournaras

Introduction

The vasculature of both the retina and brain can autoregulate, meaning that blood flow is altered in response to neuronal activity. This tight coupling between neuronal activity and blood flow, or neurovascular coupling, was first described in the brain more than a century ago by Roy & Sherrington.¹ Retinal glia are not just passive supportive cells but rather they play an active role in directly changing neuronal activity. Glial cells sense neuronal activity and alter blood flow accordingly by directly communicating with the inner retinal vasculature. Thus, glia play a pivotal role not only in maintaining normal neuronal function but also in ensuring adequate retinal blood flow.^{2,3} Even though glia are essential for normal retinal function, for the most part their roles are in response to neuronal function. Stimulation of retinal whole-mounts by light or direct glial stimulation led to either vasoconstriction or vasodilation of inner retinal blood vessels.³ In particular, these vascular caliber changes were linked to increases in intracellular calcium within retinal glia. Therefore, like their counterparts in the brain, retinal glia induce caliber changes in capillaries in response to neuronal activity.

Recently, with the advent of ion-sensitive fluorescent indicators and calcium imaging, it has emerged that glial cells can generate active responses and play a profound role in directly modulating both the activity of neurons and the vasculature.^{4,5} Glia communicate with one another via increases in intracellular calcium in the form of a calcium wave that propagates from one astrocyte to another via gap junctions or by the release of bursts of extracellular ATP.^{5,6}

Studies in cell culture, brain slices and more recently, retinal whole-mounts have demonstrated that transmitters released from neurons induce transient elevations in intracellular calcium in glia.^{4,6} Mechanical, chemical and light stimulation can evoke increases in intracellular calcium in both astrocytes and Müller cells that propagate to neighboring glia as a "wave".⁶ It is well established that extracellular ATP evokes large increases in intracellular calcium within both astrocytes and Müller cells and that glia release ATP extracellularly in response to stimulation.⁶ The source of the calcium elevations in retinal glia is thought to be primarily from intracellular stores, although there is also a range of calcium-permeable channels, pumps and

exchangers that could mediate calcium influx into glia from the environment.

The functional significance of the elevation in intracellular calcium within retinal glia is two-fold: direct modulation of neurons and alteration of vessel caliber.⁵ Studies in cortical glial cultures have shown that glia can release chemical transmitters such as ATP, glutamate and the NMDA receptor co-agonist D-serine in a calcium-dependent manner.^{4,7} Moreover, these released "gliotransmitters" can directly alter neuronal function.⁸ For example, many types of retinal neurons are known to express receptors to ATP (called P2 receptors), including photoreceptors, amacrine cells and ganglion cells.⁹⁻¹² Moreover, photoreceptor function is modulated by extracellular ATP.¹¹ Therefore, it is possible that the release of ATP extracellularly by glia could in turn modulate a variety of neuron cell types from photoreceptors to ganglion cells. In regards to a glial-dependent modulation of vessel caliber, increases in intracellular calcium within cortical astrocyte endfeet are linked to marked vasodilation in the adjacent arteriole, suggesting a relationship between astrocytes and the vasculature within different regions of the central nervous system^{13,14} in response to an increase in neural activity.

Energy for excitatory glutamatergic synaptic transmission in the mammalian retina, as elsewhere in the central nervous system (CNS), is provided by the metabolism of blood-borne glucose. Indeed, retinal preparations become synaptically silent as a result of glucose depletion.¹⁵ From the ultrastructural point of view, the remarkable concentration of mitochondria in synaptic terminals of axons¹⁶ indicates that glutamatergic synapses have high capacity for oxygen consumption and are major users of metabolic energy.¹⁷

Although electrophysiological evidence shows that neurotransmission through the inner retina is supported by glycolysis¹⁵ there is presently no experimental evidence showing that synaptic activity of pre- and post-synaptic retinal neurons is directly sustained by glucose. Indirect evidence, however, is suggested from the classical work of Lowry and co-workers¹⁸ on the distribution of enzymes of glucose metabolism determined from pure samples of each retinal layer from monkey and rabbit. A brief introductory overview of this particular paper is given below as it offers invaluable insight to the contribution of Müller glia to overall retinal function and energy metabolism.

All enzymes of glycolysis are in the cytoplasm rather than in the mitochondria. To initiate glycolysis, hexokinase irreversibly phosphorylates glucose to glucose-6-phosphate (G6P). The distribution of hexokinase was confined to the layer containing inner segments of photoreceptors, the inner synaptic layer, and to the inner-most retinal layer bordering the vitreous. The second step of glycolysis is the conversion of G6P to fructose-6P by glucose-phosphate isomerase. This enzyme's distribution was largely confined to the inner-and outer-synaptic layers. Phosphofructokinase, the third enzyme in glycolysis, irreversibly phosphorylates fructose-6P to fructose-1,6diP and its distribution was confined to both synaptic layers and the innermost retinal layer. The ninth enzyme in glycolysis, phosphoglyceromutase converts 3-phosphoglycerate to 2-phosphoglycerate and its distribution was similar to the distribution of phosphofructokinase.

In tissues with adequate oxygen supply, pyruvate formation is the 11th and last step of glycolysis. The metabolism of pyruvate for energy production consumes oxygen and completes the breakdown of glucose to CO_2 and water through the process of oxidative metabolism. Upon careful study, the distribution of the aforementioned glycolytic enzymes corresponds to the morphological position of Müller glial cells *in situ*. Müller cells extend radially through all of the retinal layers from the photoreceptor inner segments to the inner limiting membrane bordering the vitreous; and they extend fine filaments laterally in both synaptic layers. They also form an additional physical and functional cell layer to the diffusion of substances from the blood to neurons. Indeed, Kuwabara & Cogan^{19,20} undertook the first comprehensive histochemical study to identify Müller cells as the primary glucose utilizing cells in the retina.

Together, these landmark studies paved the way to our present day understanding of cellular coupling in maintaining retinal function and metabolism, and which forms the major theme of this chapter. As a concluding introductory note, one is reminded that regardless of how the energy consumption of the retina (or other parts of the CNS) is altered locally to meet changing demands, it is of major importance to know from a neurophysiological viewpoint just which cell types and what cellular events are associated with local changes in blood flow, metabolism and tissue oxygenation.

1. Retinal oxygen distribution and consumption

Under normal conditions, O_2 is the limiting factor in retinal metabolism. Oxygen is used by mitochondria, and their distribution is important in understanding locations of high O_2 demand. The O_2 consumption (QO_2) of the retinal pigment epithelial (RPE) cells is about 20% of that of the retina per mg protein.²¹ Mitochondria are densely observed in the inner segments (IS) of photoreceptors. Cones have more mitochondria than rods.^{22,23} Mitochondria are also found in each rod spherule and cone pedicle. In the inner retina, the inner plexiform layer has a larger amount of mitochondria than the nuclear layers.²⁴

Inner retina The distribution of oxygen tension (PO_2) close to the vitreo-retinal interface is heterogeneous, being higher close to the arteriolar wall.²⁵ Preretinal and transretinal PO_2

profiles indicate that O_2 diffusion from the arterioles affects the PO_2 in the juxta-arteriolar areas (Fig 12.1).^{25,26} O_2 reaches the vitreous by diffusion from the retinal circulation. In contrast, far from the vessels, the preretinal PO_2 remains constant and the average preretinal PO_2 from the vitreal side is similar to that measured in the inner retina.^{25,27,28} In the inner retina, PO_2 averages about 20 mmHg but up to 60 mmHg close to the arteriolar wall.^{25,29,30}

Dark and light O_2 consumption Inner retinal oxygen consumption was the same in light and darkness,³¹ indicating no influence of light adaptation as there is in the outer retina. In the inner retina, ganglion cells have much higher firing rates if a stimulus is presented repeatedly than if the same amount of light is delivered as a steady background. Consequently, one would expect the inner retina to use more energy when a stimulus is flickering. Indeed, there is, in response to a flickering stimulus, a higher lactate production in inner retina of rabbit than during darkness or steady illumination¹⁵ and a higher deoxy-D-glucose uptake in monkey retina.³²

Outer retina Trans-retinal PO_2 measurements have provided data about the O_2 supply to the photoreceptors and their QO_2 . PO_2 profiles made in cat,^{33,34} pig²⁵ and monkey³⁵ indicate that oxygen diffuses from the inner retina and from the choroid towards the middle of the retina, i.e. the outer plexiform layer (OPL). The choroidal circulation supplies about 90% of the photoreceptor's O_2 use.²⁹

Photoreceptor QO_2 in darkness In the dark-adapted retina, photoreceptor QO_2 (Q_{OR}) depends strongly on choriocapillary PO_2 in cat and monkey.^{29,36} In the inner segments of photoreceptors (IS) the local value of QO_2 is about five times higher than in the outer segments (OS). A similar range for QO_2 in the outer retina was obtained in rat, rabbit and pig retinas.^{15,37,38} In both cat and monkey, the average value of PO_2 in the choriocapillaries is about 50 mmHg, and the corresponding average value of QO_2 in the outer retina is 4–5 mL $\text{O}_2/100\text{g}^{-1}/\text{min}^{-1}$.^{29,36}

The average PO_2 value in cat was 5 mmHg, the minimum was frequently indistinguishable from zero in the dark²⁹ as predicted by Dollery et al.³⁹ The amount of oxygen consumed is an indirect measure of ATP synthesis and thus of ATP utilization. The ATP produced in the dark fuels many cellular processes,¹⁵ mainly the Na^+/K^+ -ATPase in the IS, which extrudes a large amount of sodium that enters through the light-dependent channels in the OS.^{1,15,40} An additional process is the turnover of cGMP that holds these channels open.^{15,41}

As noted above, there is no evidence about whether individual rods and cones use different amounts of O_2 . Cones in the primate fovea appear to use slightly less O_2 than the parafoveal photoreceptors.^{35,36}

Photoreceptor QO_2 in light QO_2 in the outer retina is lower in steady light than in darkness in various animals investigated.^{15,29,35,42} The activity of the Na^+/K^+ -ATPase decreases in light, but the turnover of cGMP increases,^{43,44} so the decrease in Q_{OR} is not as great as the decrease in the pump rate. The maximum size of the overall change appears to be species-dependent.

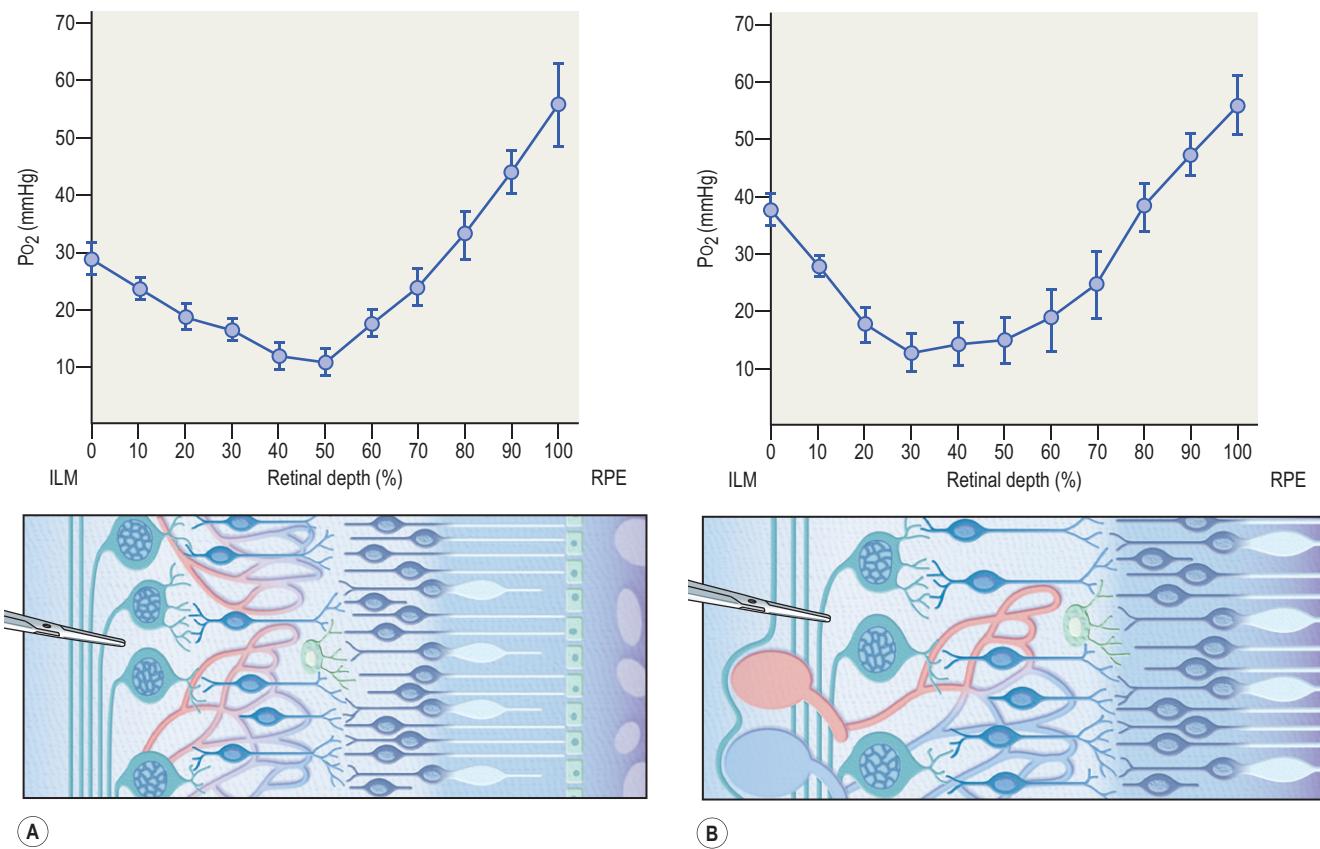

Figure 12.1 Transretinal oxygen partial pressure (PO₂) profiles recorded in intravascular (**A**) and juxta-arteriolar (**B**) retinal areas in mini pigs. The intraretinal values indicate a progressive decrease of the tissue PO₂ from both the vitreoretinal interface (ILM) and the pigment epithelium (PE) toward the middle of the retina, with the minimum mean value recorded at 40% and 50% retinal depth. At the vitreoretinal interface, the higher PO₂ suggests that oxygen diffusing from the larger vessels reaches the inner retina. Each point is the mean \pm SE of 13 measurements. The drawings indicate the pathway of the microelectrode through the retina. ILM: internal limiting membrane, RPE: retinal pigment epithelium. (Modified from Pournaras CJ, *Retina*. 1995;15(4):332–47.)

2. Role of glycolysis underlying retinal function: from whole retina to its parts

Visualization of dynamic functional activity in the retina is an *indirect* measurement of neuronal activity. It is important to appreciate that any dynamic “functional imaging” of the central nervous system, e.g. fMRI or PET imaging, measures local changes in brain metabolism and physiology that are associated with neuronal activity. Therefore, examining and evaluating retinal function necessarily involves understanding the energy metabolism of this tissue.

The significance of glucose and its metabolism down the glycolytic pathway in mammalian retina is attested to by the measured high rate of aerobic glycolysis in vitro (high capacity for oxygen consumption),^{22,45} its susceptibility to iodoacetate,⁴⁶ a strong Pasteur effect (inhibition of glucose utilization)^{22,47–49} and the aerobic and anaerobic production of lactate.^{47,50,51}

The adult retina, as is the case for every CNS region, depends on an uninterrupted supply of blood-borne glucose. Under normal conditions, glucose is virtually the sole substrate supporting the intense energy metabolism required to maintain retinal function, e.g. normal electrical responsiveness to light and neurotransmission.^{15,51,52} Lactate generated from either anaerobic glycolysis or glycogenolysis within the retina has recently been proposed as another important

energy source during synaptic transmission,⁵³ but its uptake and metabolism by retinal cells has yet to be demonstrated *in vivo*. A critical evaluation of lactate use in the CNS has been presented.^{54–59}

The distribution of key enzymes in glucose metabolism through the individual neuronal and synaptic retinal layers and the dehydrogenases for several of the intermediate stages of glucose degradation in retina have been documented in a series of pioneering histochemical work^{18,19,60} and set the stage early for later metabolic studies of the glycolytic and oxidative capacity of this tissue. Kuwabara and Cogan’s studies suggested for the first time that the Müller glial cells may serve a significant metabolic role, in stark contrast to the general view at that time as having only a structural function. Indeed, of the two major cell types in retina – the Müller glia and photoreceptors – metabolic studies have demonstrated that Müller cells both *in situ* and when acutely isolated, preferentially and massively take up and phosphorylate glucose, part of which is stored as glycogen.^{61,62} Further evidence to confirm this finding has been performed *in vivo*.⁶³

More recent supporting evidence comes from the use of iodoacetate (IAA), a well-known glycolytic poison that exerts its effect when the transformation of glucose is committed to proceed through glycolysis. In the 1950s, it was shown that intravenous delivery of sodium iodoacetate in rabbit, monkey and cat abolished the electrical response of the

visual pathway to illumination within minutes, with a resulting histological picture similar to that presented in human retinitis pigmentosa.⁶⁴ This led to the speculation that the initial effect must be on the visual cells,⁶⁵ although Warburg suggested that the different cell types in the retina may not contribute equally to the general biochemical picture.⁶⁴ Indeed, this suggestion has been unambiguously supported by the differential suppression of the component waves of the extracellular electroretinogram (ERG).^{66,67} However, beyond this evidence, the identity of the retinal cell types taking up IAA remains unknown. Recently this was explored using synchrotron-based x-ray fluorescence of IAA at the cellular level *in situ* (Fig. 12.2). The fluorescence map (Fig. 12.A) generated from the dark-adapted retina (Fig. 12.B) showed that IAA was taken up specifically by Müller glia and not by retinal neurons, including photoreceptors, indicating that the effect of IAA on neurons is not direct but secondary to inhibiting glycolysis in glia (Poity-Yamate 2009, unpublished results). Together, these results suggest a key role played by Müller glia in transporting glucose from the blood into the retina.

Acutely isolated mammalian photoreceptors produce $^{14}\text{CO}_2$ from $^{14}\text{C}(\text{U})\text{-glucose}$ ⁵³ while photoreceptor outer segments produce both lactate from glucose and $^{14}\text{CO}_2$ from $^{14}\text{C}(\text{U})\text{-glucose}$.⁶⁸ These authors interpreted their results as indicating that both glycolysis and the pentose phosphate pathway contribute to maintaining photoreceptor function. Considering that only one in six carbons from $^{14}\text{C}(\text{U})\text{-glucose}$ is converted to $^{14}\text{CO}_2$ through the pentose phosphate pathway, and the abundance of photoreceptor mitochondria, it is likely that the $^{14}\text{CO}_2$ reflects the rate of mitochondrial respiration.⁵³ Photoreceptors of some species do not express Gpi 1, the enzyme catalyzing the isomerization of glucose-6-phosphate to fructose-6-phosphate,⁶⁹ leaving the phosphate pentose pathway as the only possible downstream path, with a gain of 2 NADPH molecules potentially serving as reducing agent for the reduction of retinaldehyde.

A number of studies of glucose metabolism have been undertaken in intact retinal tissue or with acutely isolated cell models in vertebrate/mammalian retina.^{53,61–63,68,70,71} Of these, one is unique for studying not only glucose metabolism but also metabolic compartmentation: the cell model of acutely isolated Müller cells still attached to photoreceptors (termed “the cell complex”) shown in Figure 12.3 and further discussed in sections 4, 6 and 8. This study confirmed not only the previous work by Kuwabara and Cogan, but showed for the first time in a mammalian preparation of the CNS tissue that glial cells transform rather than simply transfer the primary energy substrate glucose and supply neurons with a glucose-derived metabolite.^{53,72,73}

Cell culture models of transformed rat Müller cells, human RPE and transformed mouse photoreceptor cells and ganglion cells were all found to produce lactate, aerobically and anaerobically in the presence of 5 mM glucose.⁷⁴ This may not be surprising as culturing techniques influence cell metabolism and function. The composition of culturing medium may be a key underlying factor to explain why cells are predominantly glycolytic, irrespective of cell type.⁷⁵ However, the production of lactate by these cells did not significantly differ with the addition of 10 mM lactate.⁷⁴ In general, lactate production and its release into the extracellular space as a lactate anion plus a proton (H^+) creates an extracellular pH gradient, i.e. increased proton concentration

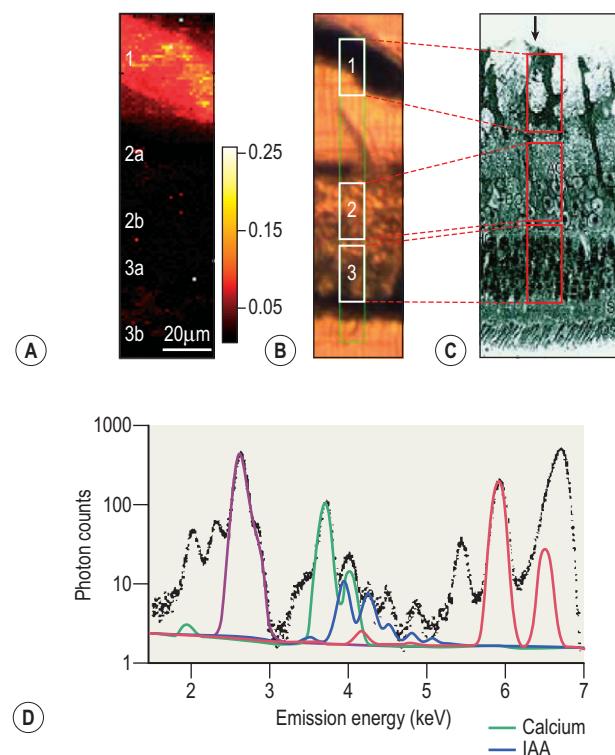

Figure 12.2 The glycolytic poison iodoacetate is localized to Müller glial cells and not to retinal neurons: indirect evidence of which cell type depends directly on glucose metabolism. (A) Synchrotron radiation-based hard x-ray fluorescence map (90 μm height \times 20 μm width) of the period table element iodine from iodoacetate (orange) subsequent to scanning the retina from the inner (top) to outer (bottom) layers. Iodoacetate was localized in the retina to Region 1 comprising the endfeet of Müller glia. The metabolic experiment consisted of dark-adapting the tissue prior to a 50 min exposure *ex vivo* to bicarbonate buffered Ringer's physiological solution carrying iodoacetate and D-glucose. Note that iodoacetate inactivates the glyceraldehyde-3-phosphate dehydrogenase reaction and therefore inhibits the 6th step in glycolysis. (B) Phase contrast image of the retina from which the fluorescence map shown in A was obtained. Region 1, Müller glial endfeet; Region 2a, inner plexiform layer; Region 2b, inner nuclear layer; Region 3a, photoreceptor layer; Region 3b, photoreceptor segments. (C) Reference, methyl-blue stained coronal section used for identifying individual retinal layers. (D) X-ray fluorescence energy emission spectra from Region 1. An La energy emission at 3.9 keV is specific to iodine from iodoacetate (blue trace). The y-axis expresses the number of fluorescence photons emitted from iodine subsequent to exposing the preparation to synchrotron light.

and consequently pH values become less than 7.4. Depending on the magnitude, direction and time course of the extracellular pH gradient, lactate may accumulate extracellularly, or alternatively, lactate may be taken up on a proton-linked monocarboxylate transporter.⁷⁶ In this context, transformed, cultured neurons did not transport or metabolize exogenous lactate,⁷⁴ consistent with a lactate-containing solution adjusted to a pH of 7.4 rather than a pH of <7.4.

3. Biochemical specialization of glial cells

The major glial cell type in vertebrate retina is the radial Müller glial cell (also termed radial fibers or sustentacular cells of Heinrich Müller). Structurally, they are elongated, possess a prominent specialized region called endfeet at the

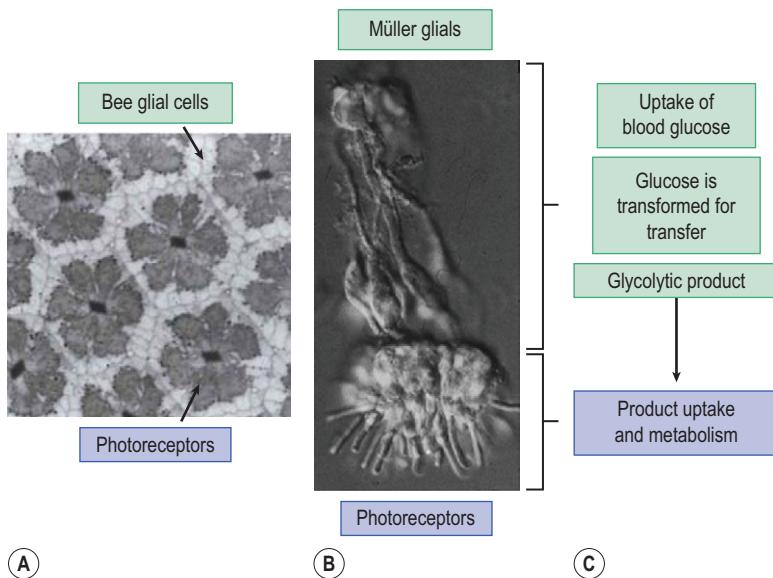

Figure 12.3 Acutely isolated cell models for exploring retinal function, metabolism and the trafficking of metabolites between glial cells and photoreceptor neurons. (A) Honeybee drone, illustrating its crystalline-like structure of 6 photoreceptors that form a rosette surrounded by glia. The outline of the extracellular space between glia is seen as web-like. The compartmentation of glycolysis to glia and of oxidative metabolism to photoreceptors renders this CNS model unique for studying neuron-glia interactions (modified from Tsacopoulos et al, *Proc Natl Acad Sci USA* 1998; 85(22): 8727–31). (B) Mammalian Müller glial cells still attached to photoreceptors (cell complex) after their acute isolation and purification from guinea pig. Prominent glial endfeet are oriented at top. The distal ends of Müller cells are hidden by photoreceptor cell bodies (modified from Poity-Yamate et al, *J Neurosci* 1995;15(7 Pt 2): 5179–91). (C) In both models, glia take up exogenous glucose and transform it to a glycolytic product (green), which in turn is released extracellularly, then taken up and metabolized by the photoreceptors (blue).

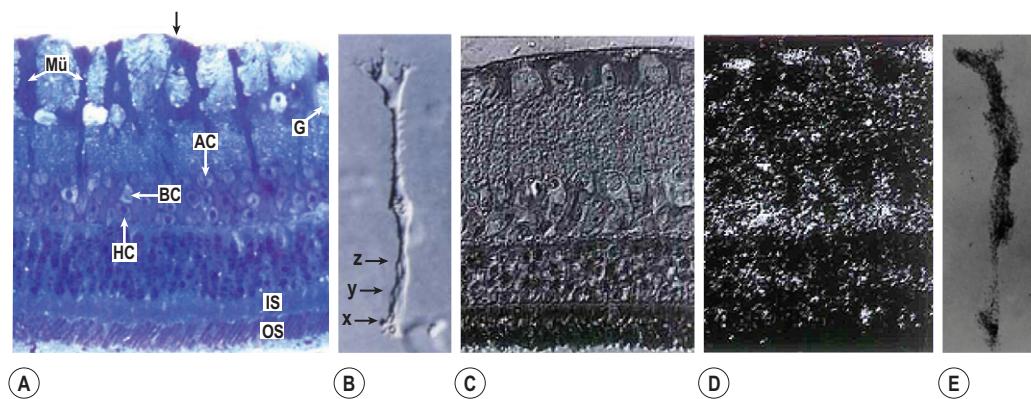

Figure 12.4 Müller glia in vertebrate retina. (A) Methyl-blue stained retinal section highlighting the large endfeet and radial structure of Müller glia (Mü) through the thickness of the retina. Laminar organization of this tissue allows for clear identification of nuclear and synaptic layers. G, ganglion cell; AC, amacrine cell; BC, bipolar cell; HC, horizontal cell; IS and OS, inner and outer segments of photoreceptors. Arrow at top indicates direction of light hitting the retina; *, synaptic layers. Müller endfeet form the vitreoretinal interface. (B) Müller cell after acute isolation and purification; approximately to scale with Müller cells shown in (A). The descending radial process (Z), radial strands (y) and terminal angular buttons (x) of the Müller cell are landmarks of that part of the Müller cell in contact with the outer synaptic layer, and the cell body and inner segments of photoreceptor, respectively (modified from Poity-Yamate et al, *J Neurosci* 1995;15(7 Pt 2): 5179–91). (C) Phase contrast image of retinal cells from guinea pig *in situ*, oriented as in a. Note that individual cell types can be distinguished using the section in (A) (modified from Poity-Yamate and Tsacopoulos, *Neurosci Lett* 1991;122(2): 241–4). (D) High resolution ^3H -DG-6P autoradiogram of retinal preparation shown in (C). The silver grains shown in white were determined by high pressure liquid chromatography and correspond to ^3H -DG-6P. (E) High resolution ^3H -DG-6P autoradiogram of a single Müller cell similar to that shown in (B), illustrating homogeneity of phosphorylated DG intracellularly extending about 120 μm starting from the endfoot (at top) to the distal end of the cell (at bottom). Autoradiograms in (D) and (E) provide evidence that Müller glia, *in situ* and when acutely isolated, take up and phosphorylate the sugar analog deoxy-D-glucose.

inner limiting membrane, and are vertically oriented with respect to the retinal layers (Fig. 12.4). Since Müller cells extend through the synaptic and nuclear layers of the retina from the inner to outer limiting membranes they are in intimate apposition to every neuron cell type.⁷⁷ Müller glia also serve as an additional physical and functional cell layer to the diffusion of substances into and out of the extracellular space, the vitreous, the subretinal space and retinal vascular supply. Histochemical evidence has shown that glycogen synthesis, glycogenolysis and anaerobic glycolysis are localized to Müller glial cells *in situ*.¹⁹ This was confirmed and quantitated in living intact, dark-adapted retina using biochemical and autoradiographic methodologies^{61,62} and provided strong experimental evidence for the working

hypothesis of all retinal cell types, Müller glia play a major role beyond the blood-retinal barriers in transporting glucose from the blood into the neural retina. However, once in the neural retina, it remains to be shown along the Müller cell's entire radial length whether the distribution of transporters related to energy substrate uptake and release are tailored to this cell's own metabolic needs, but yet adapted to the function and metabolic needs of their immediate neuronal environment.

Two functional and biochemical specializations unique to Müller glia are their capacity to inactivate the excitatory neurotransmitter glutamate^{78,79} and inhibitory neurotransmitters GABA and glycine.^{80–82} They are the exclusive and/or predominant cellular site of:

- (1) glutamine synthetase activity for the synthesis and release of glutamine, a precursor for photoreceptor neurotransmitter resynthesis,⁸³ and
- (2) carbonic anhydrase for the conversion of water and CO₂ of neuron origin to bicarbonate, an enzymatic activity implicated in the regulation of intracellular and extracellular pH and volume.^{84–86}

4. Role of glycogen

As an endogenous source of glucose-6-phosphate, glycogen, as well as glycogen phosphorylase, are exclusively localized to the cytoplasm of Müller glial cells *in situ* in a variety of mammalian species.⁸⁷ This important study suggests that Müller cells can effectively mobilize this energy store but it remains unclear whether it is for the purpose of meeting their own energy needs,⁶² or alternatively partly those of the surrounding neurons in the form of glycogenolytically generated lactate.⁵³ One isoform of glycogen phosphorylase is expressed in cone photoreceptors (brain type), while another isoform (muscle type) is expressed in the inner plexiform synaptic layers of primate retina.⁷¹ So, although glycogen metabolism in Müller glia is established (e.g. see Ripp & Witkovsky⁸⁸ for a review), the function of Müller cell glycogen is still far from clear. The prevailing view is that glycogen plays the role of an *emergency* retinal carbohydrate reservoir supporting neuron function when glucose delivery is compromised such as during retinal ischemia.⁸⁹ This is in contrast to another view that Müller cell glycogen is mobilized as an immediate and accessible energy store under normal physiological conditions (Fig. 12.5), such as changes in illumination, i.e. light and darkness, and which are linked to the direct effects of altering photoreceptor function.^{53,90} In addition, glycogenolysis can be stimulated in the retina by neurotransmitters increasing cAMP, such as vasoactive intestinal peptide, which are contained in and released from amacrine cells.⁹¹ Glycogen is also localized in neurons of the cat retina, particularly of the rod-driven pathway, whose rod-driven components are selectively sensitive to prolonged hypoglycemia,^{92,93} but whether this glycogen is mobilized is not presently known.

5. Functional neuronal activity and division of metabolic labor

A continuous supply of blood-borne glucose is vital to maintaining retinal function, but does not necessarily dictate that all retinal cells (both neurons and glia) take up and metabolize this energy substrate as is generally believed. Indeed, the conventional view of glucose metabolism in brain is that glucose is the principal substrate for oxidative metabolism in both cell types, i.e. neurons and glia.⁹⁴ The experimental evidence described in the previous sections is a major departure from this view and raises three highly controversial and still unresolved questions about the brain and about the generality of the findings in retina to other parts of the central nervous system:

- (1) is glucose, the major brain energy substrate, taken up in a cell-type specific manner?

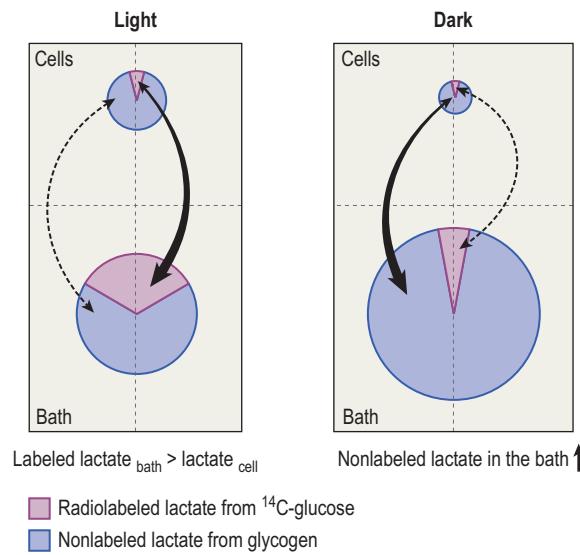

Figure 12.5 Lactate released by Müller glial cells is formed from exogenous radiolabeled glucose in the light-adapted cell complex but from glycogen in the dark-adapted cell complex. The preparation shown in Fig. 12.3B was maintained either in darkness or light before exposure to uniformly radiolabeled glucose (¹⁴C(U) glucose) with the aim to determine the contribution of glucose and glycogen to the production of lactate when modulating photoreceptor metabolism and neurotransmitter release. It is known that: (1) photoreceptors release neurotransmitter glutamate and that their metabolism is increased in darkness; and (2) glutamate release stimulates glycolysis and production of lactate. The results shown are simplified and drawn as a pie to reflect changes both inside the cells (top) and in the surrounding bath (bottom). Pie size represents the total pool size of lactate, i.e. radiolabeled + non-radiolabeled lactate. The size of the wedge represents the specific activity of lactate, so the larger the wedge, the larger is the contribution of exogenous glucose to the formation of lactate. The direction of the solid arrow in the left panel indicates that the amount of radiolabeled lactate (pink) in the bathing solution was much greater than that inside the preparation. This is only possible when lactate is produced from ¹⁴C-glucose and is released earlier than non-radiolabeled lactate formed from glycogen. In the right panel, the direction of the solid arrow indicates that the amount of non-radiolabeled lactate (blue) in the surrounding bath greatly increased. This is only possible when glycogen (gly) in glia is mobilized to produce additional, unlabeled lactate.

- (2) does glycolysis predominate in one particular cell type, physiological condition or brain region and oxidative metabolism of glucose in another? and
- (3) does coupling of metabolic and physiological changes to changes in neuronal activity involve the transformation of blood glucose by glial cells and do they supply neurons with glucose-derived metabolite(s)?

Underlying these issues is the idea of a predominant division of metabolic labor between neurons and glia. In other words, energy substrate production and substrate use is partitioned in a relatively cell-specific manner. This working hypothesis, summarized in Figure 12.6, was developed and tested in retina in the mid-1990s, in insect and mammal, and has seen a revival in recent years, particularly with regards to the recognition that the coordinated action of glial cells and neurons extends to energy metabolism throughout the central nervous system.

As will be developed in the next sections, the major theme is that glial cells *transform rather than simply transfer* the primary energy substrate glucose, and supply activated

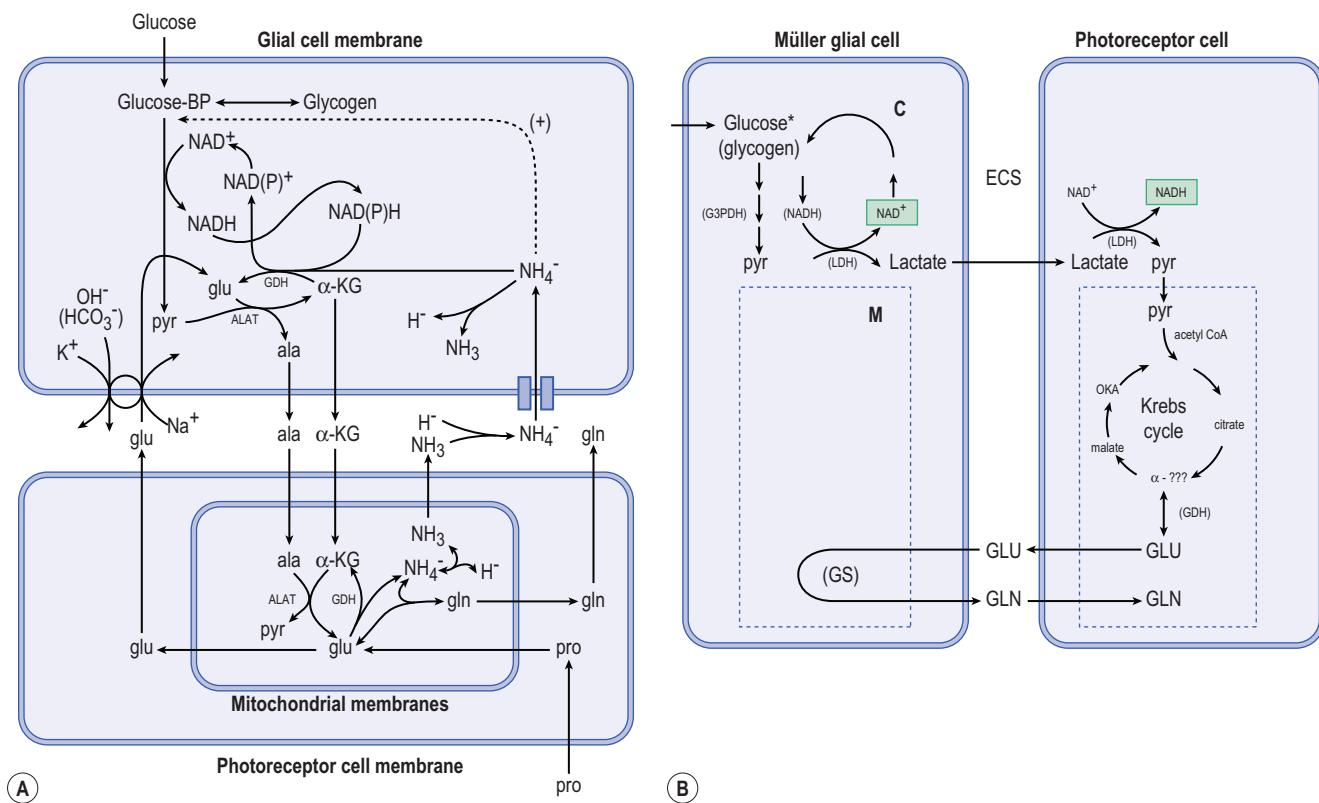

Figure 12.6 Proposed scheme of retinal function, from bee to mammals, highlighting metabolite trafficking between glial cells and photoreceptors. The honeybee drone model is shown in (A) and the mammalian model is shown in (B). Both models display relative metabolic compartmentation: glycolysis to glia and oxidative metabolism to photoreceptor-neurons. Commonalities of the models include production of a glycolytic product, i.e. lactate or alanine, their release extracellularly and uptake by photoreceptors; maintenance of the redox potential in glia, i.e. NADH/NAD ratio; and photoreceptor release of glutamate that acts to stimulate glial glycolysis. Glutamate is thus a chemical signal that turns the nourishing of neurons by glia into a function, instead of a passive process. In (B), the cytosol is indicated as **C**; mitochondria are indicated as **M**.

neurons with a glucose-derived metabolite, i.e. lactate and/or alanine. In this regards, the vertebrate retina has proven to be a CNS model of choice because its laminar organization of metabolism and blood flow lends itself to the study of compartmentation by virtue of its structure. It should, however, be recognized that the high specialization of this nervous tissue, e.g. phototransduction and high energy metabolism, makes it different from other regions of the CNS and any comparisons must be made with caution. Moreover, the retina has two barriers, the retinal capillary endothelial cells of the inner blood-retinal barrier (BRB), and the retinal pigment epithelium (RPE) comprising the outer BRB which is located between the photoreceptors and choroid. Thus, their expression and distribution of glucose transporters⁹⁵ and glycolysis will inevitably determine whether one, or alternatively both, of these barriers is the rate-limiting step for glucose delivery to the neuroretina.

6. Cellular compartmentation of energy substrates other than glucose

One distinctive property of the mammalian retina is its large production of endogenous lactate in the presence and absence of oxygen.⁴⁸ The production of lactate is a normal function of retinal tissue and can effectively replace glucose

in oxygenated Ringer's solution in maintaining retinal oxidative metabolism and photoreceptor function.⁵¹ It was only in the mid-1990s that this phenomenon was explored at the cellular level⁶² and when the idea was launched that energy metabolism underlying retinal function in mammals was relatively compartmentalized, and moreover orchestrated between glial cells and neurons.⁵³

The use of high-resolution light microscopic autoradiography of ³H-2DG in the dark-adapted retina *in situ*, coupled to HPLC for the identification of silver grains in autoradiograms⁶¹ showed that glucose is not taken up by the majority of retinal cells but preferentially taken up and phosphorylated by the Müller glia (Fig. 12.4C,D), leaving the question as to the identification of the energy substrate used by neurons. Using a cell model of acutely isolated Müller cells, the metabolic fate of glucose-6-phosphate and the identity of metabolites released by these cells was first assessed by Poity-Yamate and Tsacopoulos.⁶² The experimental results of that study raised the hypothesis that lactate, synthesized and released *in situ* by a retinal cell type having high glycolytic capacity, may be transferred to and metabolized by photoreceptors that possess a high respiratory capacity. This working hypothesis was tested in the acutely isolated retinal model of the cell complex (see Fig. 12.2B) comprising Müller cells still attached to photoreceptors, and where the effect of altering illumination on glucose metabolism was quantitated.⁵³ A major finding of that study (see section 8 below)

showed that lactate *formation* versus lactate *use* was cell-type dependent. As already discussed in section 4, sources of this glial lactate were from exogenous glucose, or alternatively, from endogenous glycogen (Fig. 12.5). The functional role for the release into the extracellular space of lactate and H⁺ by Müller glial cells during either glycolysis or glycogenolysis is expected to prevent intracellular acidification and maintain the regeneration of NAD⁺ for glycolysis to proceed. Lactate and other glucose-derived metabolites released from the Müller glia would participate in the regeneration of the excitatory neurotransmitter glutamate, released by photoreceptors in darkness.⁵³

Within a larger framework, the current debate in the neuroscientific community is whether in other parts of the CNS, a net production and extracellular release by glial cells of glucose/glycogen-derived lactate provides sufficient fuel for activated neurons *in vivo*. NMR studies on brain function and energy metabolism have in recent years provided indirect support of a lactate flux from glia to neurons as providing the coupling mechanism between increased fluxes of the glucose carbon into the glycolytic pathway in glia, and into the oxidative pathway in neurons, in the form of lactate, during glutamatergic/excitatory synaptic transmission.⁹⁶ Unraveling the current debate surrounding the glial-neuron lactate shuttle hypothesis (ANLSH)^{97,98} in the CNS at large is a key step towards: (1) understanding the regulation of retinal and cerebral energy metabolism during neuronal activity; and (2) interpreting ¹⁸F-FDG PET and fMRI images in both clinical medicine and fundamental neuroscience, and for which there is accumulating evidence for the central importance of glial cells in brain imaging signals.⁹⁹

7. Experimental models used to study the interaction between photoreceptors and glial Müller cells

In vitro studies of the retina of the honeybee drone

The most comprehensive and quantitative experimental tests in the literature demonstrating that glial cells supply neurons with a metabolic substrate to sustain neuron function were first formulated and established in the retina of the honeybee drone.^{72,100–105} This elegant crystalline-like CNS preparation is characterized by mitochondrial-rich, glycogen-poor photoreceptors grouped in rosette-shaped clusters and their surrounding mitochondrial-poor and glycogen-rich glial cells (see Fig. 12.3), indicating that glycolysis/glycogenolysis is largely confined to glia and that oxidative metabolism is largely confined to photoreceptors. What follows is a historical and chronological overview of the major experimental questions, experimental results and interpretations.

If there are no conventional synapses in drone retina and only the photoreceptors are directly excitable by light, what is the evidence that photoreceptors depend on surrounding glia for their metabolic needs?

In retinal drone slices, three lines of evidence argue that photoreceptors depend on the surrounding glial cells for their metabolic needs:

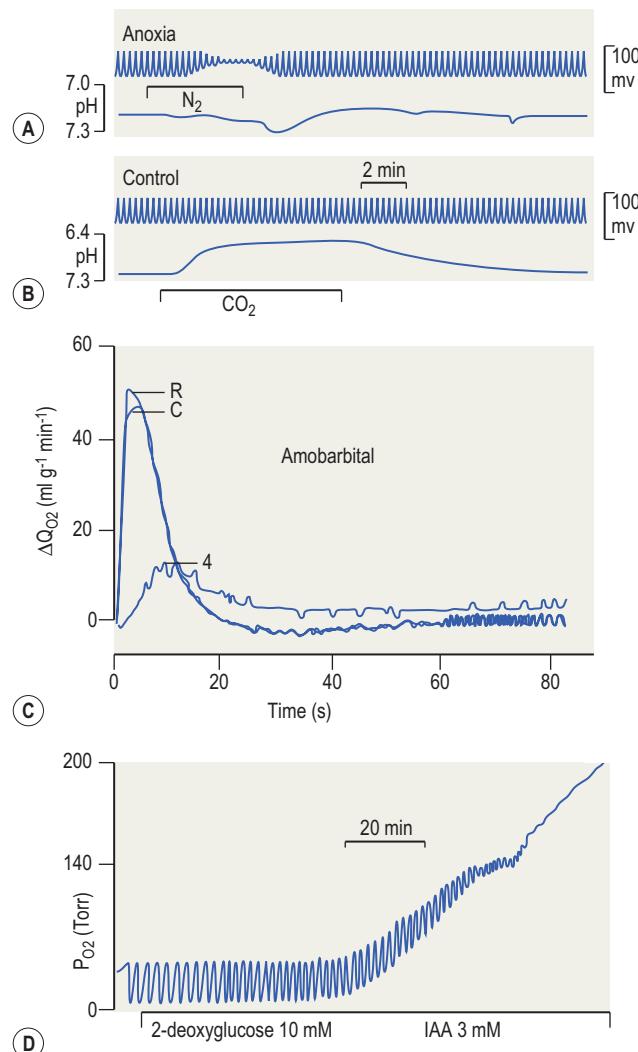

Figure 12.7 Characterization of photoreceptor metabolism and function in honeybee drone: evidence that photoreceptors metabolically depend on surrounding glia. (A) The effect of anoxia on abolishing receptor potential in photoreceptors but as shown in (B). The absence of an extracellular acidification as would be expected if anaerobic glycolysis is activated, indicates that photoreceptor energy metabolism is obligatorily aerobic. (C) The effect of blocking mitochondrial respiration (noted as 4) that uses a carbohydrate substrate reversibly suppressed the light-induced consumption of oxygen by photoreceptors. C and R are control and reversibility responses, respectively. This result indicated that the substrate of photoreceptor metabolism is obligatorily a carbohydrate. (D) The glucose analog, 2-deoxy-D-glucose (2DG) leads to a decrease in the partial pressure of oxygen (P_{O₂}), so had no effect on the light-induced increase in oxygen consumption in photoreceptors. This result indicated that the continued function of photoreceptors does not depend on their direct uptake of glucose. The effect of the glycolytic poison, iodoacetate (IAA) on oxygen consumption and thereby of the partial pressure of oxygen in bee photoreceptors is not direct as glycolysis takes place only in the glia in this preparation (see Fig. 12.7A).

- (1) Anoxia rapidly abolishes the receptor potential of photoreceptors stimulated every 5s by a light flash (Fig. 12.7A). However, simultaneous monitoring of the pH in the extracellular space changed by less than 0.02 units (Fig. 12.7B), in contrast with that of many other tissues where hypoxia leads to anaerobic glycolysis and

acidification. These results indicated that anoxia does not lead to anaerobic glycolysis in drone retinal slices and that photoreceptor energy metabolism is obligatorily aerobic.

- (2) Amobarbital (or amytal) a specific blocker of mitochondrial respiration that uses carbohydrate substrate reversibly suppresses the light-induced change of oxygen consumption by photoreceptors (Fig. 12.7C), indicating that the substrate of photoreceptor metabolism is a carbohydrate.
- (3) Superfusing slices of drone retina with the glucose analog 2-deoxy-D-glucose (2DG) had no effect on the light-induced increase of QO_2 , as monitored by decreases in PO_2 (Fig. 12.7D). As 2DG is transported into cells, phosphorylated, and little of it is metabolized further, 2DG6P accumulates intracellularly. This indicates that the continued function of photoreceptors does not depend directly on their uptake of glucose.

When bee retinal slices are exposed to the glycolytic poison IAA, the light-induced change in QO_2 is gradually abolished. Is this modulation of QO_2 a direct effect of IAA in photoreceptors?

IAA exerts its effect in cells where glucose uptake and metabolism are committed to the glycolytic pathway. Identifying whether the cellular site of glucose phosphorylation is cell-type specific is a first step towards this answer. The distribution and density of black grains biochemically identified as $^3\text{H}-2\text{DG}-6\text{-phosphate}$ ($^3\text{H}-2\text{DG}6\text{P}$) in light microscopic autoradiographs (Fig. 12.8) of bee retinal slices exposed to tritiated 2DG provides this answer. Transport and phosphorylation of this sugar analog are localized in situ to the glia and absent in photoreceptors. Hence, IAA has obligatorily exerted its direct effect on the metabolism of glucose in glial cells, which in turn lead to downstream effects on the oxygen consumption in photoreceptors.

What is the evidence that photostimulation of drone retinal slices increases the carbohydrate metabolism in the glia to sustain photoreceptor respiration?

In the absence of metabolic substrate, i.e. glucose, a drone retinal slice consumes up to $70 \mu\text{l O}_2$ per mL tissue per minute with light stimulation for > 2 hours. After 2 hours of repetitive light flashes (Fig. 12.9), the concentration of glycogen decreased by 30% (or by 15 mg per mL tissue), a value comparable with the carbohydrate requirements of photoreceptors, i.e. equivalent to 10 mg of glycogen per mL tissue. This led to the working hypothesis that glycogen in the glia is mobilized, and that a carbohydrate substrate downstream to glucose-6-phosphate is transferred from the glia to photoreceptors to maintain mitochondrial respiration and responsiveness to light.

Glucose is not the principal energy substrate used by photoreceptors, so what is the identity of the energy metabolite maintaining photoreceptor function and respiration?

This involved determining the metabolic fate of glucose-6-phosphate in glia, the identity of glial-derived metabolites released into the extracellular space, and their uptake by photoreceptors. More than 50% of uniformly labeled glucose ($^{14}\text{C}(\text{U})\text{glucose}$) transported into drone glia was transformed to alanine by transamination of pyruvate with glutamate (Fig. 12.10A). This transformation was inhibited by IAA which is expected if alanine is formed from glucose by transamination of pyruvate with glutamate through the enzymatic action of alanine aminotransferase (ALAT) and glutamate dehydrogenase (GDH) schematized in Figure 12.6A. This was confirmed when the transformation was preserved in the presence of IAA and when the labeled carbohydrate in the perfusate was $^{14}\text{C}\text{-pyruvate}$ (Fig. 12.10B). The glial cells released into the extracellular space the equivalent of $216 \mu\text{mol}$ of radiolabeled alanine / liter of retina (Fig. 12.11A) and this alanine was taken up

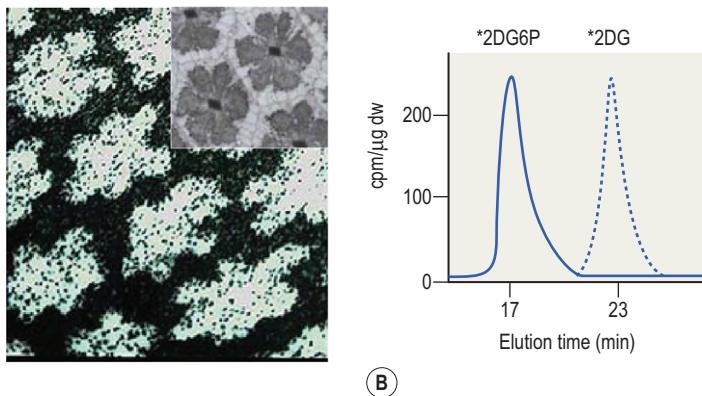

Figure 12.8 Autoradiographic and biochemical evidence that glucose transport and phosphorylation take place in glial cells and not in photoreceptors in retina. (A) The high resolution, light microscopic $^3\text{H}-2\text{DG}$ autoradiogram obtained after exposure of honeybee retina to the glucose analog $^3\text{H}-2\text{-deoxy-D-glucose}$ (DG) indicates that DG has been transported and phosphorylated specifically in the glia. The accumulation of black grains in glia corresponds to the intracellular accumulation of phosphorylated $^3\text{H}-2\text{DG}$, as DG is not further metabolized. The sparse distribution of black grains within the photoreceptor rosettes (inset, see also Fig. 12.2A) is probably the fin-like glial structures that separate individual photoreceptors within the rosette. (B) The identity of the black grains in (A) was determined biochemically using high-pressure liquid chromatography (HPLC). The chromatograph shows that the black grains correspond to the phosphorylated form of the radiolabeled substrate (* $^3\text{H}-2\text{DG}6\text{P}$), eluted at 17 min. Note that the expected eluted time of the non-phosphorylated substrate * $^3\text{H}-2\text{DG}$ is at 23 min. (Modified from Tsacopoulos et al., Proc Natl Acad Sci U S A 1998;85(22): 8727–31.)

by the tissue against a concentration gradient and transported in a Na^+ -dependent fashion (Fig. 12.11B) and which is only effective in the photoreceptors. Moreover, alanine was consumed by the photoreceptors: repetitive light stimulation lead to >60% increase in $^{14}\text{CO}_2$ production from $^{14}\text{C}(\text{U})$ -alanine.

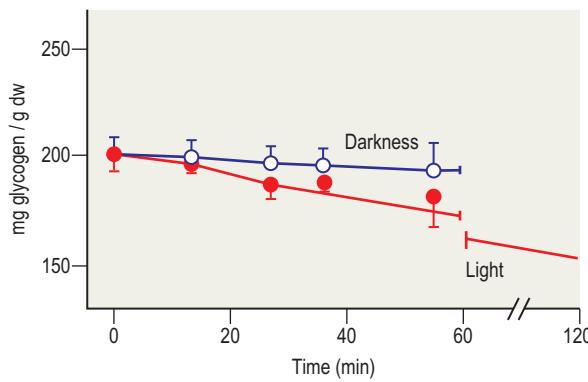

Figure 12.9 In the absence of glucose, photostimulation increases carbohydrate metabolism in the form of glycogen mobilization in glia to sustain photoreceptor respiration. The effect of darkness and light on the concentration of glycogen, expressed as mg glycogen per gram dry weight of tissue, was determined at different time points from bee retina deprived of exogenous glucose. After 2 hours of repetitive light flashes glycogen concentration decreased by 30% or by 15 mg per mL of tissue. This value is comparable to the measured carbohydrate needs of photoreceptors: 10 mg of glycogen per mL tissue. This result suggested that glial glycogen is mobilized and transformed downstream to phosphorylated glucose to a metabolite made available to photoreceptors. This metabolite would serve to maintain mitochondrial respiration and the photoreceptor's response to light.

What is the biochemical evidence for the metabolic effects of NH_4^+ and glutamate in glia?

Photoreceptors also consume proline from pollen and this consumption leads to the production and release of photoreceptor ammonia and glutamate in a stimulus-dependent manner. The production of alanine from glucose by the glial cells is coupled to the resynthesis of NAD^+ via the activity of glutamate dehydrogenase (GDH) (see Fig. 12.6A). Since NH_3 feeds into this reaction, consuming NADH to produce glutamate, it was hypothesized that $\text{NH}_3/\text{NH}_4^+$ and glutamate act on alanine production in the glial cells. In an elegant series of experiments¹⁰⁵ using bundles of freshly isolated bee glial cells, it was shown that:

- (1) $(\text{NH}_4^+ + \text{glutamate})$ are signals that photoreceptors send to glial cells to activate glycolysis and/or glycogenolysis, leading to an increased synthesis of alanine by glia and its release into the extracellular space.
- (2) glycogen is the likely substrate for alanine formation, but glucose is the likely substrate for alanine release.

Overall scheme for metabolic compartmentation and metabolic trafficking in honeybee drone retina

Honeybee drone retinal glia transform glucose to a fuel substrate taken up and used by photoreceptors, which in turn consume both alanine supplied by glia and exogenous proline (see Fig 12.5A). Ammonium (NH_4^+) and glutamate, produced and released in a stimulus-dependent manner by the photoreceptors, contribute to the biosynthesis of alanine in the glia. NH_4^+ and glutamate are subsequently transported into glia and a transient rise in the intraglial concentration

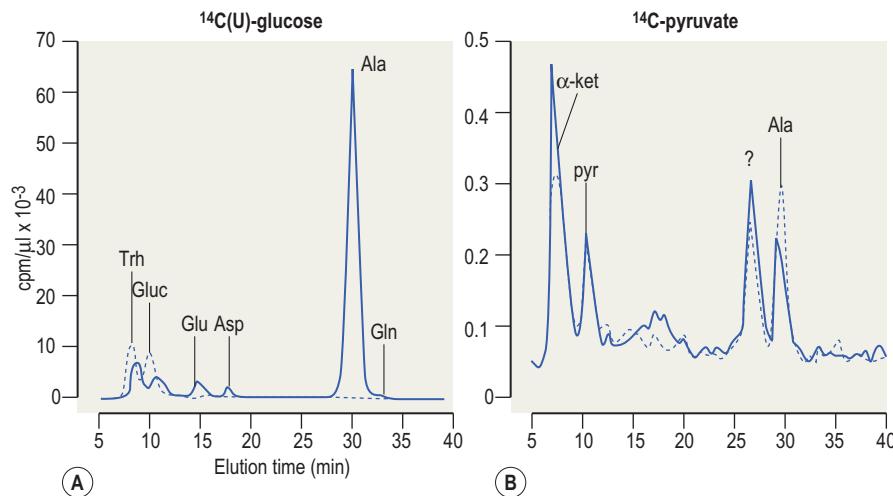

Figure 12.10 The transport of $^{14}\text{C}(\text{U})$ -glucose into bee glia is transformed to alanine by transamination of pyruvate with glutamate. The identity of the metabolite maintaining photoreceptor function and respiration was explored by first determining the metabolic fate of uniformly radiolabeled glucose in glia. The HPLC chromatogram in (A) shows that over 50% of $^{14}\text{C}(\text{U})$ -glucose was transformed to alanine (Ala). As summarized in Fig. 12.5A, alanine was formed from glucose by transamination of pyruvate with glutamate through the combined enzymatic action of alanine aminotransferase (ALAT) and glutamate dehydrogenase (GDH). This hypothesis was tested by exposing the preparation to IAA with either $^{14}\text{C}(\text{U})$ -glucose or with $^{14}\text{C}(\text{U})$ -pyruvate. Alanine formation was inhibited by IAA + $^{14}\text{C}(\text{U})$ -glucose (not shown), indicating the requirement for pyruvate. However, as shown by the dashed-line chromatograph in (B) alanine formation was preserved in the presence of IAA + $^{14}\text{C}(\text{U})$ -pyruvate since IAA exerts its effect upstream to the production of pyruvate. Thr, trehalose; Gluc, glucose; Glu, glutamate; Asp, aspartate; Gln, glutamine; α ket, α -ketoglutarate; pyr, pyruvate. (Modified from Tsacopoulos et al., J Neurosci 1994; 14(3 Pt 1): 1339–51.)

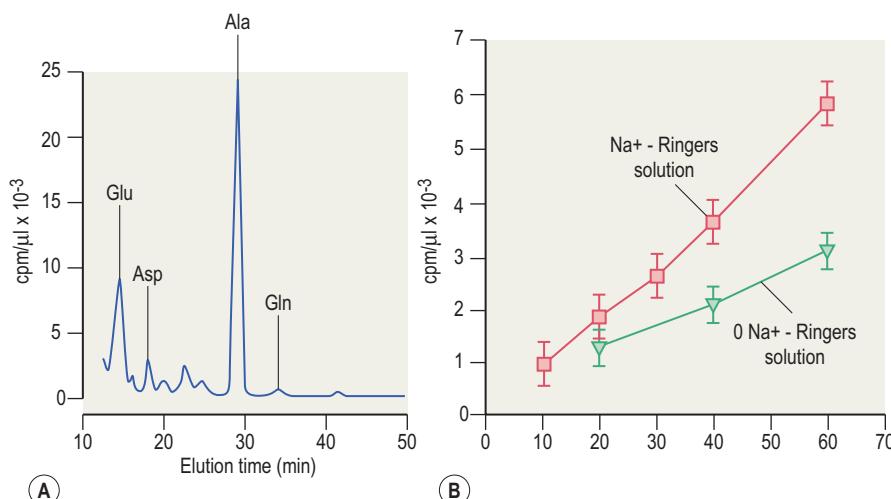

Figure 12.11 Glucose-derived alanine in glia is released extracellularly and taken up by photoreceptors. Following the determination of radiolabeled metabolites derived from ¹⁴C(U) glucose in glia, the second step was to determine which of these metabolites were released extracellularly by performing HPLC analysis of the bathing solution. The chromatogram shown in (A) shows that the major radiolabeled metabolite released by glia was alanine (modified from Poitry-Yamate et al 1995, Neurosci Lett 122(2): 241–244. Copyright Elsevier 1995). This radiolabeled extracellular alanine was taken up principally on a sodium-dependent transport system shown in (B). Alanine was subsequently shown to be taken up by photoreceptors since repetitive light stimulation lead to >60% increase in ¹⁴CO₂ production from ¹⁴C(U)-alanine.

of NH₄⁺ or of glutamate causes a net increase in the level of reduced nicotinamide adenine dinucleotides (NAD(P)H). Biochemical measurements indicated that this was due to the activation of glycolysis in the glia by the direct action of NH₄⁺ and glutamate on two enzymatic reactions: those catalyzed by phosphofructokinase and glutamate dehydrogenase. The overall effect of NH₄⁺ on glial metabolism is to increase the production and release of alanine, and that of glutamate is to adjust this production to the metabolic needs of photoreceptors. In this model (NH₄⁺) and glutamate released by photoreceptors return to glial cells not simply for nitrogen conservation but as information signals. This tight regulation of metabolic coupling between neurons and glial cells by means of chemical signals turns the nourishing of neurons by glia into a function, instead of a passive process.

Experimental models in vertebrates

The most comprehensive model *in vivo* of metabolism and function in the inner and outer retina is the cat eye followed by that in rabbit. It is unique in the literature on retinal metabolism that only one group, headed by Günter Niemeyer, has fully exploited both the *in vivo* and *in vitro* models. This group has quantitated the effects of controlled, stepwise and transient changes in arterial supply of glucose on retinal and optic nerve function at multiple levels of retinal information processing (e.g. light-evoked electrical signals of the ERG b-wave and light-independent retinal field potentials of negative polarity) in the arterially perfused enucleated eye of the cat^{106,107} and verified directly these *in vitro* findings in anesthetized cats under insulin-induced glucose clamping.^{93,108} Although the entire body of work by this group cannot be justly summarized here, Niemeyer and colleagues made a number of important observations which have current clinical and fundamental relevance in understanding retinal function as related to metabolism:

- (1) Electrophysiological measurements of the ERG b-wave, the STR (scotopic threshold response) and optic nerve action potentials indicate an exquisite, immediate and reversible sensitivity of the inner retina to changes in the supply of glucose between ~1 and 10 mmol/l glucose.

- (2) In contrast to the cone-driven light-evoked signals, the rod-driven light-evoked signals increased or decreased in parallel to changes in glucose.
- (3) Blood-borne insulin enhanced the reduction in b-wave amplitude at low (1–2 mM) glucose concentrations.
- (4) Glycogen is distributed in Müller glia, and central perivascular astrocytes. It is present in ganglion cells, on-off amacrine cells and rod bipolar cells of the rod pathway, but entirely absent in cone and rod photoreceptors⁹² under conditions where the ERG is affected by changes in plasma glucose concentrations.

These studies raise a number of interesting questions regarding retinal energy metabolism in regards to insulin-induced hypoglycemia and diabetes:

- (1) Can glycogen reserves in the retina *in vivo* serve as glucose equivalents during hypoglycemia, as has been recently shown for brain?¹⁰⁹
- (2) Does impaired glucose sensing, i.e. hypoglycemia unawareness in the brain, also affect the retina?
- (3) If retinal glycogen metabolism and content are insulin or glucose-sensitive, then do increased retinal concentrations of glucose result in a lowered glycemic threshold of counter-regulation as observed in chronic hypoglycemia?

The experiments carried out by Ames and colleagues using isolated cat retinas maintained in a miniaturized heart-lung apparatus^{15,45} characterized the energy requirements of retinal function by monitoring retinal lactate production and oxygen consumption.¹⁵ Finally, Lisenmeier and colleagues^{29,110} have devoted a great deal of effort to studying the distribution and consumption of oxygen throughout the inner and outer retina in anesthetized cats during systemic normoxia and hypoxia and more recently retinal pH changes during hypoxemia, hyperglycemia and during anaerobic glycolysis. Other important contributions to energy metabolism of the retina have been carried out in monkey and miniature pigs *in vivo*,^{111–113} and in rabbit²² and rat *in vitro*.^{51,114}

Complementary to laser Doppler flow measurements^{115–117} and oxygen electrode measurements in anesthetized pig,^{25,118} recent, exciting developments using BOLD fMRI (blood-oxygen-level-dependent functional magnetic resonance

imaging) and intravascular contrast agents in the intact eye of the cat^{119–121} provide significant promise for non-invasive, real-time visualization of retinal function, structure, blood flow and oxygenation in health and disease, for example in diabetic retinopathy. Multiple MRI contrast mechanisms presently permit laminar spatial visualization of the retina, corresponding to the inner and outer retina and choroid microvasculature.¹²²

8. Metabolic interactions between vertebrate photoreceptors and Müller glial cells

Can the experimental findings in insect retina be generalized to mammals? This question was explored in the retina of the guinea pig⁵³ (see Figs 12.3 and 12.4) where analogous experimental findings supported the concept of metabolic compartmentation (see Fig. 12.6B). Four conclusions were drawn from that study and are summarized in Figure 12.12:

- (1) Müller glial cells massively produced lactate from radiolabeled glucose, most of which was found extracellularly in the corresponding cell bath (Fig. 12.12A and B, blue bars).
- (2) The effects of altering illumination of the cell complex (thereby specifically altering photoreceptor function and metabolism) affect the production, release and/or uptake of glucose/glycogen-derived lactate in Müller glia (Fig. 12.12A and B, a purple and green bars).
- (3) From numerical calculations, the “missing lactate” in the bath of the cell complex (vertical arrow in Fig. 12.12B) matched the expected production of $^{14}\text{CO}_2$ by photoreceptor oxidative metabolism (see Box 12.1) and was antagonized by the addition of unlabeled lactate (Fig. 12.12C).
- (4) Glial-derived lactate is preferentially consumed by purified populations of acutely isolated photoreceptors (Fig 12.12D), even in the presence of millimolar concentrations of glucose (Fig 12.12E).

These results show that a *relative compartmentation* of substrate *formation* to the glial cells and substrate *use* to the photoreceptor neurons previously established in bee retina can be generalized to mammals (see Fig. 12.6). Such compartmentation may underlie the need for a continuous trafficking of lactate/alanine from glia to neurons (see also section 6). It should be noted that guinea pig photoreceptors do in fact take up and phosphorylate glucose,⁵³ but when challenged with either one alone or a combination of both, lactate is a preferred substrate as evaluated by $^{14}\text{CO}_2$ produced (Fig. 12.12E). Lastly the reader is reminded of the finding that the presence of photoreceptors, thus the model of Müller cells still attached to photoreceptors, modifies in a light/dark-dependent manner either the synthesis, release or metabolic fate of glucose-derived metabolites, i.e. lactate and glutamine, in the Müller glia.⁵³

To summarize, the neuroretina can serve as an important CNS model in which to assess the use of energy fuel as related to function. Neurons and glia divide metabolic labor in a way that is vital to function. The general finding that substances released by neurons, i.e. excitatory neurotransmitter

Box 12.1 Appendix: Numerical calculations of missing lactate and its consumption by photoreceptors (PH)

- To a first approx, the amount of CO_2 produced by PH = amount of oxygen consumed
- PH ~50% of tissue; major contributors to CO_2 production; consume 40 $\mu\text{l O}_2/\text{gram min}$
- 30 min incubation: ~16,000 cpm $\mu\text{g protein lactate in Muller cell bath}$
- ~3000 in cell complex bath (dark conditions)
- 13,000 cpm/ $\mu\text{g prot} \cdot (45 \text{ dpm } 40 \text{ cpm}) \cdot [2.22 \times 10^6 \text{ dpm } \mu\text{Ci} \cdot 146 \mu\text{Ci}/\mu\text{mol glucose}]^{-1}$
- $\Rightarrow 4.6 \cdot 10^{-6} \mu\text{mol glucose}/\mu\text{g prot} \text{ or } 4.6 \cdot 10^{-6} \mu\text{mol glucose}/10^{-8} \text{ liters or } 4.6 \text{ mM glucose}$
- Therefore, 4.6 mM glucose 30 min $\approx 0.15 \text{ mM glucose min}$
- 1 glucose $\rightarrow 1 \text{ O}_2$, so 0.9 mM O_2 min; 0.9 mM $\text{O}_2 \text{ l} \cdot \text{min} \times 22.4 \text{ mL O}_2/\text{mM}$
- $\Rightarrow 20 \text{ mL O}_2/\text{l} \cdot \text{min} \text{ is } 20 \mu\text{l O}_2 \text{ cm}^3 \cdot \text{min}; \Rightarrow 40 \mu\text{l O}_2/\text{cm}^3 \text{ photoreceptors} \cdot \text{min}$
- Therefore, 40 $\mu\text{l O}_2$ 40 $\mu\text{l O}_2$ or (value from literature for PH in darkness/ $\text{cm}^3 \cdot \text{PH} \cdot \text{min}$):
- (measured value for PH in cell complex/ $\text{cm}^3 \cdot \text{PH} \cdot \text{min}$) $\times 13,000 \text{ cpm}/\mu\text{g prot}$
- Yields 13,000 cpm/ $\mu\text{g protein}$
- \Rightarrow amount of CO_2 that would be produced from missing lactate \sim amount of O_2 consumed by PH

glutamate, constitute signals to glia as well as being materials to be removed or regulated underscores the emerging paradigm that neurons and glia act in concert as metabolic partners, with information in the form of metabolic intermediates and signaling molecules continuously flowing between them. Lastly, the similarity of metabolic shuttling between insect and mammalian retina strongly suggests that this mechanism might be universally operative in the CNS, although direct experimental evidence remains difficult to come by.

9. Metabolic interaction between photoreceptors and retinal pigment epithelia

The retinal pigment cell epithelium (RPE) forms part of the choroidal blood /outer retinal barrier, facing the outer photoreceptor segments on its apical membrane side, Bruch's membrane on its basolateral membrane side and plays an essential role in maintaining photoreceptor excitability and sensitivity and the reisomerization of all-trans-retinal after photon absorption.¹²³ In rod outer segments (ROS), all-trans-retinal is transformed to all-trans-retinol by retinol dehydrogenase using NADPH. NADPH is restored in ROS by the pentose phosphate pathway utilizing high amounts of glucose supplied by choriocapillaries. The retinal formed is transported to PE cells where regeneration of 11-cis-retinal occurs (see Chapter 13).

The RPE apical membrane is separated from the neuroretina by the subretinal space which serves to mediate the

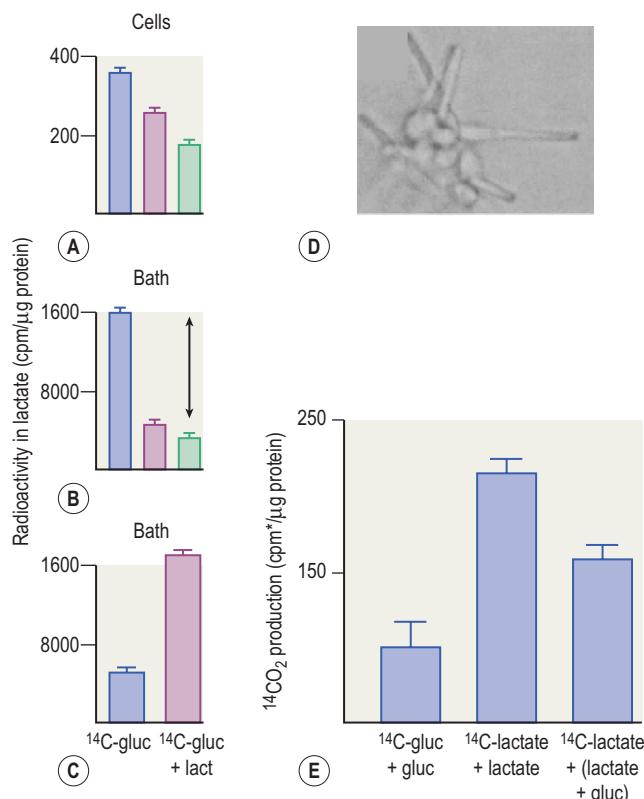

Figure 12.12 Glial lactate is released extracellularly and consumed by photoreceptors in mammalian retina. Metabolic trafficking between neurons and glia was explored using three cell models: purified populations of acutely isolated Müller glia (Fig. 12.4B), acutely isolated photoreceptors (D) and the acutely isolated cell complex (Fig. 12.3B) from guinea pig retina. The effect of altering illumination of the cell complex (purple: maintained in light vs green: maintained in darkness) was the strategy used to specifically alter photoreceptor function and metabolism. Darkness increases photoreceptor metabolism and the release of neurotransmitter glutamate. Retinal glia are not directly affected by light. Müller cells alone massively produced lactate from uniformly radiolabeled glucose, most of which was released into the extracellular space, as shown by the blue columns in (A) and (B). The effects of altering illumination of the cell complex, particularly in darkness, lowered significantly the amount of radiolabeled lactate in the corresponding bath (B, second and third columns) compared to the bath of Müller cells alone (B, first column). This “missing lactate” matched the expected production of $^{14}\text{CO}_2$ by photoreceptor oxidative metabolism. As expected, this “missing lactate” was also antagonized by the addition of unlabeled lactate to the cell complex bath (C), indicating that lactate released extracellularly by glia was consumed. Finally, (E) shows the amount of $^{14}\text{CO}_2$ produced by the cells in (D) as a function of 3 different substrate mixtures. The conclusion drawn was that glial lactate was preferentially consumed by photoreceptors, even in the presence of millimolar concentrations of glucose. Overall, the effects of altering illumination of the cell complex affected the production, release and or uptake of glucose-derived glial lactate. (Modified from Poiry-Yamate et al 1995, *Neurosci Lett* 122(2): 241–4. Copyright Elsevier 1995.)

transport of metabolic intermediates, ions and water between the choroid and the retina. Considering the vascular sources of fuel substrate, the choroidal microcirculation is one source of glucose for photoreceptor outer segments. However, it is presently unclear whether glucose crosses the RPE on glucose transporters GLUT1 and GLUT3¹²⁴ or if it is consumed and transformed through the glycolytic pathway to lactate for transfer and to a lesser extent oxidized through

the Kreb’s cycle.²¹ This is a relevant point since RPE cells depend on glucose as their primary energy substrate.¹²⁵ The expression of the monocarboxylate transporter MCT3 on the RPE basolateral side for the efflux of lactate from RPE to the choroidal microcirculation and the expression of MCT1 on the apical side for the transport of lactate and water from the retina to choroid⁷⁶ (see Chapter 13) suggests that lactate is not used by RPE cells, at least when glucose is non-limiting.¹²⁵ Thus, if RPE cells synthesize and release glucose-derived lactate in vivo, as has been demonstrated in acutely isolated RPE²¹ and in cultured RPE,⁷⁴ then any lactate leaving the eye as determined by either choroidal venous drainage or femoral artery-choroidal vein differences³⁸ is a two-fold contribution (neuroretina and RPE). Presently the contributions from these two sources have not been quantitated nor their contribution to the amount of effluxed lactate to the choroidal vein. These unknowns need to be taken into account when critically evaluating the ANLSH hypothesis that aerobic glycolysis in glia increases in response to activation of neurotransmitter glutamate systems and the neuronal oxidation of glial lactate.⁵⁵ In the eye, *endogenous* lactate production does not appear to be linked only to energy metabolism: the cotransport of H⁺ and lactate with water in the direction from retina to choroid plays a role in volume regulation and thereby retinal adhesion.¹²⁶

10. Metabolic factors in the regulation of retinal blood flow

In a series of original papers on the metabolic factors involved in the regulation of retinal blood flow in monkey and miniature pigs, Tsacopoulos proposed that an extravascular, intraretinal acidosis was a key step in the process leading to retinal arteriolar vasodilation, either by hypercapnia, hypoxia or ischemia.^{111,112,127–129} Moreover, he proposed that this acidosis would provoke the release of a substance from the periarteriolar glial cells which in turn would act on the smooth muscle cells of the arteriolar wall. This idea that retinal glia plays a central role in the mechanisms linking neuron function to blood flow was highly original at that time and recognized the anatomical disposition of the glia as cells interpositioning themselves between the neurons and retinal vasculature. Indeed, his working hypothesis that the retinal arteriolar tone might be controlled by factors, such as K⁺, lactate and NO released from the retinal tissue surrounding the arterioles was tested in the miniature pig.^{130–132} Of these factors, intraretinal lactate and NO, both of which can be synthesized from glucose in Müller glia, were found to either mediate acute hypoxia-induced vasodilation or basal retinal arteriolar tone (e.g. for review, see Pournaras et al¹³³).

Further experimental evidence supporting the role of extracellular lactate as a dynamic vasoactive signal was provided by studying freshly isolated rat retinal microvessels using a combination of patch-clamp, fluorescence imaging and time-lapse photography.¹³⁴ In that study, lactate exposure was associated with an intracellular rise of calcium in pericytes, cell contraction and lumen constriction when energy supplies were adequate. Hypoxia, on the other hand, switched lactate’s effect from vasoconstriction to

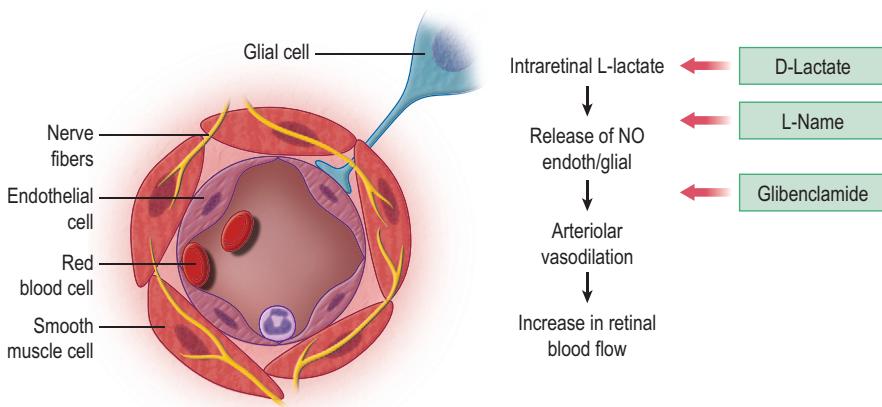

Figure 12.13 Components of the blood vessel wall hypothesized to play a role in arteriolar vasodilation and retinal blood flow. Endothelial cells and smooth muscle cells are two major components of retinal arteries and arterioles. The retinal glial cells send their endfoot processes out and over the vascular wall. The putative regulatory role of lactate is shown in the schema. Retinal arteriolar tone is controlled by the dynamic vasoactive signals lactate and NO. Intraretinal L-lactate, but not D-lactate, causes a pH-independent dilation of retinal arterioles. Juxta-arteriolar application, but not intravenous delivery, of L-NAME, an inhibitor of NO synthase, suppresses the vasodilatory effect of L-lactate, suggesting a glial rather than an endothelial source of NO. The L-lactate-induced vasodilatory response is mediated by stimulation of NO synthase and subsequent activation of smooth muscle guanylyl cyclase, leading to the opening of glibenclamide-sensitive K_{ATP} channels in smooth muscle. The regulation of arterial smooth muscle membrane potential through activation or inhibition of K^+ channel activity provides an important mechanism to dilate or constrict arteries or arterioles. Local changes in retinal arteriolar diameter in response to intraretinal vasoactive metabolites links the regulation of retinal blood flow to the metabolic needs of the surrounding retinal tissue.

vasorelaxation. This dual vasoactive capability may provide an efficient mechanism to match microvascular function to local metabolic needs.

In mini-pigs preretinal microinjections of L-lactate (0.5 mol/l, pH 2 and 7.4) close to the retinal arterioles produced a local, segmental and reversible arteriolar dilation while D-lactate had no effect. This effect was not pH-dependent nor mediated by prostaglandins. On the other hand, both systemic and sublingual administration of L-lactate (0.1 mol/l, pH 2) had no effect on retinal arteriolar diameter,¹³¹ suggesting that exposure to endothelial cells of the arterioles to lactate was not sufficient to trigger a vasomotor response. These authors concluded that to induce vasodilation, lactate had to reach the vascular smooth muscle cells from the vitreoretinal side, raising the hypothesis that intra-retinal lactate is a mediator of acute hypoxia-induced vasodilation.

Intravenous administration of sodium lactate has been reported to increase retinal blood flow at steady state¹³⁵ or during flicker stimulation.^{135,136} High-dose lactate reduced flicker response, whereas low-dose lactate increased it. This is most likely related to the fact that high-dose lactate leads to pronounced pre-vasodilation and a reduced flicker response, whereas low-dose lactate shifts the ratio of cytosolic free NADH to NAD⁺, resulting in increased flicker response. Both observations indicate that the ratio of cytosolic-free NADH to NAD⁺ plays a critical role in the maintenance of retinal vascular tone (also known as the "pseudohypoxia hypothesis").¹³⁵

Uptake of intravenous or intravitreal lactate by vascular endothelial cells or glial cells via monocarboxylate transporters¹³⁷⁻¹⁴⁰ causes retinal arteriolar dilation, predominantly via stimulation of NO synthase¹⁴¹ and subsequent activation of guanylate cyclase. In turn, guanylate cyclase/cGMP signaling triggers opening of K_{ATP} channels for vasodilation. This

process suggests that lactate either mediates the release of endothelial vasoactive substances (i.e. NO) or interferes with the metabolism and release of vasoactive substances by cells surrounding the arterioles (i.e. glial cells).

Juxta-arteriolar administration of L-lactate induced vasodilation of retinal arterioles in minipigs was also observed during continuous intravenous infusion of L-NAME, inhibiting endothelial-derived NO. In contrast, juxta-arteriolar L-NAME microinjection inhibiting NOS within the neuronal/glial cells significantly suppressed the vasodilatory effect of L-lactate. Those findings suggested that, *in vivo*, neuronal/glial cells are the major source of NO mediating the retinal arteriolar vasodilatation response to lactate in minipigs (Fig. 12.13).¹⁴²

11. Metabolic pathway leading to nitric oxide release

The diffusible and non-polar gas, nitrogen monoxide (NO) is synthesized from L-arginine by nitric oxide synthase (NOS). Until recently, NO has been generally recognized as an endothelium-derived releasing factor that controls vascular tone. Acutely isolated mammalian retinal Müller cells were shown to synthesize the NO precursor L-arginine from glucose as well as the key requisite amino acids – fumarate and aspartate – through which arginine is synthesized.^{132,143} Moreover, NOS has been shown to be localized to Müller cells using NADH diaphorase histochemistry and NOS immunocytochemistry.^{144,145} Hence, the conversion of L-arginine and oxygen into NO and L-citrulline through the enzymatic action of NOS highlights the role of glia in the generation and release of extravascular, intraretinal and periarteriolar NO, for either target neurons or in promoting

arteriolar vasodilation and/or controlling the basal dilating arteriolar tone.

Support for this hypothesis *in vivo* in the inner retina of the miniature pig is the finding that:

- (1) an increasing NO gradient from the vitreous towards the inner retina is measurable using an NO microprobe; this gradient is reversibly modulated by light; and light flicker stimulation of the dark-adapted retina induces a reversible increase of NO;¹³²
- (2) focal microinjection, but not intravenous infusion, of the NO-synthase inhibitor nitro-L-arginine leads to a segmental and reversible arteriolar vasoconstriction of 45%.¹³² Intravenous¹³⁵ and intravitreal administration of L-arginine also increases retinal blood flow, but it remains to be shown that this effect is related to an increase of NO production; and
- (3) *in vivo*, neuronal/glial cells are the major source of NO mediating the retinal arteriolar vasodilatation response to lactate in minipigs.¹⁴²

Local factors released by neurons and perivascular glial cells appear to be involved in the regulation of the vascular tone of the retinal resistance vessels through the interaction of myogenic and metabolic mechanisms. These factors may be ionic, molecular or related to arterial blood gas modifications. They affect the arteriolar tone and thus regulate the retinal vasomotor responses, relaxing or contracting the tone. Nitric oxide (NO) and prostacyclin (PGI₂) are probable relaxing factors, whereas the contracting factors include endothelin-1 (ET-1), angiotensin II, and cyclo-oxygenase (COX) products, such as thromboxane-A₂ (TXA₂) and prostaglandin H₂ (PGH₂).¹³³

What may be the role of extracellular lactate in the contraction and relaxation of the vessel wall according to the metabolic needs of the tissue? Lactate could either mediate the release of endothelial vasoactive substances (i.e. NO), or alternatively, lactate could interfere with the metabolism of cells surrounding the arterioles namely glial cells and neurons, leading either to release of vasoactive substances (NO, PGs) or activation of retinal endothelin receptors.

The close interaction between PG and NO metabolic pathways could insure that, when one process is inhibited, the other may rapidly compensate for the deficiency and maintain blood flow constant. However, whether this interaction is a major component of the control of vasomotion and autoregulation in the inner retina remains to be shown.

Impairment of structure and function of the neural tissue and endothelium is the cause of abnormal retinal blood flow regulation observed during the evolution of ischemic microangiopathies.¹³³ However, impaired metabolism may underlie alterations of both neural structure and function. This raises the question whether impaired glycolysis leads to a decrease in preretinal lactate, which in turn affects the NO pathway. Equally as important is the transport of glucose to neural cells which is compromised in ischemia and/or by alterations of the retinal–blood barrier, both of which are functional triggers leading to neovascularization and formation of macular edema.

In this regard, the expression of hypoxia-related vascular endothelial growth factor (VEGF), known as the major inducer of angiogenesis, correlates in a temporal and spatial

manner with the formation of neovessels and retinal–blood barrier alterations. It would be of future clinical importance to determine whether a restoration of blood flow in retinas with chronic ischemic microangiopathies is correlated with a decrease in VEGF expression. Insights into the multiple pathways controlling retinal blood flow, tissue oxygenation and metabolism should offer new therapeutic strategies to restore retinal blood flow and prevent damage observed during the evolution of ischemic microangiopathies.

The Function of the Retinal Pigment Epithelium

Olaf Strauss & Horst Helbig

Introduction

The retinal pigment epithelium (RPE) is a monolayer of pigmented cells located between the light-sensitive photoreceptor outer segments and the fenestrated endothelium of the choriocapillaris. On both sides, specialized extracellular matrices enable a close interaction of the RPE with its adjacent tissues. On the basolateral side the multilayered Bruch's membrane combines barrier function and selective transport matrix as part of the blood-retina barrier. On the apical side of the RPE, the interphotoreceptor matrix provides an interface for interaction between the photoreceptor outer segments and the RPE. In this interaction, the RPE forms a functional unit with the photoreceptors (Fig. 13.1).¹⁻³ In humans, every RPE cell is in interaction with a mean of 23 photoreceptors.⁴ The formation of that functional unit is already of importance during the embryonic development.⁵ The RPE and the neuronal retina depend on each other in the process of differentiation and maturation. Mutations in genes expressed in the RPE can lead to primary photoreceptor degeneration and mutations in genes expressed in photoreceptors can lead to primary RPE degenerations. In this functional unit the RPE fulfills a multitude of tasks which are essential for visual function. The failure of one of these functions leads to retinal degeneration.

Absorption of light

As a pigmented layer of cells the RPE covers the inner wall of the bulbus and absorbs scattered light to improve the optical quality. In the human eye light is focused by a lens onto the macula. This represents a high density of energy which is absorbed by the melanin granula of the RPE leading to an increase in the temperature of the RPE choroid complex.⁶ The heat is transported away by the bloodstream in the choriocapillaris. However, this functional arrangement bears the danger of photo-oxidative damage.^{7,8} The relative blood perfusion of the choriocapillaris is higher than that of the kidney.^{9,10} However, only small amounts of oxygen are extracted by the adjacent tissues and venous blood from the choroid still shows an oxygen saturation of more than 90 percent. Thus, there is an overflow of oxygen in combination with a large density of light energy. This

leads to a large production of reactive oxygen species. The RPE is protected by various lines of defense against this intoxication:¹¹ melanin of the melanosomes and the carotenoids lutein and zeaxanthin absorb light energy, ascorbate, α -tocopherol and β -carotene, and glutathione are non-enzymatic antioxidants and melanin itself can function as an anti-oxidant. This is supplemented by the cell's natural ability to repair damaged DNA, lipids and proteins.

Transepithelial transport

The RPE cells form a part of the blood-retina barrier. The RPE is by its electrophysiological parameters a tight epithelium: the paracellular resistance is at least ten times larger than that of the transcellular resistance.^{12,13} This barrier function is of great importance for the immune privilege of the eye (see below). Due to this tight barrier function, the complete exchange of molecules and ions between the bloodstream and the photoreceptor side relies on transepithelial transport through the RPE.

Transport from the blood side to the photoreceptor side

The transport from the blood to the photoreceptor side consists mainly of transport of nutrients such as glucose, $\omega 3$ fatty acids and retinal.

For glucose transport, the RPE contains an abundance of the glucose transporters GLUT1 and GLUT3 in both the apical and the basolateral membrane.^{14,15} GLUT3 mediates the basic transport whereas GLUT1 is responsible for an inducible glucose transport to adopt the glucose transport to different metabolic demands.

All-trans retinol is taken up from the bloodstream via a receptor-mediated process involving a serum-retinol-binding protein/transthyretin complex. Retinol is formed to all-trans retinyl ester and then enters directly the visual cycle (see below).

Docosahexaenoic acid (a polyunsaturated ω -3 fatty acid; 22:6 ω 3) is essential for the renewal process of the photoreceptor outer segments and cannot be synthesized by the photoreceptors.¹⁶⁻¹⁹ The compound is synthesized in the liver from the precursor linolenic acid and transported to

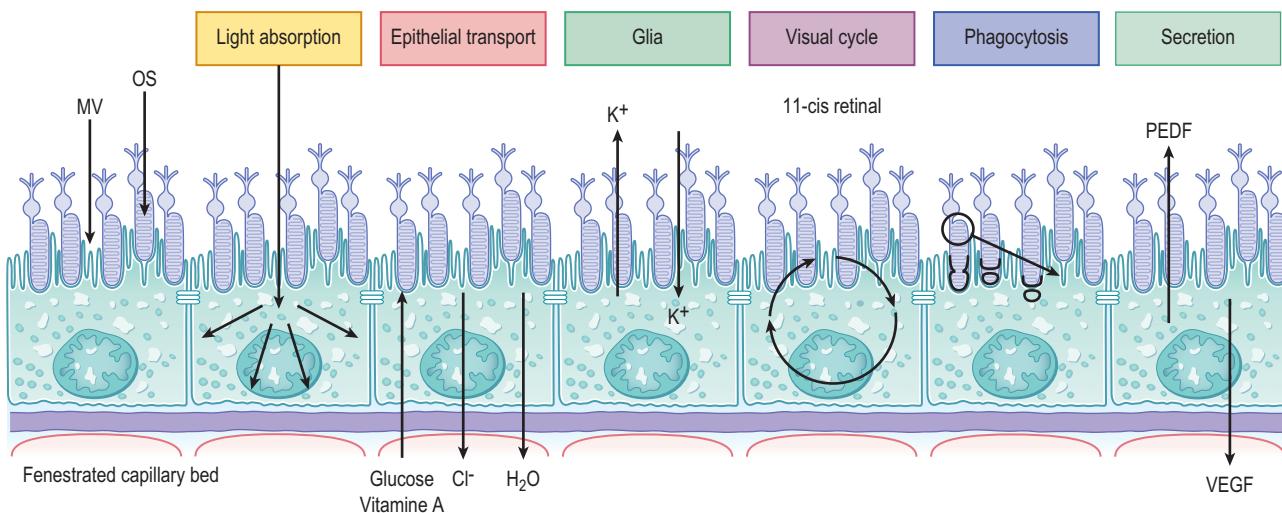

Figure 13.1 Summary of the different functions of the RPE by which a functional unit between photoreceptors is formed. (Modified from Strauss O: The retinal pigment epithelium in visual function, Physiol Rev 85:845–81, 2005. Used with permission.³)

the eye in the blood bound to plasma protein. The RPE preferentially takes up docosahexaenoic acid in concentration-dependent manner. Docosahexaenoic acid is incorporated into glycerolipids for synthesis and storage.

Transport from the retinal side to the blood side

The retina is the tissue with the highest density of cells. Neuronal cells show a high metabolic activity. This results in the production of large amounts of water and accumulation of lactic acid. Additional amounts of water are moved towards the retina by intraocular pressure from the vitreous. Since the RPE is a tight epithelium water cannot pass in the paracellular route. Water and lactic acid are eliminated from subretinal space by active transcellular transport by the RPE (see Box 13.1).²⁰

The transport of water is driven by an active transport of Cl⁻ from the retina to blood side (Fig. 13.2).^{12,21,22} It is energized by the apically located Na⁺/K⁺-ATPase which uses the energy of ATP to transport Na⁺ out of the cell in exchange with a transport of K⁺ to the cytosol of the RPE. The K⁺ ions recycle across the apical membrane through inward rectifier potassium channels which provide the large K⁺-conductance of the apical membrane. This recycling keeps the K⁺ gradient across the apical membrane small to support the activity of the Na⁺/K⁺-ATPase. In the apical membrane a Na⁺/2Cl⁻/K⁺-co-transporter uses the Na⁺ gradient across the apical membrane to transport K⁺ and Cl⁻ into the cytosol of the RPE. Since K⁺ moves back through inward rectifier channels to the subretinal space the Na⁺/2Cl⁻/K⁺-cotransporter accumulates Cl⁻ in the intracellular space of the RPE cells (40–60 mM).²³ This high Cl⁻ concentration provides a driving force for Cl⁻ to leave the cell. The basolateral membrane displays a large conductance for Cl⁻ through which Cl⁻ leaves the cell from intracellular space to the blood side. This is the last step of transepithelial Cl⁻ transport from subretinal space to the blood side resulting in a basolateral negative transepithelial potential between -6 to -15 mV.²⁰ ClC2 Cl⁻ channels seem to provide the major part of the

Box 13.1 Retinal Detachment

Retinal detachment is characterized by a separation of the retinal pigment epithelium from the photoreceptor layer of the neuroretina. This separation prevents close interaction between the two layers leading to reduction of visual function. After successful closure of the retinal break, preventing access of fluid from the vitreous to the subretinal space, remaining subretinal fluid reabsorbs spontaneously. Subretinal fluid is eliminated by the electrolyte and fluid pump of the retinal pigment epithelium.⁷¹

RPE cells usually do not divide, but under certain circumstances they may become activated to play a role in wound repair. These wound repair mechanisms can also have devastating consequences by creating so called "proliferative vitreoretinopathy" (PVR). RPE cells migrating through retinal tears in the vitreous cavity and on the retinal surface may metaplastically transform to myofibroblasts, creating contracting membranes which cause complicated tractive forms of retinal detachment that are difficult to repair.⁷²

basolateral Cl⁻ conductance.²⁴ Other channels providing basolateral Cl⁻ conductance are Cl⁻ channels linked to intracellular second-messenger systems. Cl⁻ transport can be increased by rises in intracellular free Ca²⁺²⁵ or by increases in cytosolic cAMP concentration²⁶ resulting from either activation of Ca²⁺-dependent Cl⁻ channels or cAMP-dependently regulated Cl⁻ channels.

The metabolic activity in the retina results in large subretinal concentrations of lactic acid which is transported away by the RPE.^{14,27} This transport requires a tight regulation of the intracellular pH.^{28,29} Lactic acid is removed from subretinal space by the monocarboxylate transporter 1 (MCT1)³⁰ which transports H⁺ in cotransport with lactic acid (can be as high as 19mM). This transport is driven by the activity of the Na⁺/H⁺-exchanger which eliminates H⁺ from cytosol of the RPE cells using the gradient for Na⁺ provided by the activity of the Na⁺/K⁺-ATPase.³¹ Across the basolateral membrane lactic acid leaves the cell via the activity of the monocarboxylate transporter 3 (MCT3) which is

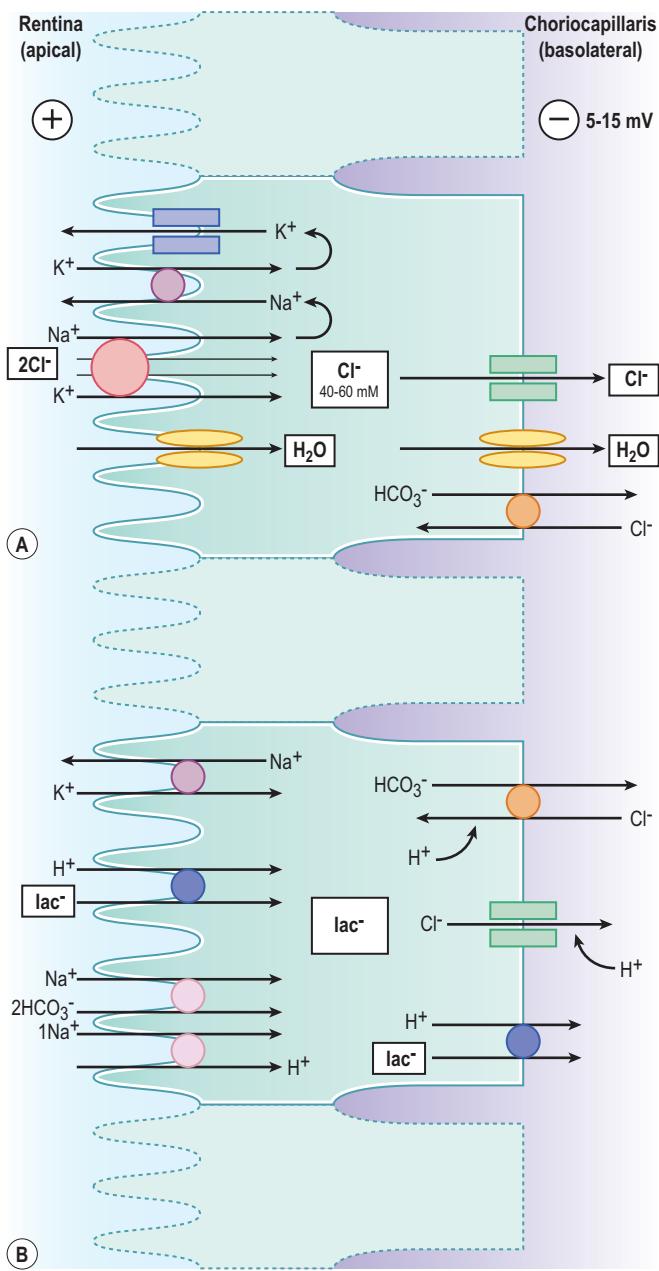

Figure 13.2 Transport of water and ions from subretinal space to blood side. (A) Using the energy of ATP hydrolysis the Na^+/K^+ -ATPase establishes a gradient for Na^+ which drives the uptake of Na^+ , K^+ and Cl^- by the $\text{Na}^+/\text{K}^+/2\text{Cl}^-$ cotransporter. K^+ recycles across the apical membrane through inward rectifier K^+ channels. The concerted transport activity of the three transport proteins results in the accumulation of Cl^- in the cytosol of the RPE. Cl^- leaves the cell through a variety of basolateral Cl^- channels. The net transport of Cl^- results in a basolateral negative transepithelial potential. The transport of Cl^- as osmolytes drives a transcellular transport of water through aquaporine water channels located in both the apical and the basolateral membrane. (B) Lactate is taken up from subretinal space via the activity of the MCT1 (monocarboxylate transporter-1) and accumulated in the cell. The driving force for this transport is large because the activity of retinal neurons produces large amounts of lactic acid (concentration in the subretinal space can be as high as 19 mM). Lactate leaves the cell through the basolateral membrane via the activity of the MCT3 transporter. The required pH regulation occurs at the apical membrane by the activity of sodium-dependent transporters: Na^+/H^+ exchanger and the $\text{Na}^+/\text{HCO}_3^-$ cotransporter which use the sodium gradient of the Na^+/K^+ -ATPase. At the basolateral membrane pH regulation occurs by the activity of Cl^- -dependent transport proteins which use the large intracellular Cl^- activity. In this part of the pH regulation a $\text{Cl}^-/\text{HCO}_3^-$ exchanger and the Cl^- channel CIC2 are involved.

an $\text{H}^+/\text{lactic acid}$ cotransporter too. Intracellular pH is stabilized by the transport of bicarbonate.^{28,29} HCO_3^- is transported into the cell across the apical membrane by the $\text{Na}^+/\text{HCO}_3^-$ cotransporter which uses the Na^+ gradient established by the Na^+/K^+ -ATPase. HCO_3^- leaves the RPE cell across the basolateral membrane by the activity of the HCO_3^- exchanger.³²

Production of metabolic water and accumulation of lactic acid are linked to each other. Therefore, transport of water and pH regulation are also coupled.²⁷ An increase in the transport of lactic acid leads to intracellular acidification which inhibits the transport activity of the $\text{Cl}^-/\text{HCO}_3^-$ exchanger. Since the $\text{Cl}^-/\text{HCO}_3^-$ exchanger transports Cl^- in the opposite direction to the Cl^- channels the exchanger decreases the Cl^- transport efficiency in resting conditions. The inhibition of the HCO_3^- exchanger, thus, increases the transepithelial transport of Cl^- and water. This is further increased by the CIC2 channels which are activated by a decrease in extracellular pH. Extracellular acidification would result from the increased transport of lactic acid by the MCT3 in the basolateral membrane.

Capacitative compensation of fast changes in the ion composition in the subretinal space

In the dark cGMP-dependent cation channels in the photoreceptor outer segments generate an inward current of Na^+ and Ca^{2+} which is counterbalanced by a K^+ outward current at the inner segments. In the light, cGMP-dependent cation channels close and the K^+ current is decreased resulting in a decrease of the K^+ -concentration in the subretinal space from 5 to 2 mM. The decrease of the Na^+ conductance in the outer segments leads to an increase in the subretinal Na^+ concentration. Furthermore, illumination of the retina results in an increase in the subretinal volume. Both changes are compensated for in the moment when they occur by modulation of the ion transport by the RPE.^{2,33-36}

Both, compensation for changes in the K^+ concentration and in extracellular volume are linked to the potassium transport.²⁰ The apical membrane of the RPE displays a large K^+ conductance. Decrease in the subretinal K^+ concentration leads to hyperpolarization of the apical membrane which corresponds to the c-wave in the electroretinogram. The decrease in the potassium concentration decreases the activity of the $\text{Na}^+/\text{K}^+/2\text{Cl}^-$ cotransporter which subsequently decreases the intracellular Cl^- activity and hyperpolarizes the basolateral membrane.³⁷ In the electroretinogram this can be seen as the delayed hyperpolarization. The hyperpolarization of the apical membrane activates inward rectifier K^+ channels which generate an efflux of K^+ into the subretinal space to compensate for the light-induced decrease in the subretinal K^+ concentration. At the same time the apical hyperpolarization decreases the activity of the $\text{Na}^+/\text{HCO}_3^-$ cotransporter which is an electrogenic transporter by its stoichiometry. The subsequent intracellular acidification increases the transepithelial Cl^- and water transport as described above.

The light-induced increase in subretinal Na^+ concentration is compensated for by the activity of the $\text{Na}^+/\text{K}^+/2\text{Cl}^-$ cotransporter and by the Na^+/H^+ exchanger.^{38,39} The Na^+/K^+ -ATPase seem to uptake Na^+ to compensate for the increase

in the subretinal Na^+ concentration during the transition from light to dark. It is believed that this task is the reason for its localization in the apical membrane of the RPE.

Visual cycle

Vision starts in photoreceptor outer segments with absorption of a photon by the chromophore of rhodopsin, 11-*cis* retinal, which undergoes a conformational change from 11-*cis* retinal to all-*trans* retinal. For the absorption of the next photon, rhodopsin replaces all-*trans* retinal to a new 11-*cis* retinal. To maintain visual function, a re-isomerization of all-*trans* to 11-*cis* retinal takes place in the RPE (Fig. 13.3).^{1,40–43} All-*trans* retinal leaves the disc membrane as N-retinylidine-phosphatidylethanolamine (N-retinylidine-PE) by the transport activity of the ABC (ATP-binding cassette protein) transporter ABCR4. Released from N-retinylidine-PE, all-*trans* retinal is reduced to all-*trans* retinol by RDH (all-*trans* retinol dehydrogenase), leaves the photoreceptor outer segments into subretinal space, is loaded onto the IRPB.

(interphotoreceptor matrix retinal binding protein) and transported to the RPE.⁴⁴ In the cytosol of the RPE it binds to the CRBP (cellular retinol binding protein) as entry into a reaction cascade catalyzed by a protein complex composed of LRAT (lecithin:retinol transferase), RPE65 (RPE specific protein 65 kDa, function as isomerase⁴⁵) and 11cRDH (11-*cis*-retinol dehydrogenase or RDH5) which performs the re-isomerization. After re-isomerization 11-*cis* retinal loaded to CRALBP (cellular retinaldehyde binding protein), leaves the cell and is transported back to photoreceptors by IRBP. This pathway accounts for the re-isomerization of retinal from rods. Cones might have an additional secondary pathway involving Müller cells.

Since the visual cycle maintains the excitability of the photoreceptors (see Box 13.2) it needs to be adapted to the different photoreceptor activities between light and darkness.⁴⁶ In the light there is a fast turnover of retinal whereas in the dark the turnover occurs much slower. Retinal which is not needed in the state of a slower turnover must be quickly available for the transition from darkness to light and vice versa. The different retinal binding proteins represent

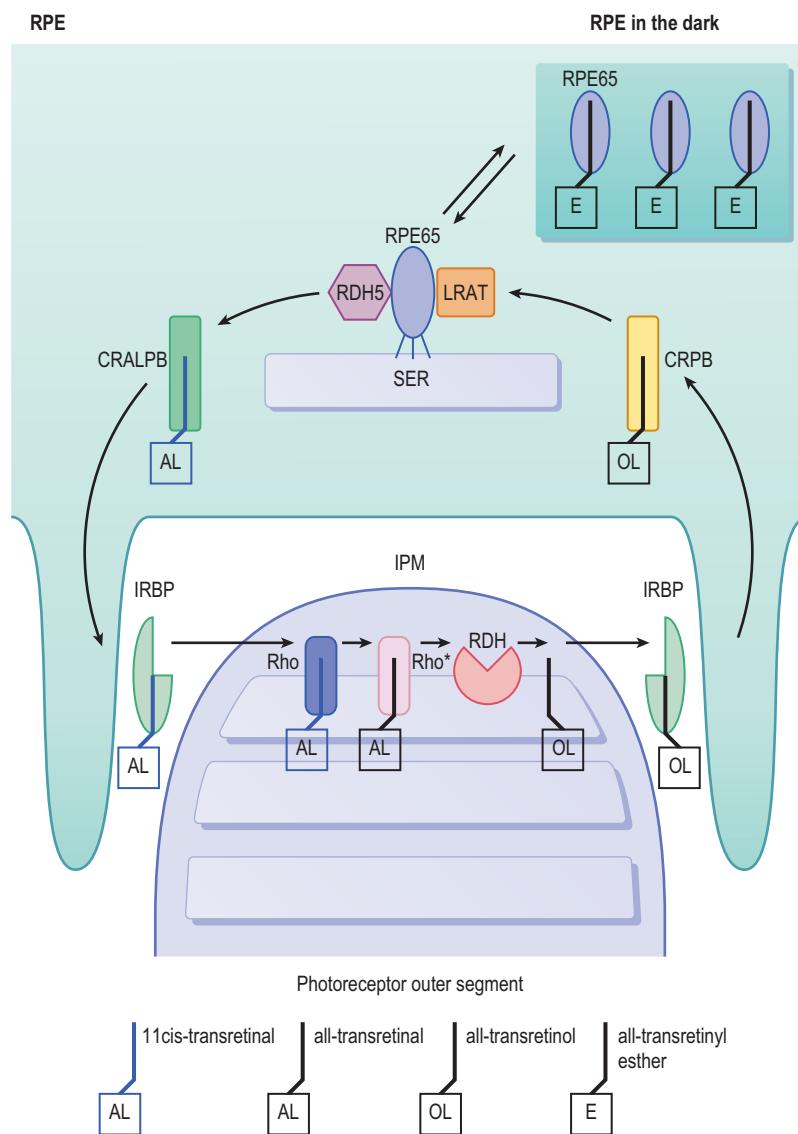

Figure 13.3 Cycle of retinal (visual cycle). The process of vision is started by the conformational change of the chromophore of rhodopsin from 11-*cis* retinal to all-*trans* retinal. The first step into this cycle is the reduction of all-*trans* retinal into all-*trans* retinol. all-*trans* retinol leaves the photoreceptor and binds to IRPB and is transported to the RPE. Inside the RPE all-*trans* retinol binds to CRBP and enters with this step the re-isomerization pathway. The reaction is catalyzed by a protein complex consisting of LRAT, RPE65 and RDH5. The reaction product, 11-*cis* retinal binds to CRALBP, leaves the cell where it binds to IRPB again to be transported to the photoreceptors. RPE65 modulation adapts this cycle to different light intensities. In the light it is palmitoylated and membrane bound with isomerase function. In the dark it is freely diffusible in the cytosol and serves as retinal pool when the visual cycle has a lower turn-over rate (CRBP = cellular retinol binding protein; CRALBP = cellular retinaldehyde binding protein; IPM = interphotoreceptor matrix; IRPB = interstitial retinal binding protein; LRAT = lecithin retinol acyltransferase; RDH = retinol dehydrogenase; RPE 65 = retinal pigment epithelium specific protein 65 kDa; RDH5 = 11-*cis* retinol dehydrogenase; Rho = rhodopsin; SER = smooth endoplasmic reticulum).

Box 13.2 Diseases Caused by Genetic Defects in the RPE

The regeneration of the visual pigment in the RPE involves a complex cascade of steps and a variety of molecules. Mutations in these molecules may cause retinal diseases. Mutations in RPE65 can cause severe congenital blinding disease called Leber's congenital amaurosis (LCA). Different mutations within the ABCR gene may cause Stargardt's macular dystrophy, cone-rod-dystrophy or recessive retinitis pigmentosa. Mutations in the RLBP1 gene and its product CRALBP are found in autosomal recessive retinitis punctata albescens, a tapetoretinal degeneration.⁷⁹⁻⁸¹

Clinically these diseases manifest with different degrees of visual loss ranging from congenital blindness (LCA), night blindness with progressive loss of the peripheral visual field, and finally blindness at an adult age (retinitis pigmentosa), to slow loss of central vision with peripheral visual field remaining intact throughout life (Stargardt's disease).⁷⁹⁻⁸¹ Gene therapy for defective RPE65 has been recently successfully performed in dogs and first attempts have been made in humans.⁸²

connected pools for retinal. In the transition from darkness to light IRPB represent the first pool which delivers retinal.⁴⁴ This pool cannot be depleted because it refills retinal from the pool of CRALBP proteins. CRALBP in turn can recruit retinal from RPE65. Thus, with increasing light intensity retinal can be recruited from the different pools and in the transition from light to darkness retinal can be stored away. Of importance are IRPB which can carry in the dark larger amounts of retinal than in the light. Another key function is the modulation of the RPE65 function.⁴⁵ In the dark RPE65 is water soluble and freely diffusible in the cytosol. With this configuration RPE65 functions as a retinal store. In the light RPE65 is palmitoylated and bound to intracellular membranes. In this configuration, RPE65 predominantly catalyze the re-isomerization of all-trans retinol to 11-cis retinol.

Phagocytosis of photoreceptor outer segments

The focus of a large density of light energy onto the retina and increased formation of reactive oxygen species by photo-oxidation constantly exposes photoreceptor outer segments to toxic compounds. This leads to destruction of the photoreceptor outer segments (POS). In order to maintain the excitability of the photoreceptors, outer segments are newly built at the connecting cilium from the inner segments.^{48,49} The destroyed tips of the POS are shed and phagocytosed by the RPE.⁵⁰⁻⁵² The process of shedding and phagocytosis must be tightly coordinated to maintain the proper length of the outer segments. On the other hand the tight coordination ensures the efficient degradation of the internalized POS (see Box 13.3). The process of regeneration is regulated in a circadian manner.⁵³⁻⁵⁶ With the onset of light in the morning the phagocytic activity is triggered and maintains a peak for 1–2 hours. Every 11 days a whole length of a photoreceptor outer segment is renewed.

Three receptors are involved in the process of phagocytosis (Fig. 13.4). Binding occurs via α_5 -integrins.⁵⁶ This binding

Box 13.3 Age-related Maculopathy (ARM)

RPE cells must ingest and degrade rod outer segment material amounting to 7 percent of RPE cell volume every day. This is an enormous burden for a non-dividing cell. As a consequence, lipofuscin accumulates in RPE cells with age. In addition, Bruch's membrane thickens from approximately 2 μm at birth to 6 μm with age. Oxidative stress (light, smoking, low levels of antioxidant vitamins) will increase lipofuscin accumulation as well as thickening of the extracellular matrix.⁷³

It is assumed that these age-related changes plus additional changes will lead to significantly impaired RPE-function in genetically susceptible patients predisposed to age-related macular degeneration (AMD).⁷³ Gene loci associated with AMD include complement factor H, complement C2 and C3, as well as LOC387715.^{74,75} Toll-like receptor 3 has been recently found to be associated with geographic atrophy.⁷⁶ These genetic risk factors and the finding that inflammatory molecules are found in drusen deposition led to the assumption that inflammation plays an important role in ARM pathophysiology.

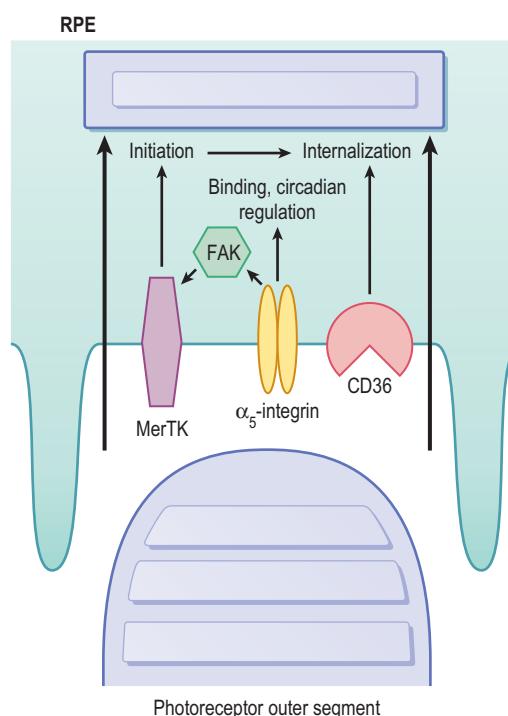

Figure 13.4 Phagocytosis of the photoreceptor outer membranes.

With onset of light destroyed tips of the photoreceptor outer segments are shed from the photoreceptors and phagocytosed by the RPE. The binding and circadian regulation occurs via α_5 -integrin which enables the initiation of the cascade which regulates the phagocytosis. This cascade is initiated by the activation of the MerTK receptor. The internalization of the shed photoreceptor outer segments is permitted by the activity CD36 (α_5 -integrin = vitronectin binding integrin; CD36 = macrophage phagocytosis receptor; FAK = focal adhesion kinase; MerTK = c-mer tyrosinekinase receptor).

initiates a signal cascade in the RPE involving the activation of focal adhesion kinase (FAK).⁵⁷ This process serves two functions. One leads to phosphorylation of another receptor which is involved in the regulation of phagocytosis, MerTK (c-mer tyrosine kinase). The second function leads to the circadian regulation of phagocytosis. MerTK is a receptor tyrosine kinase which triggers the process of internalization of POS^{58–60} after binding to $\alpha 5$ -integrin. The downstream cascade initiated after activation of MerTK involves the generation of inositol-1,4,5-trisphosphate and an increase of cytosolic free Ca^{2+} as second-messenger. The third receptor, CD36, is important for the process of internalization.⁶¹

Secretion

The RPE is capable of secreting a large variety of growth factors, cytokines or immune modulators.^{62,63} This function serves to maintain the structural integrity of photoreceptors,⁶⁴ to maintain the fenestrated structure of the endothelium of the choriocapillaris and to actively interact with the immune system³ (Fig. 13.5). The intracellular regulation of the secretion involves voltage-dependent L-type Ca^{2+} channels of the neuroendocrine subtype (Cav1.3) which are regulated by tyrosine kinase. With this regulation the secretion is linked to the influence of growth-factor receptors which mainly act via activation of tyrosine kinase.

Structural integrity of neighboring tissues

For the maintenance of structural integrity of photoreceptors the RPE secretes PEDF (pigment epithelium-derived factor; protects against hypoxia- and glutamate induced apoptosis), CNTF (ciliary neurotrophic factor; protects against photoreceptor cell death) and members of the fibroblast growth factor family. To stabilize the choroidal endothelium the RPE secretes and VEGF (vascular endothelial growth factor) and tissue inhibitors of matrix metalloproteases (TIMP) (see Box 13.4). The latter protein stabilizes the extracellular

matrix and prevents neovascularization. Basically, the regulation of secretion is embedded into a network of paracrine and autocrine stimulation.^{65,66} To coordinate the secretion with the neighboring tissues, the RPE is equipped with receptors which are activated by factors as such IGF-1 (insulin-like growth factor-1), TNF α (tumor necrosis factor- α), VEGF or glutamate. The secretion of ATP by the RPE seems to be of importance for an autocrine regulation of phagocytosis.^{67,68}

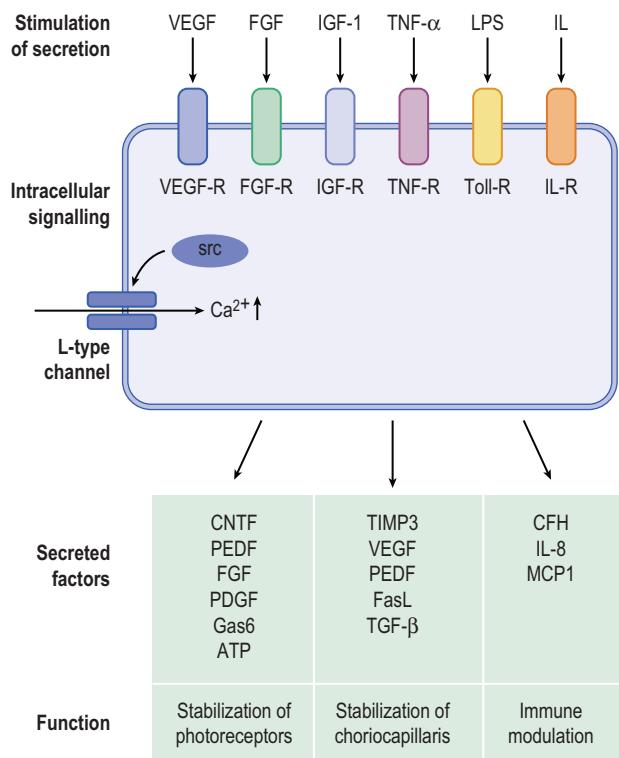

Figure 13.5 Secretion by the RPE. The secretion of different factors serves to maintain the structural integrity of the neighboring tissues and to modulate the immune system which helps to establish the immune privilege of the eye. To establish communication between the RPE and the according tissues the RPE is equipped with a large variety of receptors. The secretion itself is mainly regulated by voltage-dependent Ca^{2+} channels of the neuroendocrine subtype.⁶³ This Ca^{2+} channel is regulated by src-kinase which activated by different receptors of mediators leading to higher secretion rates. This illustration shows the major receptor types. From each different group several different receptors are expressed (e.g. VEGF-R includes VEGFR-1, VEGFR-2, VEGFR-3). The factors indicated represent the major family (e.g. VEGF includes VEGF-A, VEGF-C). Furthermore, as can be concluded from the figure, the secretion itself is not only regulated in a paracrine but also in an autocrine manner (Factors: ATP = adenosine triphosphate; CFH = complement factor H; CNTF = ciliary neurotrophic factor; FasL = CD95 apoptosis receptor ligand; FGF = fibroblast growth factor; Gas6 = growth arrest protein 6; IL = interleukin; IGF-1 = insulin-like growth factor-1; LPS = lipopolysaccharides; PEDF = pigment epithelium-derived factor; PDGF = platelet-derived growth factor; TIMP3 = tissue inhibitor of metallo matrix proteases; VEGF = vascular endothelial growth factor; TGF- β = transforming growth factor- β ; TNF- α = tumor necrosis factor alpha. Receptors: FGF-R = fibroblast growth factor receptor; IGF-R = insulin-like growth factor receptor; IL-R = interleukin receptor; MCP-1 = monocyte chemotactic protein 1; TNF-R = tumor necrosis factor receptor; Toll-R = toll-like receptors; VEGF-R = vascular endothelial growth factor receptor. Intracellular signaling: L-type channel = voltage-dependent L-type Ca^{2+} channel; src = src-type intracellular tyrosine kinase).

Box 13.4 Advanced Age-related Macular Degeneration (AMD)

In the development of age-related maculopathy (ARM), degenerative changes in RPE-cells, extracellular matrix and possibly choriocapillaries probably lead to malnutrition of photoreceptors and RPE-cells. Two different types of responses to this malnutrition lead to the two forms of advanced AMD: neovascular and atrophic.

The atrophic form ("geographic atrophy") is characterized by insufficient production of survival factors by damaged RPE cells, leading to apoptosis of the functional complex formed by choriocapillaries, RPE and photoreceptors.⁷⁷

In the neovascular type of AMD RPE-cells and possibly photoreceptors produce excess angiogenic factors, especially vascular endothelial growth factor (VEGF). This stimulates outgrowth of new capillaries from the choroid (choroidal neovascularization, CNV) through irregularities in Bruch's membrane under the RPE (occult CNV) or through gaps in the RPE under the neuroretina (classic CNV).⁷⁷ Clinically antagonists of VEGF are injected into the eye in exudative AMD, often stabilizing or even improving vision.⁷⁸

Box 13.5 Clinical Role of Immune Privilege

The immune privilege of the inner eye is believed to represent a specific modulation of the cellular immune response, down-regulating defence mechanisms, which would lead to destruction of surrounding cells ("innocent bystander destruction").⁷⁰ This phenomenon can be used clinically for transplantation of RPE cells in cases of macular degenerations. Functional results have been disappointing so far, however, significant inflammation or graft rejection has not been observed.⁸³ For retinal gene therapy viral vectors with the new gene are injected in the subretinal space. For this approach the immune privilege is helpful, since there must be no significant immune reaction after injecting viral antigen into the subretinal space.⁸⁴

Immune privilege of the eye

The inner eye represents an immune privileged space.^{69,70} This is enabled on one hand by the barrier function of the RPE. On the other hand the RPE is able to actively participate in the modulation of the immune system by secretion.⁶⁶ The RPE expresses a large variety of membrane receptors which coordinate the regulation of the immune system such as MHC receptors, toll-like receptors and receptors for cytokines which are involved in immune signaling such as receptors for TNF α or interleukins. Furthermore, the RPE is able to secrete a variety of immune modulatory factors such as TGF- β transforming growth receptor- β , members of the interleukin family or factors of the complement systems, for example factor H (see Box 13.3 and 13.5).

Functions of the Orbit and Eyelids

Gregory J. Griepentrog & Mark J. Lucarelli

Introduction

The cranium protects the brain and provides scaffolding for facial structures. During primate evolution, the orbits were enlarged and reoriented towards the front of the face.¹ This, along with the gradual flattening of the face, allowed for improved binocular vision due to overlapping visual fields. Along with morphologic skull changes, facial mimetic musculature evolved in primates as a means of close-proximity non-vocal communication.² It is in this context that the function of the eyelids to protect, lubricate, and cleanse the ocular surface, is most fully appreciated. This chapter will examine anatomy of the eyelids, orbits, and related facial structures.

Orbital anatomy and function

Orbit osteology

Derived from cranial neural crest cells, the bony orbit consists of seven individual bones combining into four walls that surround the globe, extraocular muscles, nerves, fat, and blood vessels. The orbital bones include the sphenoid (greater and lesser wings), frontal, ethmoid, maxillary, zygomatic, palatine, and lacrimal bones. Posteriorly approaching the apex, this four-sided pyramid becomes three-sided with the gradual merger of the medial wall and orbital floor after the floor is cut off by the inferior orbital fissure. The adult orbit has a volume of 25–30 mL, with the globe filling approximately 7 mL or 25% of the space.³ The orbit depth as measured from the center of the orbital margin to the apex is approximately 45 mm. The widest diameter of the orbit occurs 1 cm behind the orbital rim. The lateral walls of the orbit are oriented 90 degrees from one another and run approximately 40–45 mm, while the medial walls are parallel to one another (Fig. 14.1). Due to this bony orientation, the eyes tend to diverge, and thus are tonically held in adduction by the medial rectus muscles to achieve ocular alignment.

The orbital rim provides a hard tissue shield to surround and protect the eye. It is a thick discontinuous spiral that begins medially at the anterior lacrimal (maxillary bone) crest and coils to end at the posterior lacrimal (lacrimal

bone) crest (Fig. 14.2). The lacrimal fossa, which contains the lacrimal excretory sac, lies between these two crests. Formed by the zygomatic bone and the zygomatic process of the frontal bone, the lateral orbital rim is the strongest and thickest portion of the rim. While the posteriorly directed concavity of the lateral orbital rim allows for a wide visual field, it also makes the eye prone to injury from objects approaching from a lateral direction. The superior orbital rim is formed by the frontal bone. Medially, the superior rim contains the supraorbital notch through which the supraorbital nerve and artery pass. In some individuals, a supraorbital foramen replaces the notch.⁴ The infraorbital nerve and artery exit through the infraorbital foramen approximately 4–6 mm below the inferior orbital rim medially.

The orbital roof is comprised of the orbital plate of the frontal bone along with a minor contribution from the lesser wing of the sphenoid posteriorly. The frontal bone is the strongest component of the craniofacial skeleton, withstanding between 800 and 2200 pounds of force before fracturing.⁵ This is equivalent to the force achieved in a frontal collision at 30 mph for an unrestrained adult passenger. Orbital roof “blow-in” fractures may be associated with a number of ocular and neurologic injuries including proptosis, ptosis, optic nerve contusion, orbital hematoma, as well as contusive and hemorrhagic injuries to the ipsilateral frontal and parietal lobes.⁶ Important bony landmarks of the orbital roof include the lacrimal gland fossa temporally and another small depression 3–5 mm behind the orbital rim anteromedially known as the trochlear fossa. Here resides the fibrocartilaginous trochlea through which the superior oblique tendon passes.

The frontal sinus begins to develop between 1 and 2 years of age through invagination of the frontal bone by frontoethmoidal air cells. The filling of air or pneumatization of the sinus begins at about 5–8 years old and continues into adulthood.⁷ Therefore, there is a relative absence of frontal sinusitis in very young children. Yet, orbital complications due to frontal sinusitis such as orbital cellulitis and abscess most often occur between the ages of 5 and 10 years.⁸ It has been hypothesized that direct extension through the relatively thin orbital roof in children or congenital bony dehiscences (gaps) posterior to the trochlear and supraorbital notch may account for these findings.⁹

The lateral wall is comprised of the zygomatic bone anteriorly and the greater wing of the sphenoid posteriorly. The vertically oriented zygomaticosphenoidal suture represents the thinnest portion of the lateral wall, and is a convenient breaking point during lateral orbitotomy. The posterior boundaries of the wall are marked by the superior and inferior orbital fissures. The frontosphenoidal suture forms the boundary between the lateral wall and orbital roof. About one-third of individuals have a meningeal foramen just superior to this suture which transmits the recurrent meningeal artery (a branch of the external carotid system) to form

an anastomosis with the lacrimal artery (a branch of the internal carotid system). This collateral system has potential importance if the primary internal carotid vascular supply becomes compromised. An important bony prominence of the lateral wall is Whitnall's lateral tubercle, a small rounded protuberance of the zygomatic bone 3–4 mm inside of the lateral orbital wall and approximately 11 mm below the frontozygomatic suture.^{10,11}

Fractures to the lateral wall may result from blunt trauma to the zygomatic bone and lateral orbital rim. Due to its multiple bony articulations, fractures of the zygoma may disrupt the wider anatomy and are often referred to as zygomaticomaxillary complex fractures or ZMC fractures (Fig. 14.3). Clinical signs include lateral canthal dystopia (inferior displacement of the lateral canthal angle), cheek depression and trismus (difficulty opening the mouth owing to spasm of the masticatory muscles or impingement of the coronoid process of the mandible). Hypoesthesia may be noted at the lateral midface from disrupted branches of the zygomaticotemporal and zygomaticofacial neurovascular bundles (V1 branches traveling through the zygomatic bone), as well as in the distribution of the infraorbital nerve (V2 branch).

The orbital floor consists of the maxillary bone, the zygoma anterolaterally, and the palatine bone posteriorly. It is triangular in shape and extends from the maxillary-ethmoid buttress (the relatively dense bone strut at the union of the orbital floor and medial wall) to the inferior orbital fissure. The shortest of the walls, it travels posteriorly from the rim 35–40 mm and ends before the orbital apex at the pterygopalatine fossa. The infraorbital neurovascular bundle passes in the infraorbital groove and infraorbital canal of the orbital floor as it travels towards infraorbital foramen. The floor remains strong laterally, but thins posteromedially with expansion of the maxillary sinus. This thinned maxillary bone is where the floor usually fractures during trauma and is also a convenient site to initiate an inferior wall decompression. The infraorbital nerve is often contused during an orbital floor fracture but is rarely severed,

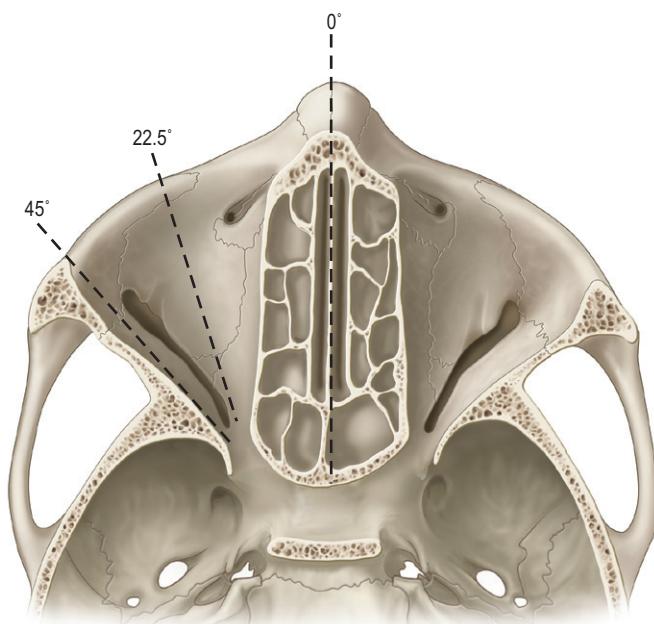

Figure 14.1 Horizontal section through orbits. Medial walls are nearly parallel, and lateral walls diverge 45 degrees from midline (© Virginia Cantarella).

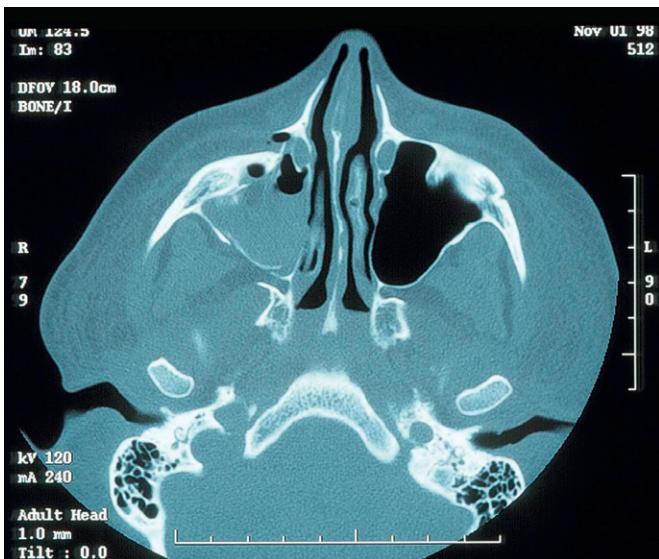

Figure 14.3 Axial section of CT scan revealing a right zygomatic fracture as part of a zygomaticomaxillary complex (ZMC) fracture.

thus, initial hypoesthesia in the V2 distribution will commonly resolve over several months' time.

The medial wall consists of the maxillary, lacrimal and ethmoid bones, as well as the lesser wing of the sphenoid bone. The two medial walls are parallel to one another and extend 45–50 mm from the anterior lacrimal crest to the orbital apex. The lamina papyracea of the ethmoid bone is an extremely thin portion of bone that has a honeycombed structure. Giving support to the medial wall, the multiple bullae that form this structure develop secondarily to pneumatization of the ethmoid bone. This helps to explain why the medial wall fractures less often than the thicker orbital floor. Landmarks important to the orbital surgeon include the anterior and posterior ethmoidal foramina that reside at the frontoethmoidal suture and convey respective branches of the ophthalmic artery and nasociliary nerve. The anterior ethmoidal foramen is located approximately 24 mm posterior to the anterior lacrimal crest and the posterior ethmoidal foramen 36 mm posterior to the rim. The orbital foramen is located approximately 6 mm behind the posterior ethmoidal foramen. The frontoethmoidal suture may also be used surgically to approximate the level of the floor of the anterior cranial fossa.

Providing support for the inferomedial wall and helping to maintain globe position is the thickened region of bone known as the inferomedial strut. The strut is constructed using elements of multiple orbital and facial bones including the maxillary bone, ethmoid bone, and palatine bone posteriorly.^{12,13} Preservation of the anterior portion of the inferomedial strut during orbital decompression has been shown to reduce the incidence of post-operative globe dystopia.¹⁴

As previously mentioned, the lacrimal sac fossa lies between the anterior (maxillary bone) crest and posterior (lacrimal bone) crest of the orbital rim (Fig. 14.4). The relative contribution of these two bones may vary. The lacrimal bone at the lacrimal sac fossa has a mean thickness of 106 µm, which allows easy penetration during

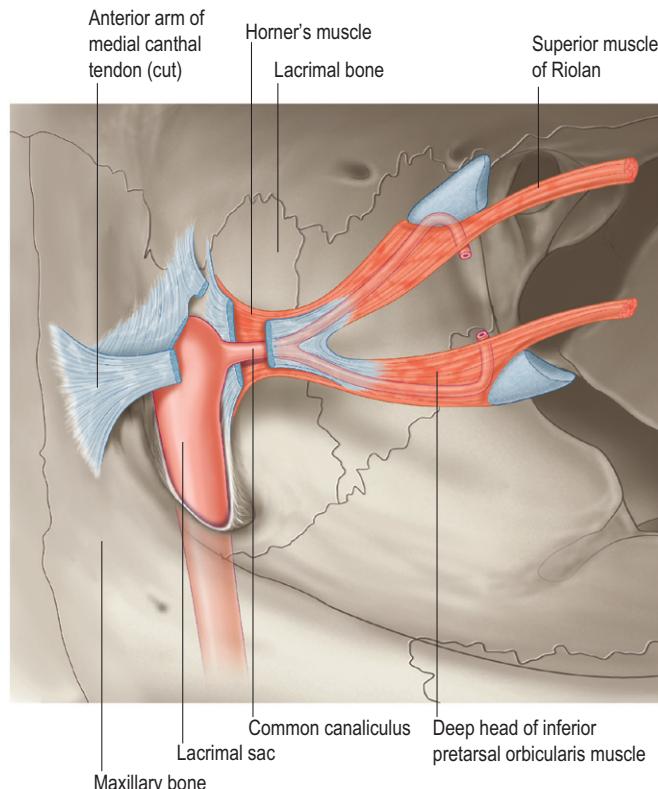

Figure 14.4 Lacrimal drainage system, superficial anatomy. (Modified from Dutton JJ. Atlas of clinical and surgical orbital anatomy. Philadelphia: WB Saunders, 1994.)

dacryocystorhinostomy surgery (surgical procedure to restore the normal flow of tears into the nose from the lacrimal sac by bypassing the nasolacrimal duct).¹⁵ The maxillary bone is considerably denser than the lacrimal bone, and may require the surgeon to create a more posterior osteotomy during dacryocystorhinostomy. The nasolacrimal canal directs the nasolacrimal duct to the inferior meatus of the nose under the inferior turbinate.

The orbital apex

Many important neural and vascular structures pass through the orbital apex including cranial nerves II through VI, the origins of all the extraocular muscles except the inferior oblique, and arterial and venous blood supplies (Fig. 14.5 and Box 14.1). Pathology in this crucial location of the orbit may lead to the orbital apex syndrome with characteristic hallmarks of visual loss from optic neuropathy and ophthalmoplegia.¹⁶

The optic foramen conveys the optic nerve and ophthalmic artery from the optic canal into the orbit. The canal is housed in the lesser wing of the sphenoid bone with a contribution from the inferomedial optic strut. It runs 8–10 mm in length and is 5–6 mm in diameter. The optic canal and foramen attain adult dimensions by 3 years and are symmetric in most persons. A canal/foramen that is larger in diameter by at least 1 mm than the contralateral side may be considered abnormal.

The superior orbital fissure is located just lateral to the optic canal. Approximately 20–22 mm in length, the fissure

Box 14.1 Orbital apex

- Passing through the optic foramen: optic nerve, ophthalmic artery, and sympathetic fibers
- Passing through the superior orbital fissure: oculomotor nerve, trochlear nerve, abducens nerve, the ophthalmic division of the trigeminal nerve (frontalis, lacrimal, and nasociliary nerves), sympathetic fibers, and the superior ophthalmic vein
- Passing through the annulus of Zinn: optic nerve, ophthalmic artery, oculomotor nerve, abducens nerve, nasociliary nerve, and sympathetic fibers
- Passing through the inferior orbital fissure: maxillary division of the trigeminal nerve, branches from the sphenopalatine ganglion, and the inferior ophthalmic vein

divides the lesser and greater wings of the sphenoid bone. The superior ophthalmic vein, as well as the lacrimal, trochlear, and frontal nerves, passes through the superolateral portion of the fissure outside the annulus of Zinn, a fibrous ring formed by the common origins of the rectus muscles. The annulus is further subdivided by the oculomotor foramen through which the superior and inferior divisions of the oculomotor nerve, the abducens nerve, the nasociliary nerve (a terminal sensory branch of the ophthalmic division of the trigeminal nerve), and sympathetic fibers all pass.^{17,18} Also passing through the annulus of Zinn are the optic nerve and ophthalmic artery. As the extraocular rectus muscles proceed forward to their insertions on the globe, they form a conoid enclosure known as the intraconal space. This compartment is useful radiologically (Fig. 14.6). Intraconal pathology of the fat, vessels, and optic

nerve-sheath complex may be distinguished from extraconal pathology of the lacrimal gland, bony orbit, and remaining extraconal fat.^{19,20}

The inferior orbital fissure divides the greater wing of the sphenoid laterally from the maxillary bone of the orbital floor inferomedially. The fissure measures approximately 20 mm in length. It communicates with the pterygopalatine fossa which rests behind the maxillary sinus. Traveling through the fissure are the maxillary division of the trigeminal nerve, branches from the sphenopalatine ganglion, and the inferior ophthalmic vein. Branching away from the fissure and entering the infraorbital groove and canal are the infraorbital (V2) and the terminal branch of the internal maxillary artery.

Orbital soft tissues

Periorbital fascia

The periorbital fascia is a single interconnecting network emanating from the periosteal lining of the orbital walls, globe (Tenon's capsule), and extraocular muscles (Figs 14.7 & 14.8).²¹ There are also check ligament extensions from the extraocular muscle fascia that attach to the bony orbit as well as sheaths that extend between the rectus muscles. The peri-orbita is firmly attached at the suture lines, foramina, fissures, arcus marginalis, and the posterior lacrimal crest.

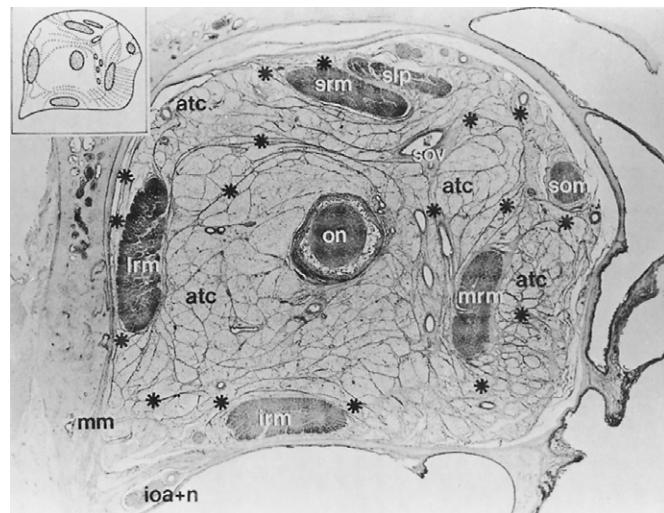

Figure 14.8 A view 1.4 mm from hind surface of eye. Vertical diameter, 2.4 cm; transversal diameter, 2.7 cm; magnification approximately 3.5x. Note artifacts in superior, medial, and inferolateral areas (*on*, optic nerve; *sov*, superior ophthalmic vein; *slp*, superior levator palpebrae muscle; *srm*, superior rectus muscle; *lrm*, lateral rectus muscle; *irm*, inferior rectus muscle; *mrm*, medial rectus muscle; *som*, superior oblique muscle; asterisks (*), connective tissue septa; *atc*, adipose tissue compartment; *ioa + n*, infraorbital artery and nerve; *mm*, Müller's muscle. (Reproduced from Kooreef L: Spatial aspect of orbital musculo-fibrous tissue in man: a new anatomical and histological approach, Amsterdam, 1976. Swets en Zeitlinger B.V.)

Elsewhere, it is loosely attached to the bone which creates a potential space for accumulation of blood, pus, or tumor growth. It is most firmly attached along the arcus marginalis. The orbital septum is a thin, multilayered extension of the periorbita and is the anterior soft tissue boundary of the orbit. It functions as a physical barrier to pathogens and contributes to the normal posterior position of the orbital fat pads. In the upper eyelid, the fibrous lamellae of the orbital septum gradually blends with those of the levator aponeurosis on average 3.4 mm above the superior tarsal border (with a range of 2–5 mm).²² In the lower eyelid, the septum inserts onto the inferior border of the tarsus after joining with the inferior retractors 4–5 mm below the tarsus.²³ Laterally the septum fuses with the lateral canthal tendon and attaches 2–3 mm posterior to the rim at the lateral orbital tubercle (Whitnall's tubercle). Medially the septum splits and inserts onto the anterior and posterior lacrimal crest. Finally, it is anchored anteriorly to the orbicularis muscle by multiple fibrous attachments.²⁴

Tenon's capsule, or fascia bulbi, is a fibroelastic membrane that extends anteriorly from the dural sheath to encircle the globe and fuse with the conjunctiva just behind the limbus. Posteriorly it separates orbital fat from the globe and muscles. Openings within the fascia allow passage of the extraocular muscles which are in turn surrounded by their own muscular fascia. Anteriorly the muscular fascia thickens and connects with the orbital wall to form the check ligament of the extraocular muscles, preventing overaction of the muscle from which they extend.²⁵ The strongest of these is the lateral check ligament that inserts on the lateral orbital tubercle, while the medial rectus check ligament inserts behind the posterior lacrimal crest.²⁶

Orbital fat

Orbital fat provides cushioned support for the globe and other intraocular structures. Eyelid fat pads are the anterior projections of the orbital fat. Changes in orbital fat appear to have a significant role in the development of thyroid-associated orbitopathy (TAO). Orbital fat and extraocular muscle volume expansion may result in soft tissue swelling, proptosis, lid retraction (with characteristic temporal flare), strabismus (usually due to muscle fibrosis), and compressive optic neuropathy.^{27,28} Fibroblasts residing within the orbital connective/adipose tissue are believed to be the targets of an autoimmune attack consisting of primarily T lymphocytes,²⁹ and there is ongoing research to isolate key autoantibodies.³⁰ Patients with a hyperthyroid state are not the only patients affected with TAO. Euthyroid patients may also develop TAO. There appears to be a shift in the phenotypes of peripheral blood lymphocytes in euthyroid patients with TAO when compared to normal controls which may permit an orbital immune reaction.³¹

Orbital nerves

Entering the orbit are the optic (cranial nerve II), oculomotor (cranial nerve III), trochlear (cranial nerve IV), abducens (cranial nerve VI), the first and second divisions of the trigeminal (cranial nerve V), parasympathetic, and sympathetic nerves. The trigeminal nerve will be discussed in the eyelid portion of this chapter while the extraocular muscles are discussed in Chapter 7.

Composed of approximately 1.2 million nerve fibers, the optic nerve is an extension of the central nervous system. It has supportive neuroglial cells and is surrounded by the three layers of the meninges: the dura mater, arachnoid layer, and pia mater. Cerebrospinal fluid flows freely within the space between the arachnoid and pia. The nerve arises from the ganglion cell layer of the retina. These axons converge at the optic nerve head which is approximately 1.5 mm in diameter. As the nerve exits the globe at the lamina cribrosa and enters the orbit, its diameter increases to 3.5 mm due to the addition of the myelin sheath. The intraorbital portion of the nerve runs approximately 25 mm, although the distance from the globe to the optic foramen is 18 mm.

This extra slack allows freedom of movement of the globe and a certain degree of proptosis. When excessively stretched, the nerve may exert tension on the globe – seen radiologically as “globe tenting” – which may result in vision loss due to compromise of the nerves’ vascular supply.³² The intracanalicular portion of the nerve is tethered within the bone, making it susceptible to damage from blunt trauma.^{33,34} The intracranial portion of the optic nerve runs approximately 15 mm just medial to the internal carotid artery ending at the optic chiasm.

Motor innervation of the orbit involves the oculomotor (cranial nerve III), trochlear (cranial nerve IV), and abducens nerves (cranial nerve VI) (Fig. 14.9). The oculomotor nerve innervates the superior, inferior, and medial recti, the inferior oblique, and the levator palpebrae superioris muscles. Additionally, parasympathetic fibers travel within the inferior division of the nerve. The nerve exits the brainstem medially and travels through the superolateral portion of the cavernous sinus while dividing into a superior and inferior division. Both branches enter the orbit through the oculomotor foramen within the annulus of Zinn. The superior branch enters the underside of the superior rectus, on its way to innervate the overlying levator palpebrae superioris muscle. The inferior branch of the oculomotor nerve travels beneath the optic nerve and supplies innervation to the medial and inferior rectus, as well as the inferior oblique.

Studies in both monkeys and man have revealed that parasympathetic fibers, issued from cells of the pterygopalatine ganglion, pass into the orbit.³⁵ Nilsson et al showed that parasympathetic fibers responsible for uveal vasodilation travel to the eye from the facial nerve via the pterygopalatine ganglion.³⁶ As previously mentioned, a small bundle of parasympathetic fibers destined for the ciliary ganglion travel within the inferior division of the oculomotor nerve. Included within this parasympathetic bundle are pupillomotor fibers. During orbital floor repair, damage to these fibers may result in post-operative mydriasis.³⁷

The trochlear nerve is the only cranial nerve to exit dorsally from the midbrain; crossing the midline to emerge adjacent to the superior cerebellar peduncle. It travels within the wall of the cavernous sinus and enters the orbit via the superior orbital fissure *outside* of the annulus of Zinn. It is

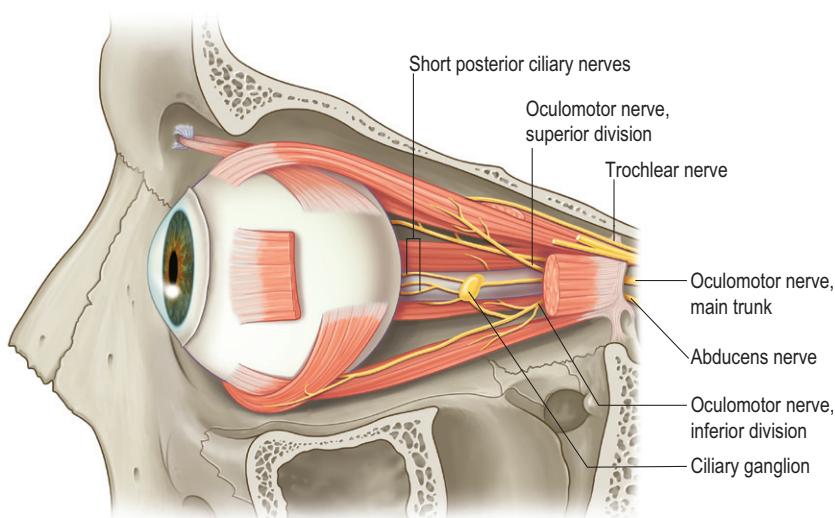

Figure 14.9 Lateral orbital view and major orbital motor nerves. (Adapted from: Dutton JJ. Atlas of Clinical and Surgical Orbital Anatomy. Philadelphia: WB Saunders; 1994.)

the only extraocular cranial nerve that travels extraconally within the orbit. It crosses medially over the origin of the superior rectus and levator palpebrae superioris, and enters the superior oblique muscle. The long intracranial course of the trochlear nerve makes it particularly vulnerable to closed head trauma.³⁸

The abducens nerve may exit between the pons and the medulla in one or multiple trunks.³⁹ The nerve ascends through the subarachnoid space, then climbs along the bony clivus before passing through Dorello's canal into the posterior cavernous sinus. Unlike the oculomotor and trochlear nerves, the abducens nerve is not located in the lateral wall of the cavernous sinus. Instead it travels within the body of the sinus with the internal carotid artery. It enters the orbit through the oculomotor foramen and inserts onto the inner surface of the lateral rectus at approximately one-third the distance from the muscle origin to its insertion.

Sympathetic fibers, originating in the superior cervical ganglion, travel along the internal carotid artery through the cavernous sinus, and into the orbit along the ophthalmic artery. Fibers have also been shown to travel with the abducens and ophthalmic (V1) division of the trigeminal nerve.¹⁷

While in the orbit, some of the sympathetic fibers pass through the ciliary ganglion without synapsing. Orbital sympathetics allow for pupillary dilation of the iris dilator muscle, function of the smooth muscle of the eyelid (Müller's muscle), and vasoconstriction.

Vascular anatomy

Arterial supply

The arterial supply to the orbit is an anastomotic network with contributions from the internal and external carotid circulation. Most of the arterial supply of the eye and orbit is provided through the ophthalmic artery; the first intracranial branch of the internal carotid artery (Fig. 14.10). The most important branch of the external carotid artery in regards to orbital supply is the internal maxillary artery.

The ophthalmic artery branches off from the internal carotid artery just before the latter artery exits the cavernous sinus. It travels with the optic nerve within the inferolateral portion of a common dural sheath, and gradually bends medially at which point branching of the artery occurs.^{40,41} There is a great deal of variability in the order of branching

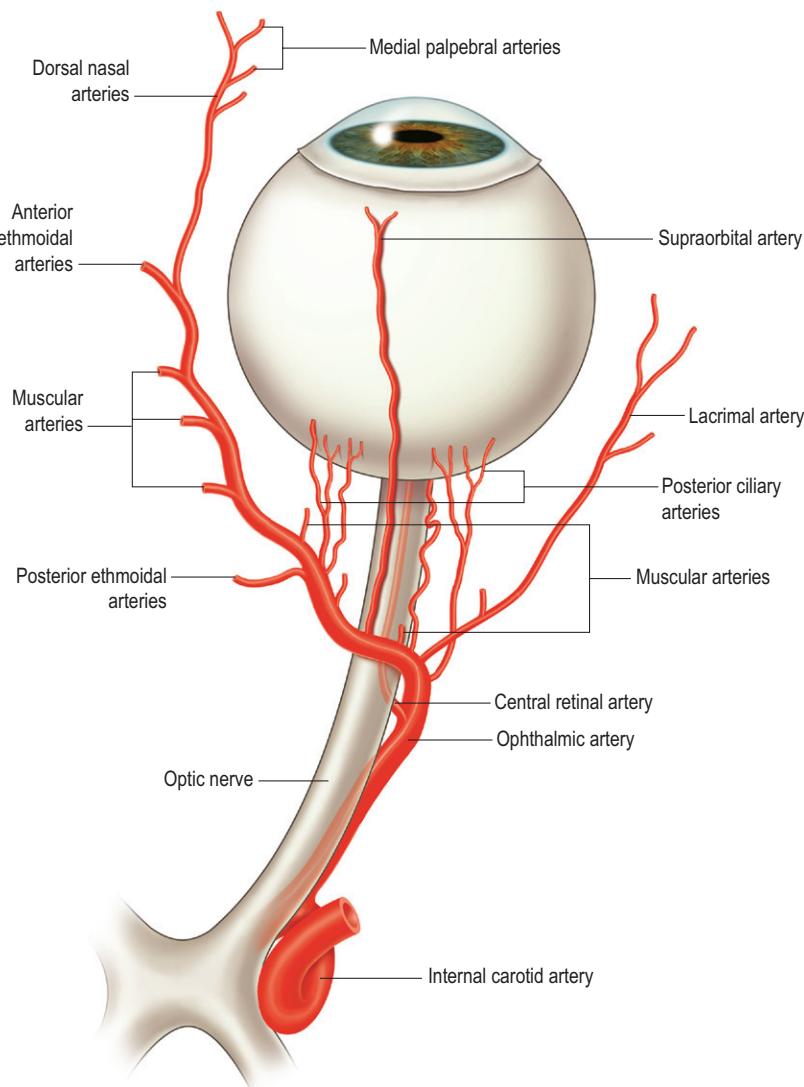

Figure 14.10 Typical branching pattern of the ophthalmic artery. (Adapted from: Lemke BN, Lucarelli MJ: Anatomy of the ocular adnexa, orbit, and related facial structures. In Nesi FA, Lisman RD, Levine MR [eds]: Smith's ophthalmic plastic and reconstructive surgery, ed 2, St. Louis, 1998, Mosby.)

vessels originating from the ophthalmic artery. In general, the first branch is the central retinal artery. Originating at the level of the orbital apex and eventually supplying the outer layers of the retina, the central retinal artery travels lateral or inferior to the optic nerve and penetrates the nerve at 5–16 mm posterior to the globe (average 10 mm).^{42,43} Also arising near the medial bend of the ophthalmic artery are the lateral and medial posterior ciliary arteries. Constituted of typically two or three branches, these arteries give rise to 15–20 short posterior ciliary arteries as well as the two long posterior ciliary arteries. The short posterior ciliary arteries supply the optic nerve head and choroid, while the long posterior ciliary arteries travel within scleral canals anteriorly to supply the ciliary muscle, anterior choroid, and iris.

Other intraorbital structures supplied by the ophthalmic artery include the extraocular muscles and lacrimal gland. There are two main muscular branches which supply the extraocular muscles: the medial and lateral branches. The medial muscular branch supplies the medial rectus, inferior rectus, and inferior oblique muscles, while the lateral branch supplies the levator palpebrae superioris, superior rectus, superior oblique, and lateral rectus muscles. The vessels run along the muscle belly or medial surface of the muscle. Each rectus muscle artery branches into two anterior ciliary arteries, except for the lateral rectus muscular artery, which terminates into one anterior ciliary artery. The anterior ciliary arteries anastomose with the long posterior ciliary arteries to supply the globe. Simultaneous surgery on three rectus muscles or two muscles in patients with poor vascular supply may result in anterior segment ischemia, characterized by corneal edema and a mild anterior uveitis.⁴⁴ The lacrimal artery travels superolaterally in the orbit to reach the posterior surface of the lacrimal gland. It also gives off the zygomaticotemporal, zygomaticofacial, and the lateral palpebral arterial branches. The latter branch supplies the lateral portion of the arcades of the upper and lower eyelids. Portions of the lacrimal artery anastomose with the middle meningeal artery through branches of the recurrent meningeal artery and temporal arteries.

The posterior and anterior ethmoidal arteries course medially from the ophthalmic artery. While traveling at the level of the frontoethmoidal suture, they exit the orbit through the posterior ethmoid foramen and anterior ethmoid foramen respectively. They supply the ethmoid and frontal sinus mucosa as well as the frontal dura.

The supraorbital artery comes off from a more distal portion of the ophthalmic, exits through the supraorbital foramen or notch, and supplies mainly the eyebrow, forehead, and the medial portion of the eyelids. The anterior continuation of the ophthalmic artery is the nasofrontal artery. Just posterior to the trochlea, the nasofrontal artery divides into the supratrochlear artery which supplies the medial forehead and scalp, and the dorsal nasal artery. The dorsal nasal artery and its branches, the medial palpebral arteries, supply the medial eyelids and nose.

The two terminal branches of the external carotid artery are the maxillary and superficial temporal arteries. The maxillary artery branches off from the external carotid artery just behind the neck of the mandible an average of 25.7 mm (range, 24.86–27.47 mm) below the condyle.⁴⁵ It passes deep to the mandible and enters the pterygopalatine fossa

through the infratemporal fossa.⁴⁶ Among its branches are the middle meningeal and infraorbital arteries. The middle meningeal artery, which has been previously discussed, may anastomose with the lacrimal artery via the recurrent meningeal artery. Rarely, it may provide the majority of orbital blood in patients with ipsilateral carotid stenosis or congenital atresia (lack of patency) of the ophthalmic artery.⁴⁷ Branches from the infraorbital artery supply the inferior rectus and inferior oblique muscles, the lacrimal sac, orbital fat, upper cheek, and lower eyelid.⁴² The superficial temporal artery supplies the forehead and may anastomose with the supraorbital and supratrochlear arteries of the internal carotid circulation.

Venous drainage

Venous drainage of the orbit consists of a valveless anastomotic system with multiple tributaries that drain anteriorly to the facial veins or posteriorly into the cavernous sinus or pterygoid plexus. The major venous branches of the orbit are the superior and inferior ophthalmic veins. The superior ophthalmic vein is formed at the confluence of the angular, supraorbital, and supratrochlear veins. It travels posteriorly along the roof of the orbit, before diving into the muscle cone where it picks up venous drainage from the globe through the superior vortex and ciliary veins. The superior ophthalmic vein then drains into the cavernous sinus after passing through the superior orbital fissure. The inferior orbital vein is responsible for venous drainage of the inferior orbit. It collects venous blood from the inferior extraocular muscles and inferior vortex veins, and drains into both the cavernous sinus and pterygoid plexus. Some of the venous blood from the surrounding periorbita drains through a system of anterior facial veins. These typically drain directly into the external jugular vein.

Orbital lymphatic drainage

The goal to identify the orbital lymphatic drainage system has been pursued in both human and animal studies.^{48–50} Traditionally thought to be absent in the orbit, the more recent use of selective lymphatic markers has identified lymphatics in at least some areas of the human orbit.^{51,52} Using CD-34 and D2-40 monoclonal antibodies, specific for blood vessel endothelium and a protein on lymphatic endothelium respectively, lymphatics were confirmed in human lacrimal gland and optic nerve dura.⁵² Further studies should help to clarify and expand these findings.

Facial and eyelid anatomy and function

The eyebrow and forehead

The eyebrow plays an important role in facial expressions. Brow position and contour are maintained by a group of muscles innervated by the temporal branch of the facial nerve (CN VII). The muscles of the eyebrow and forehead may be divided into superficial (frontalis, procerus, orbicularis oculi), intermediate (depressor supercilii) and deep (corrugator supercilii) groups.⁵³ (Fig. 14.11). The skin of the brow and accompanying subcutaneous fibroadipose are the thickest layers on the face.

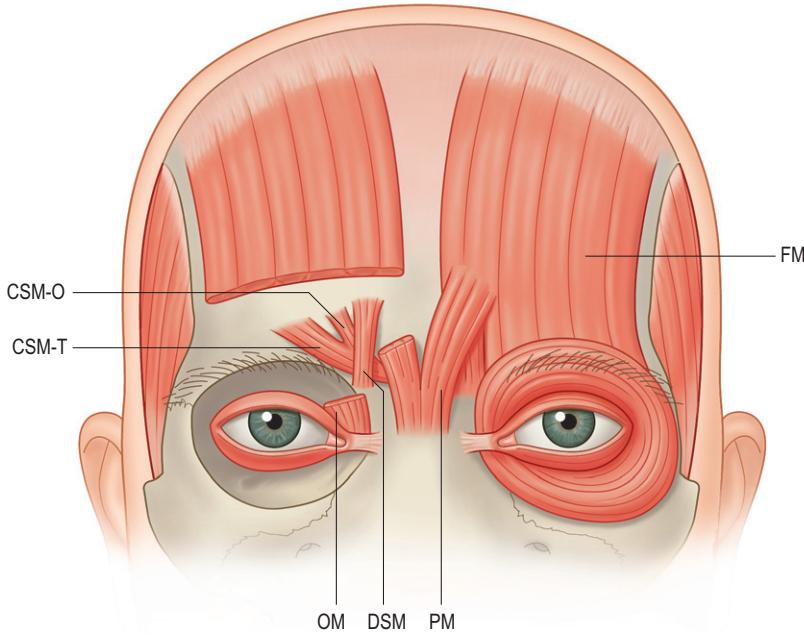

Figure 14.11 Forehead muscles. *FM*, frontalis muscle; *PM*, procerus muscle, *DSM*, depressor supercilii muscle, *CSM-O*, corrugator supercilii muscle – oblique head; *CSM-T*, corrugator supercilii muscle – transverse head. (Adapted from: David M. Knize, Mel Drisko. The Forehead and Temporal Fossa: Anatomy and Technique. Lippincott Williams & Wilkins, 2001.)

The main elevators of the eyebrows and forehead are the paired frontalis muscles. Recruitment of the vertically oriented frontalis may be used to compensate in cases of eyelid ptosis. The frontalis muscle interdigitates with the remaining superficial forehead muscles including the orbicularis oculi, which surrounds the anterior orbit. The orbicularis may be conceptually divided into three topographic regions: the orbital, preseptal, and pretarsal regions. The orbital portion of the muscle is responsible for forced eyelid closure and is an important depressor of the eyebrow and forehead. The pretarsal portion of the muscle is responsible for spontaneous blinking. The procerus muscle arises from the nasal bones and upper lateral cartilages and inserts into eyebrow skin medially. It depresses the glabella to form horizontal skin folds.

The depressor supercilii muscle originates on the frontal process of the maxillary bone and inserts into the dermis of the medial eyebrow.⁵⁴ During this course, it travels over the origin of the corrugator muscle. The bilateral corrugator supercilii muscles (transverse head and deep head) lie deep to the frontalis muscle and travel from their insertion on the superomedial orbital margin to insert into the muscle and skin of the respective medial eyebrow. Contraction of the corrugator draws the eyebrow medially and inferiorly resulting in vertical glabellar rhytids (wrinkles).

The midface

Our understanding of the anatomy of the midface and its dynamic relationship with other periocular structures has advanced considerably during the past 30 years. The midface extends from the upper lip to the inferior orbital rim. The facial soft tissue layers include skin, subcutaneous fat, superficial fascia (superficial musculopaponeurotic system), mimetic muscles, deep facial fascia, and a plane containing the parotid duct, buccal fat pad, and facial nerve.

The superficial musculopaponeurotic system (SMAS) was first described in the parotid and cheek area by Mitz &

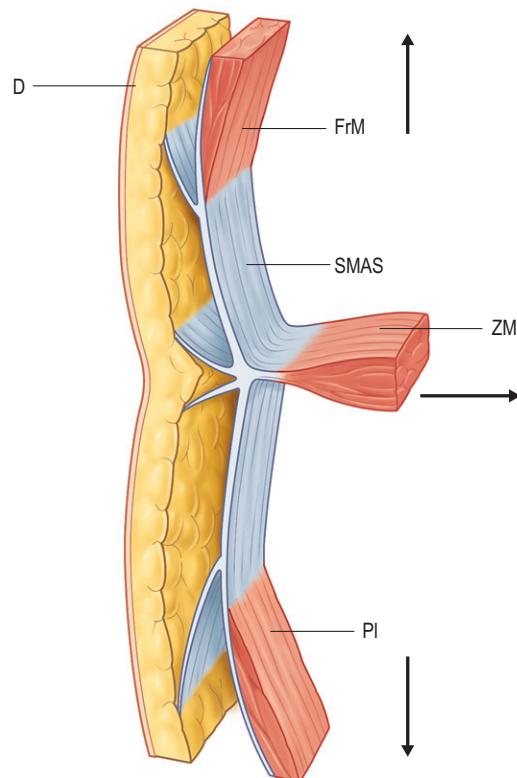

Figure 14.12 Schematic view of the superficial musculopaponeurotic system (SMAS) showing relation to frontalis muscle (*FrM*), zygomatic muscle (*ZM*), dermis (*D*), and platysma (*Pl*). (From Mitz V, Peyronie M: Plast Reconstr Surg 58:80, 1976.)

Peyronie (Fig. 14.12 and Box 14.2).⁵⁵ Multiple fibrous extensions from the SMAS to the skin are thought to distribute muscular contractions that aid in facial expression. Initially described as dividing the parotid and cheek fat into two layers, it has subsequently been shown to lie 11–13 mm

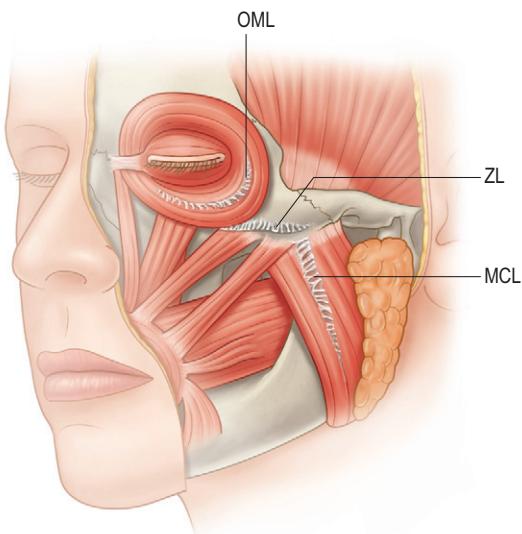

Figure 14.13 Ligamentous support of the midface. MCL, Masseteric cutaneous ligaments; OL, orbitomalar ligament; ZL, zygomatic ligaments. (From Lucarelli MJ et al: Ophthal Plast Reconstr Surg 16(1):7-22, 2000.)

Box 14.2 Key midfacial support components

- The SMAS is an aponeurotic system that is contiguous with the occipitalis, frontalis, orbicularis, and platysma
- Fibrous extensions from SMAS to the skin may help to transmit facial muscular contractions
- Midface bony attachments: zygomatic ligaments and orbitomalar ligaments; attenuation of these ligaments contributes to mid-facial ptosis.

deep to the skin at the mid-cheek and invest the zygomaticus major, zygomaticus minor, and levator labii superioris.⁵⁶ It is continuous with the platysma in the lower face and the frontalis in the upper face as well as the anterior and posterior fascia of the orbicularis oculi muscle.^{57,58} The facial nerve courses beneath the SMAS.

The SMAS has a number of bony attachments. Shortly after its initial description, the SMAS was recognized as an important structure in facial rhytidectomy (face-lift).⁵⁹ In the midface, the zygomatic ligaments and orbitomalar ligaments have been characterized (Fig. 14.13).^{60,61} The mandibular ligaments have been described in the lower face. The orbitomalar ligament has been characterized to provide major osseocutaneous midfacial support due to its steadfast lateral component found approximately 5 mm lateral to the lateral orbital rim.⁶² Work by Lucarelli and colleagues showed that attenuation of the zygomatic, masseteric cutaneous, and orbitomalar ligament is associated with age-related midfacial ptosis (Fig. 14.14).⁶² Others have recently referred to the orbitomalar ligament as the orbital retaining ligament.⁶³

The facial mimetic muscles are arranged into lamella. Freilinger et al have categorized in detail the mimetic muscle into four distinct layers.⁶⁴ A superficial layer consists of the orbicularis oculi, zygomatic minor, and depressor anguli oris. The second layer contains the platysma, depressor labii

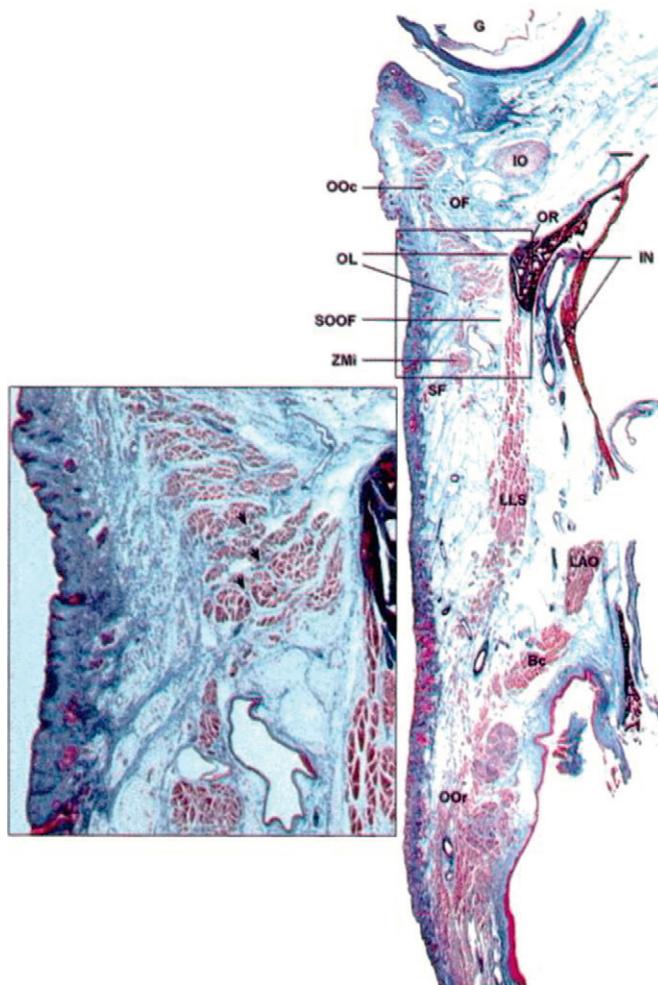

Figure 14.14 Merged sections through central lower eyelid extending to the oral commissure from specimen with midfacial ptosis (Masson trichrome staining). The globe (G), inferior oblique (IO), and orbital fat (OF) are visible superiorly. The orbitomalar ligament (OL) extends off the orbital rim (OR) and passes through the orbicularis oculi muscle (OOc) to the dermis. The nasolabial fold (NLF) is seen inferiorly. The subcutaneous fat (SF) can be seen anterior to the orbicularis oculi and zygomatic minor (ZMi) muscles. The suborbicularis oculi fat (SOOF) rests posterior to the orbicularis oculi muscle and surrounds the proximal portion of the levator labii superioris muscle (LLS). Note the continuity of the inferior SOOF and the subcutaneous fat. The infraorbital nerve (IN) and accompanying vessel can be seen traversing the SOOF deep to the levator labi superioris muscle. The levator labi superioris muscle extends into the upper lip. The levator anguli oris (LAO) arises from the maxilla inferior to the infraorbital foramen. The orbicularis oris (OOr) and buccinator (Bc) are visible in the inferior portion of the specimen. The inset details the orbitomalar ligament (arrowheads) traversing the orbicularis oculi muscle. (From Lucarelli MJ et al: Ophthal Plast Reconstr Surg 16(1):7-22, 2000.)

inferioris, the levator labii superioris alaeque nasi, and zygomatic major muscles. The third layer consists of the levator labii superioris and orbicularis oris. Finally, the deepest layer consists of the mentalis, the levator anguli oris, and the buccinator. Branches of the facial nerve supply the first three layers of muscles from the undersurface, while the deepest layer is innervated from the outer surface.

Paralysis of the facial nerve may have profound effects on facial symmetry and corneal protection. Idiopathic facial

Box 14.3 Idiopathic facial nerve palsy

- Incidence of approximately 25 cases per 100,000 persons
- Must be differentiated from infectious, inflammatory, neoplastic, traumatic, and congenital etiologies
- May lead to corneal exposure and ulceration
- Mild exposure may require intensive lubrication, patching, or lid taping
- Severe exposure may require surgical correction (temporary or permanent tarsorrhaphy or implantation of a gold weight)

nerve palsy or Bell's palsy is estimated to have an incidence of 25 cases per 100,000 (Box 14.3).⁶⁵ The differential diagnosis of facial palsy includes infectious (Ramsey Hunt, herpes zoster/Lyme disease), neoplastic (facial nerve neuroma or hemangioma, acoustic neuroma, meningioma, metastatic), inflammatory (Wegener's granulomatosis, sarcoidosis), traumatic (basilar skull fracture, temporal bone trauma, parotid injury), and congenital etiologies. Lagophthalmos (inability to close the eyelid fully) and a poor blink may lead to corneal exposure. Intensive lubrication, patching, lid taping and use of a moisture chamber may be adequate therapies to prevent complications of corneal exposure. More severe cases may require surgery (upper lid weight or eyelid closure from a tarsorrhaphy).⁶⁶

The eyelid

The eyelid margin

The eyelid margin may be divided into anterior and posterior lamella. The anterior lamella is composed of skin, muscle, and associated glands, while the posterior lamella consists of the tarsal plate, conjunctiva, and associated glands (Fig. 14.15). The two lamella may be separated from one another along the gray line; a terminal extension of the orbicularis known as the muscle of Riolan. This portion of the muscle has been hypothesized to keep the eyelid edges in close approximation to the surface of the globe as well as help expel glandular contents during blinking.^{67,68} The cilia serve to protect the globe from large airborne particles. They are also highly sensitive to touch, and elicit the blink reflex when stimulated.

The anterior lamella functions as a single anatomic unit. The eyelid skin is the thinnest in the body, due in part to a relative thinning of dermis and absence of a subcutaneous fat layer. In adults, the palpebral fissure measures 9–12 mm vertically while the horizontal distance between the medial and lateral commissures measures approximately 30 mm. The lower eyelid rests at or up to 1.5 mm above the inferior limbus while the upper eyelid rests at approximately 1.5–2.0 mm below the superior limbus.⁴² The highest point of the upper eyelid rests just nasal to the central pupillary axis.

The orbicularis muscle is located beneath the eyelid skin. The pretarsal portion of the muscle originates from the anterior and posterior arms of the medial canthal ligament. The deep head of the muscle (Horner's muscle) inserts onto the posterior lacrimal crest and lacrimal fascia while the anterior head attaches to the anterior lacrimal crest (see Fig. 14.4). The muscle therefore surrounds the lacrimal sac, and during

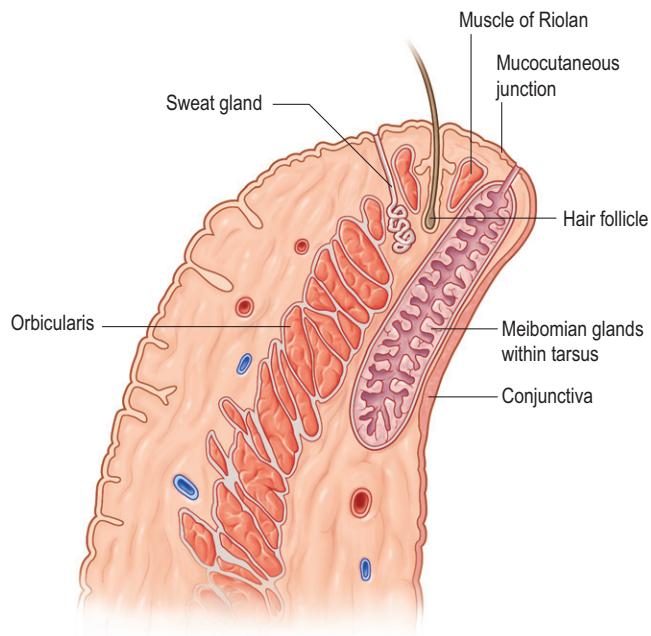

Figure 14.15 Sagittal section of the eyelid margin. (From Lemke BN, Lucarelli MJ: Anatomy of the ocular adnexa, orbit, and related facial structures. In Nesi FA, Lisman RD, Levine MR [eds]: Smith's ophthalmic plastic and reconstructive surgery, ed 2, St. Louis, 1998, Mosby.)

contraction assists the lacrimal pump mechanism.⁶⁹ Laterally, the pretarsal orbicularis muscle inserts in to the lateral canthal tendon.

Glands of the anterior lamella include the glands of Zeis and Moll. The Zeis glands are sebaceous glands while the tubular glands of Moll are apocrine sweat glands. The Zeis glands empty into the ciliary follicular infundibulum while the tubular glands of Moll are located in between the lash follicles.

The posterior lamella of the eyelid consists of the tarsal plate, meibomian glands, and conjunctiva. The tarsal plates are composed of collagens (types I and III collagen) as well as components more typical of cartilage (aggrecan, chondroitins 4 and 6 sulfate).⁷⁰ They provide both rigidity and allow for dynamic movement of the eyelids. The height of the upper tarsus measures approximately 10 mm centrally, while the height of the lower tarsus measures on average 3–4 mm.⁷¹ Medially and laterally, both the upper and lower tarsal plates taper to become the medial and lateral canthal tendons. As previously described, the medial canthal tendon splits into an anterior and posterior head which attach to the anterior lacrimal crest and posterior lacrimal crest respectively. The lateral canthal tendon inserts at Whitnall's lateral tubercle, a small rounded protuberance of the zygomatic bone a few millimeters inside of the lateral orbital wall. Laxity of the canthal tendon may lead to ectropion (turning outward of the eyelid) and may require an eyelid-tightening procedure by shortening and reattaching the lateral canthal tendon. Whitnall's lateral tubercle is also an insertion site for the lateral horn of the levator aponeurosis, the inferior (Lockwood's) and superior (Whitnall's) transverse ligament, the deep pretarsal orbicularis, and the expansion of the superior rectus muscle sheath.^{11,72}

The tarsal plates of both the upper and lower eyelids contain the sebaceous meibomian glands. There are approximately 25 in the upper eyelid and 20 in the lower eyelid.²² The glands secrete the lipid layer (outer layer) of the tear film which helps prevent evaporation of the tears. In the setting of meibomian gland dysfunction, the relative absence of the lipid layer may result in dry eyes.⁷³ Chronic inflammation of the glands or meibomitis, may lead to dysplastic hair follicles that curve towards the globe, known as distichiasis.⁷⁴ Treatment for distichiasis (misdirected lashes from the meibomian gland orifices) or trichiasis (misdirection of normal eyelash follicles) may include cryotherapy, argon laser, electrolysis, trephination and other lid-modifying modalities.⁷⁵⁻⁷⁷

Tightly bound to the posterior aspect of the tarsal plates is the palpebral conjunctiva. It consists of a non-keratinized stratified columnar epithelium overlying loose connective tissue known as substantia propria. The accessory glands of Wolfring, located in the tarsal conjunctiva, and Krause, located in conjunctival fornix, help to produce the aqueous layer of the tear film. This middle layer of the tear film is tightly bound to the hydrophilic mucin layer (inner layer) produced from conjunctival goblet cells. Mucocutaneous disorders such as ocular cicatricial pemphigoid, Stevens-Johnson syndrome, and bullous pemphigoid, may lead to destruction of goblet cells and their progenitor stem cells

leading to severe chronic inflammation with scarring and conjunctival contraction.⁷⁸

The inferior and superior puncta provide entrance to the lacrimal excretory system. The lower eyelid punctum is approximately 10 mm from the lacrimal tear sac with the upper punctum 8 mm from the sac. The puncta are normally oriented towards the tear lake.

Eyelid musculature

The major protractor of the eyelids is the orbicularis muscle, which may be divided into the orbital, preseptal, and pretarsal components. The orbicularis myofibers have the smallest diameter of any skeletal muscle, and although they vary somewhat in length, are overall relatively short.⁷⁹ The variability in myofiber length may help to explain the variety of complex eyelid movements including blinking, winking, and spasm.

The main retractor of the upper eyelid is the levator palpebrae superioris (Fig. 14.16). Assistance is also provided by the superior tarsal muscle (Müller's muscle) which is supplied by sympathetic innervation. The levator is divided into muscular and aponeurotic portions. The muscular portion of the levator measures approximately 36 mm in length and lies just above the superior rectus.⁸⁰ The two muscles can be separated easily except along the medial borders, where they are bound by a fascial sheath. As the muscle moves

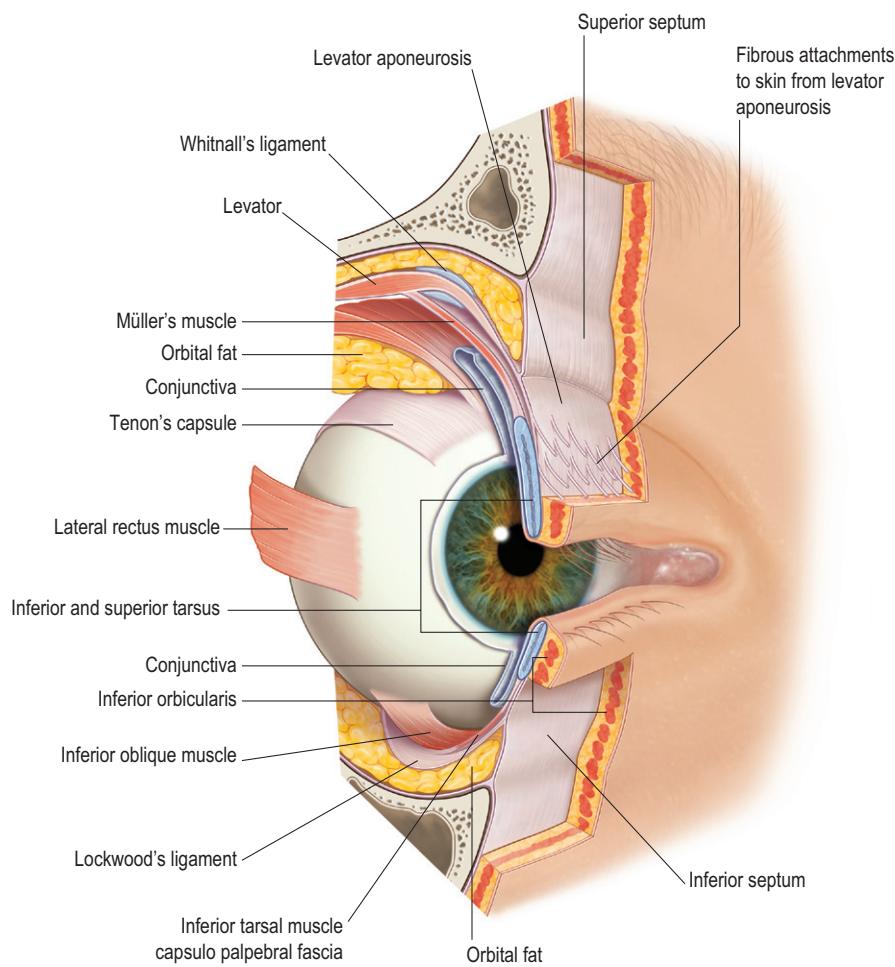

Figure 14.16 Oblique section through the upper and lower eyelids. (Modified from Lemke BN, Lucarelli MJ: Anatomy of the ocular adnexa, orbit, and related facial structures. In Nesi FA, Lisman RD, Levine MR [eds]: Smith's ophthalmic plastic and reconstructive surgery, ed 2, St. Louis, 1998, Mosby.)

anteriorly in the orbit it begins to widen, eventually joining Whitnall's ligament; a transverse fibrous condensation just posterior to the superior orbital rim.¹⁰ Whitnall's ligament provides structural support to the upper eyelids. It has been suggested that it acts as either a fulcrum or swinging suspender for the levator.^{13,81} After passing Whitnall's ligament, the levator muscle transitions into the fibrous levator aponeurosis. The aponeurosis courses another 14–20 mm to insert onto the inferior third of the anterior surface of the tarsus. An anterior portion of the aponeurosis sends fine attachments to the upper eyelid skin as well as multiple elastic fiber insertions of the levator muscle complex that includes the levator aponeurosis, the conjoined fascia, the lid crease area, and Müller's muscle tendon.⁸² The upper eyelid crease is formed by attachments to the skin.

The smooth superior tarsal muscle of Müller arises from the underside of the levator muscle approximately 15 mm above the superior tarsal border and inserts at the upper border of the tarsus.⁸³ This sympathetically innervated muscle provides approximately 2 mm of upper eyelid lift. Interruption of this innervation may result in Horner's blepharoptosis (oculosympathetic paresis). Approximately 2 mm of ptosis along with miosis and occasional unilateral anhidrosis, is highly suggestive of Horner's syndrome due to an interruption of the sympathetic system. The vascular arterial arcade is found between the levator aponeurosis and Müller's muscle. This serves as a useful surgical landmark to identify the underlying Müller's muscle.

The lower eyelid retractors are palpebral extensions from the inferior rectus muscle and are utilized, along with the rectus muscle, during down-gaze. This muscular extension splits to surround the inferior oblique muscle as it travels anterior in the orbit. The outer division or capsulopalpebral fascia is analogous to the levator palpebrae superioris, while the inner division, which is composed of smooth muscle fibers, is analogous to Müller's muscle.²³ The two layers are typically not distinct during surgical dissection. The lower eyelid retractors have three distinct insertions. Anteriorly, the capsulopalpebral fascia fuses with the orbital septum 4 mm inferior to the tarsus. A middle layer of inferior tarsal muscles fibers terminates a few millimeters inferior to the tarsus. Finally, a posterior layer of retractors inserts on Tenon's fascia.

Blinking

Spontaneous blinking occurs every 3–8 seconds with an average of 12 blinks per minute. During the normal blink cycle, eyelid closure is a result of activity *and* co-inhibition of two groups of muscles: the protractors of the eyelids (the orbicularis oculi, corrugator, and procerus muscles), and the voluntary retractors of the eyelids (the levator palpebra superioris and frontalis muscles), respectively. The pretarsal portion of the orbicularis muscle is thought to be responsible for spontaneous blinking.

Blinking assists in the maintenance of a normal ocular tear surface. A blink initiates a cycle of secretion, dispersal, evaporation, and drainage of tears.⁸⁴ Closure of the eyelids occludes the puncta, thus preventing fluid regurgitation. At the same time the canaliculi and sac are compressed, which forces fluid down the nasolacrimal duct. When the eyelid opens, both the puncta and canalicular system open, creating a partial vacuum which sucks in tears from the ocular

Box 14.4 Benign essential blepharospasm

- Bilateral, involuntary, spastic forced eyelid closure
- Typically presents in 5th–7th decade of life
- Absent during sleep
- May be due to an abnormality of the basal ganglia
- Repeated administration of botulinum toxin type A (Botox) injections is the treatment of choice

surface. Closure of the eyelids also stimulates the expression of the aqueous tear layer from the lacrimal and accessory lacrimal glands.

During delayed blinking the normal tear cycle is altered. This may result in dry eye or secondary reflexive tearing. Seen in a variety of clinical scenarios including reading, older age, and in patients with Parkinson's disease, delayed blinking results in decreased tear expression, increased tear evaporation, and potentially decreased tear drainage.⁸⁵

Benign essential blepharospasm (BEB) is a bilateral, involuntary, spastic forced eyelid closure with accompanying brow depression in the absence of any other ocular or adnexal cause (Box 14.4). It may initially begin with simply an increased blink rate. Blepharospasm may also be secondary to ocular surface disease or neurodegenerative diseases such as Parkinson's.⁸⁶ BEB affects women more often than men, and typically presents during the fifth to seventh decades of life.⁸⁷

During BEB, the normal activation/inhibition pathways (possibly basal ganglia in origin) are disrupted, resulting in sustained activation of the protractors with sustained inhibition of the retractors. Repeated botulinum toxin type A (Botox) approximately every 3 months is the treatment of choice for many patients with BEB. The neurotoxin, which is produced from *Clostridium botulinum*, inhibits the release of acetylcholine (ACh) and may be used to temporarily paralyze the eyelid protractors.⁸⁸

Eyelid fat

Bounded by the orbital septum anteriorly and the levator muscle/aponeurosis posteriorly, there are two upper eyelid fat pads separated by the trochlea and superior oblique tendon. The most medial fat pad takes on a fibrous white appearance while the central preaponeurotic fat pad is yellow, due to a high level of free-radical scavenging carotenoids.⁸⁹ The fatty acid levels found in the fat are similar in samples throughout the orbit, despite these color variations. Orbital fats are typically unsaturated. Some of these fatty acids include oleic acid (18:1) and linoleic acid (18:2), among others. The preponderance of unsaturated fats may provide a lubricating surface with advantages for ocular motility. Laterally, the pink and firm lacrimal gland should not be confused with eyelid fat during surgery. The lower eyelid contains three fat pads that are enclosed in fibrous compartments: medial, central, and lateral.

Eyelid vasculature

The eyelids are highly vascularized with contributions from both the external and internal carotid systems. The external carotid system supplies the eyelid through branches from the

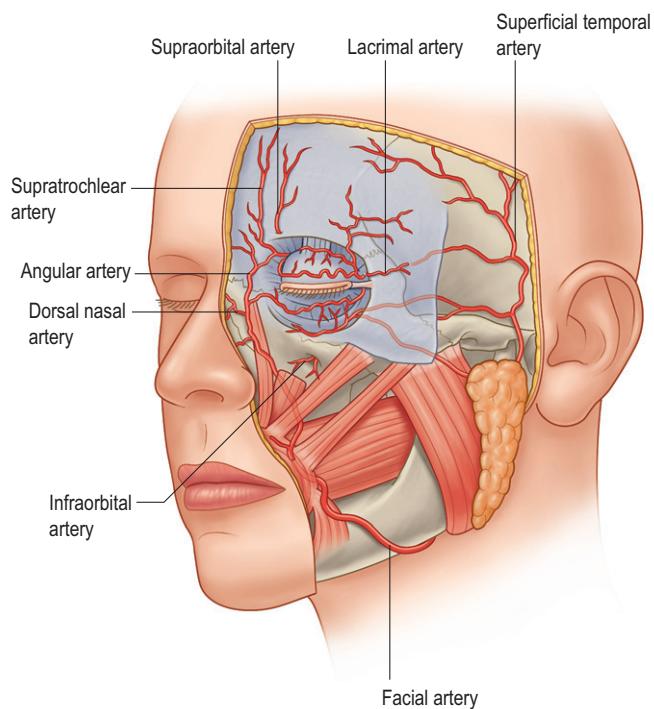

Figure 14.17 Superficial facial arteries in the ocular region. (Adapted from: Lemke BN, Lucarelli MJ: Anatomy of the ocular adnexa, orbit, and related facial structures. In Nesi FA, Lisman RD, Levine MR [eds]: Smith's ophthalmic plastic and reconstructive surgery, ed 2, St. Louis, 1998, Mosby.)

facial artery, superficial temporal artery, infraorbital artery (via the maxillary artery), and superficial temporal artery (Fig. 14.17). The facial artery arises from the external carotid artery just below the angle of the jaw and travels superomedially along the nasolabial fold. As it approaches the medial canthus it becomes the angular artery. The artery runs approximately 5–6 mm medial to the medial canthus. External dacryocystorhinostomy incisions should be positioned to avoid damage to the artery. The artery perforates the orbital septum to anastomose with branches of the ophthalmic artery. The superficial temporal artery supplies the forehead and may anastomose with the supraorbital and supratrochlear arteries of the internal carotid circulation. The maxillary artery and its branches were discussed in the orbital section.

The main arterial supply of the upper eyelids is supplied by four arterial arcades: the marginal, peripheral, superficial orbital, and deep orbital arcades.⁹⁰ In the upper and lower eyelids, the marginal arcades lie anterior to the tarsus approximately 2–4 mm from the eyelid margin. Anastomoses between the supratrochlear, lacrimal, and angular arteries compose the superior arcade, while anastomoses from the infraorbital, angular, and zygomaticofacial arteries form the inferior arcade. During tarsal sharing procedures such as free tarsoconjunctival grafts or tarsoconjunctival flaps (e.g. Hughes procedure), proper care should be taken to maintain vascular supply to both eyelids.

Arising from the confluence of the frontal and supraorbital veins, the facial vein is the main venous drainage pathway of the eyelids. It starts as the angular vein 6–8 mm

medial to the medial canthus and travels roughly with the facial artery, ending at the external jugular vein. A minor proportion of the facial venous drainage passes posteriorly through veins that empty into cavernous sinus and pterygoid plexus, as discussed earlier.

Eyelid lymphatics

Lymphoscintigraphy of Cynomolgus monkey eyelids has revealed discrete lymphatic drainage pathways for the upper and lower eyelids and a dual pathway for the central upper eyelid.^{91,92} The lateral and medial portions of the upper and lower eyelids drain to the superficial preauricular and submandibular lymph nodes, respectively. This drainage continues through the deep cervical nodes.

Eyelid innervation

The eyelids and periocular structures are innervated by the oculomotor nerve (CN III), facial nerve (CN VII), trigeminal nerve (CN V), and sympathetic fibers.

The facial nerve supplies most of the motor innervation to the face. After passing through the parotid gland the nerve divides into five divisions: temporal, zygomatic, buccal, mandibular, and cervical nerves. There is a great deal of overlap of regions innervated by the nerve. In general, the temporal branch innervates the frontalis muscle while the zygomatic, temporal, and buccal divisions innervate the orbicularis oculi. Motor innervation to the levator palpebrae is provided by the superior division of the oculomotor nerve. Sympathetic fibers innervate the underlying Müller's muscle. The exact course of these sympathetic fibers is controversial.

Sensory innervation to the face is supplied by the trigeminal nerve. The nerve is composed of the ophthalmic (V1), maxillary (V2), and mandibular divisions (V3), of which the ophthalmic and maxillary divisions provide sensory innervation to the periorbita (Fig. 14.18).

The ophthalmic (V1) division enters the orbit through the superior orbital fissure after dividing into three branches: the lacrimal, frontal, and nasociliary nerves. The frontal and lacrimal nerves enter the orbit in the superolateral portion of the superior ophthalmic fissure outside of the annulus of Zinn. A superior division of the lacrimal nerve supplies sensation to the nearby conjunctiva, the lateral upper eyelid, and the lacrimal gland. An inferior division of the nerve anastomoses with the zygomaticotemporal branch of the maxillary trigeminal nerve and is joined by parasympathetic secretory fibers destined for the lacrimal gland.

While traveling just below the periorbita in the anterior orbit, the frontal nerve divides into the supraorbital and supratrochlear divisions. The supratrochlear nerve innervates the glabellar skin, medial upper eyelid, and lower forehead. The supraorbital nerve typically divides into a superficial (medial) division that supplies the anterior margin of the scalp and forehead skin, and a deep (lateral) division that provides sensation to the frontoparietal scalp (Fig. 14.19).⁹³ Damage to this deep (lateral) division during a forehead lift may result in a large area of scalp numbness and paresthesia.⁹³

The nasociliary branch of the ophthalmic trigeminal nerve passes through the annulus of Zinn and travels within the intraconal space. It gives off a small sensory branch to the ciliary ganglion and long ciliary nerves to the globe,

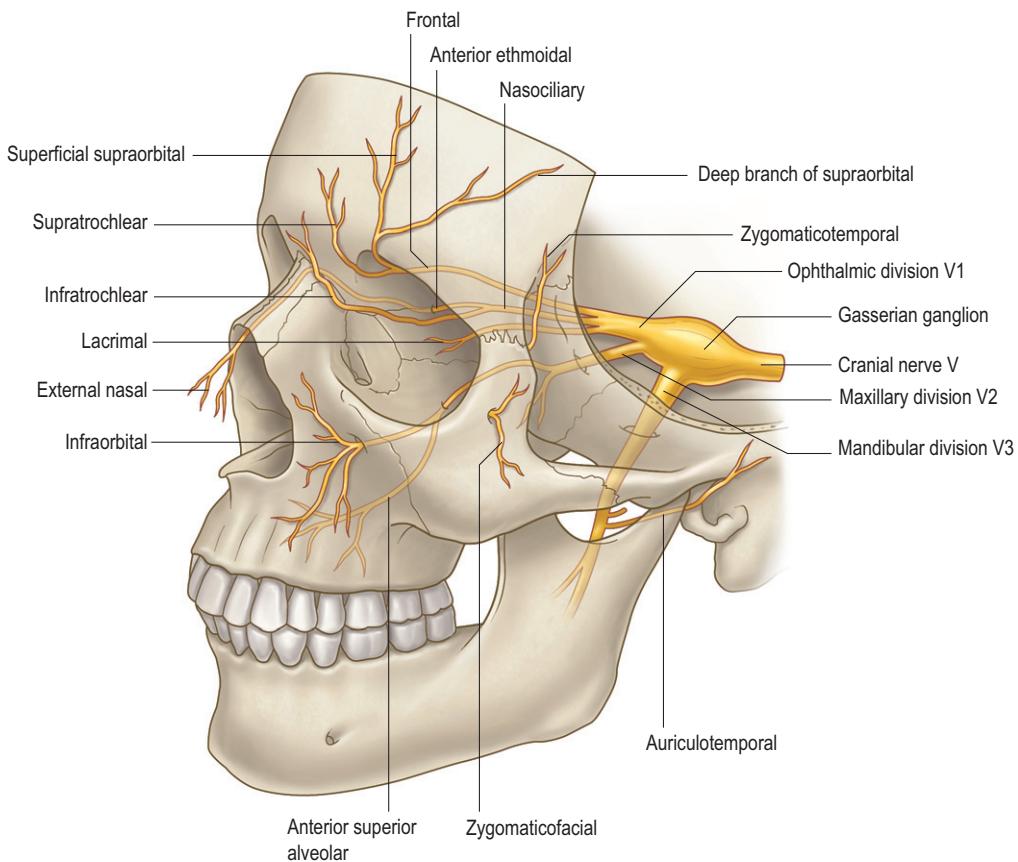

Figure 14.18 Trigeminal nerve pathways. (Adapted from: Lemke BN, Lucarelli MJ: Anatomy of the ocular adnexa, orbit, and related facial structures. In Nesi FA, Lisman RD, Levine MR [eds]: Smith's ophthalmic plastic and reconstructive surgery, ed 2, St. Louis, 1998, Mosby.)

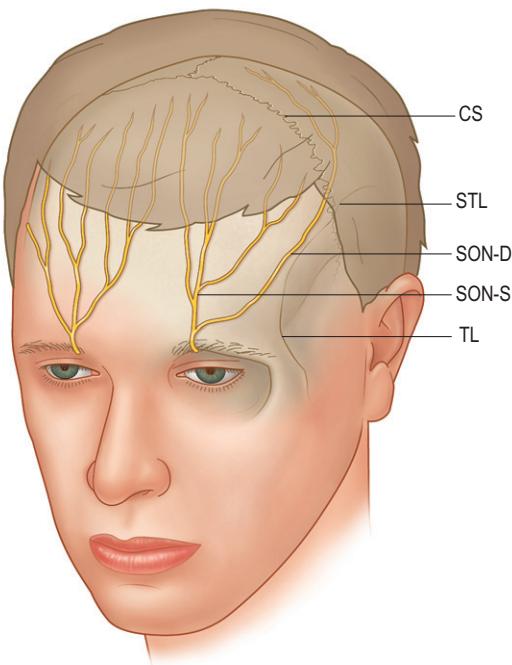

Figure 14.19 Diagram illustrating the courses of the deep (SON-D) and the superficial (SON-S) divisions of the supraorbital nerve trunk. (Adapted from Knize, DM. A Study of the Supraorbital nerve. Plast Reconstr Surg 1995;96:564–569.)

before dividing into the ethmoid and infratrochlear end branches. The long ciliary nerves innervate the iris, cornea, and ciliary muscle. The ethmoid branch provides sensation to the nasal mucosa and skin on the anterior tip of the nose. A small unilateral vesicular rupture of herpes zoster on the tip of the nose is known as Hutchinson's sign, and is associated with an increased risk of herpes zoster ophthalmicus.

The maxillary (V2) division of the trigeminal nerve exits the middle cranial fossa at the foramen rotundum, and passes through the lateral wall of the cavernous sinus and pterygopalatine fossa to enter the inferior orbital fissure. Within the pterygopalatine fossa, it also gives rise to the zygomatic, sphenopalatine, and posterior superior alveolar branches. The infraorbital nerve is the terminal branch of the maxillary nerve which enters the infraorbital groove approximately 30 mm posterior to the orbital rim. The zygomatic nerve divides into the zygomaticofacial and zygomaticotemporal nerves, which provide innervation to the lateral cheek and lateral brow respectively. Parasympathetic secretory fibers join the zygomaticotemporal nerve prior to joining the lacrimal nerve en route to the lacrimal gland.

Formation and Function of the Tear Film

Darlene A. Dartt

1. Tear film overview

The tear film overlays the ocular surface, which is comprised of the corneal and conjunctival epithelia, and provides the interface between these epithelia and the external environment. The tear film is essential for the health and protection of the ocular surface and for clear vision as the tear film is the first refractive surface of the eye.¹

Tears produced by the ocular surface epithelia and adnexa are distributed throughout the cul-de-sac. Using ocular coherence tomography the thickness of the precorneal tear film was $3.4 \pm 2.6 \mu\text{m}$,² agreeing with previous measurements using less accurate techniques.³⁻⁷

The tear film is an exceedingly complex mixture of secretions from multiple tissues and epithelia (Fig. 15.1) and consists of four layers (Fig. 15.2). The innermost layer is a glycocalyx that extends from the superficial layer of the ocular surface epithelia. The second is a mucous layer that covers the glycocalyx and may mix with the third aqueous layer. The outermost layer contains lipids. Similarly to mucous and aqueous layers, aqueous and lipid layers may mix. Production and function of tear film layers are distinct and will be presented separately.

Tear secretion by all ocular adnexa and ocular surface epithelia must be coordinated. For mucous and aqueous layers, secretion is regulated by neural reflexes. Sensory nerves in cornea and conjunctiva are activated by mechanical, chemical, and thermal stimuli that in turn activate the efferent parasympathetic and sympathetic nerves, which innervate the lacrimal gland and the conjunctival goblet cells, and cause mucous and fluid secretion. For the lipid layer, the blink itself regulates release of pre-secreted meibomian gland lipids stored in the meibomian gland duct. When the eyelids retract a thin film of lipid overspreads the underlying aqueous and mucous layers.

Tear secretion is balanced by drainage and evaporation. Tears on the ocular surface are drained through lacrimal puncta into the lacrimal drainage system. Drainage of tears can be regulated by neural reflexes from the ocular surface that cause vasodilation and vasoconstriction of the cavernous sinus blood supply of the drainage duct (Fig. 15.3). Both vasoconstriction and vasodilation cause a change in geometry of the lumen that decreases drainage.⁸ Evaporation

depends on the amount of time the tear film is exposed between blinks and temperature, humidity, and wind speed. The remainder of the chapter will focus on regulation of tear secretion.

2. Glycocalyx

A. Structure

The glycocalyx is a network of polysaccharides that project from cellular surfaces. In corneal and conjunctival epithelia, the glycocalyx can be found on the apical portion of the microvilli that project from the apical plasma membrane of the superficial cell layer (Fig. 15.2). Mucins are a critical component of the glycocalyx. Mucins consist of a protein core of amino acids linked by O-glycosylation to carbohydrate side chains of varying length and complexity. Mucins are classified by the nomenclature MUC1–21 and are divided into secreted and membrane-spanning categories (Fig. 15.4). Membrane-spanning mucins consist of a short intracellular tail, membrane-spanning domain, and large, extended extracellular domain that forms the glycocalyx. Secreted mucins are either gel-forming or small soluble. Gel-forming mucins are large molecules (20–40 million Da) secreted by exocytosis from goblet cells. Small soluble mucins are secreted by the lacrimal gland.

The ocular surface contains the membrane-spanning mucins, MUC1, MUC4, and MUC16.⁹ These mucins are produced by stratified squamous cells of the cornea and conjunctiva and are stored in small clear secretory vesicles in the cytoplasm (Fig. 15.1). Fusion of secretory vesicles with plasma membrane inserts these molecules into the plasma membrane. Mucin molecules are localized to the tips of the squamous cell microplicae.

There is limited information on regulation of membrane-spanning mucin synthesis and secretion. Regulation of secretion would be by regulation of insertion of mucins into plasma membranes or by control of ectodomain shedding whereby matrix metalloproteinases (MMPs) cleave the mucin releasing the extracellular, active domain of the protein into the extracellular space. In immortalized stratified corneal-limbal cells, tumor necrosis factor induced the ectodomain shedding of MUC1, MUC4, and MUC16,

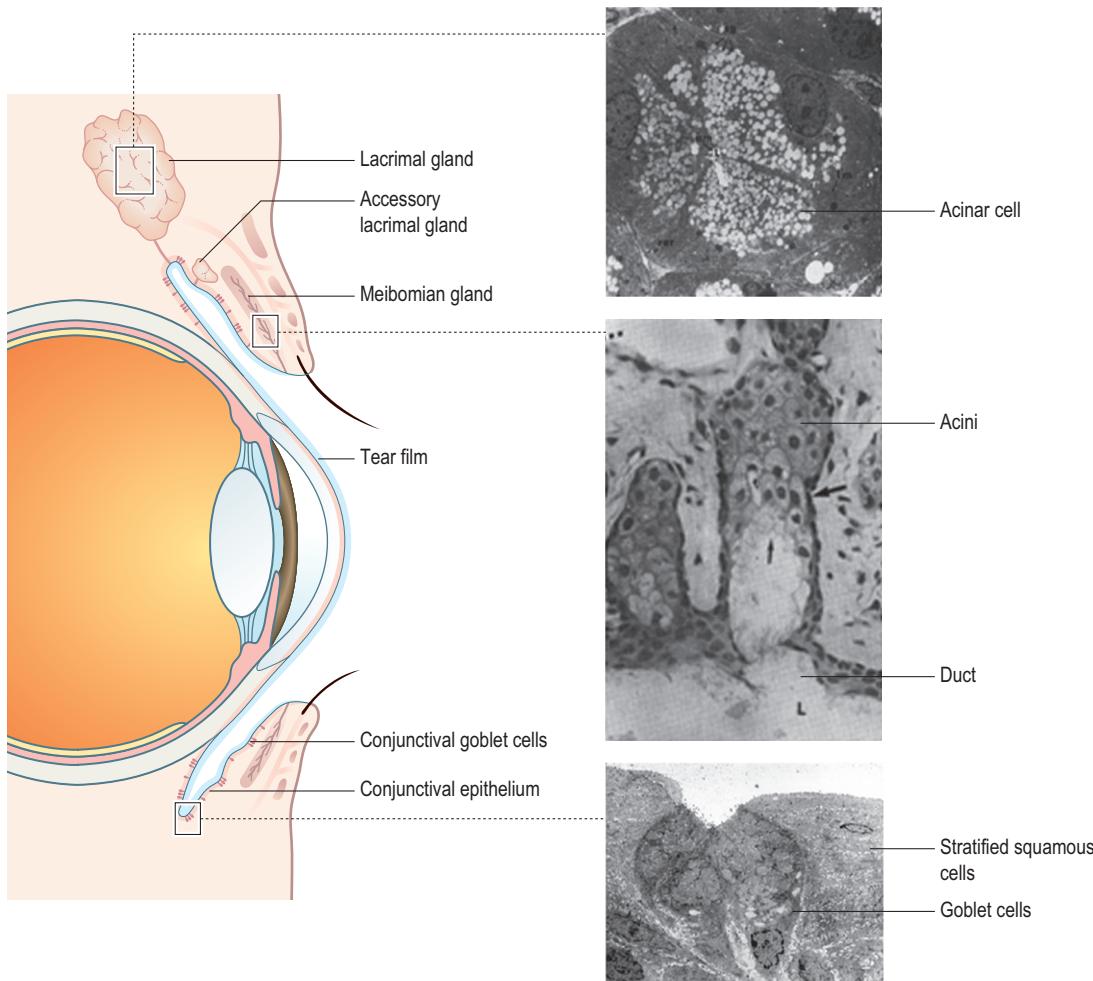

Figure 15.1 Schematic of the glands and epithelia that secrete tears. The ocular surface epithelia are in beige and lacrimal glands in pink and their contribution to the tear film is in blue. An electron micrograph of conjunctival goblet cells is in the bottom inset. An electron micrograph of a lacrimal gland acinus, is shown in the top inset. An electron micrograph of a meibomian gland acinus with its attached duct is shown in the middle inset. (Modified from Dartt DA. The Lacrimal Gland and Dry Eye Diseases. In: Ocular Disease: Mechanism and Management. Ed. Levin and Albert. Elsevier Ltd. Amsterdam. Copyright Elsevier 2010.)

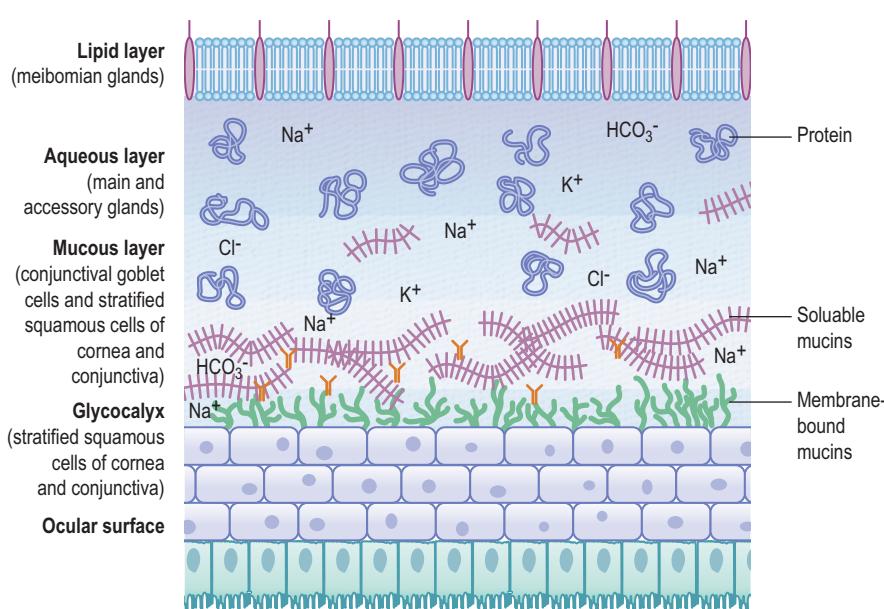

Figure 15.2 Schematic of the tear film. The outer lipid layer is secreted by meibomian glands. The middle layer contains electrolytes, water, proteins, and small soluble mucins produced by lacrimal glands and conjunctival epithelium. The inner mucous layer consists of MUC5AC, proteins, electrolytes, and water secreted by conjunctival goblet cells. The glycocalyx is comprised of membrane-bound mucins produced by stratified squamous cells of the corneal and conjunctival epithelial cells. The tear film overlies the ocular surface. (Modified from Hodges RR, Dartt DA. Regulatory pathways in lacrimal gland epithelium. *Int Rev Cytol*. 2003;231:129–196. Copyright Elsevier 2003.)

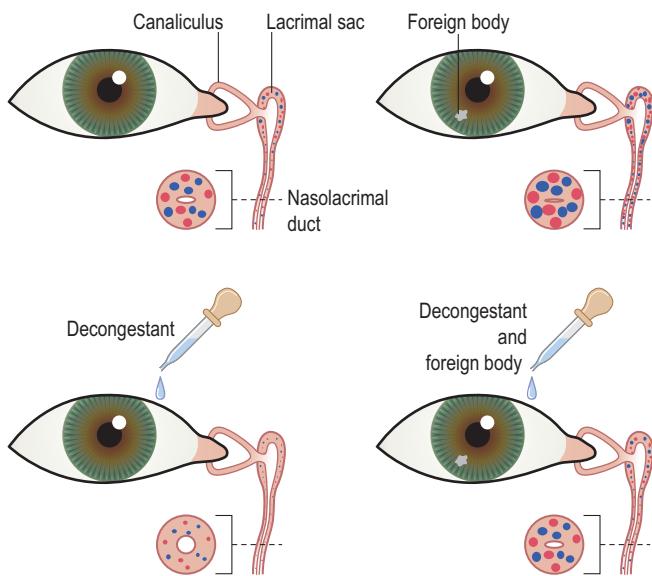

Figure 15.3 Schematic anatomic model of the state of the cavernous body and lacrimal passage. The top left illustration shows the lumen of the nasolacrimal duct under resting conditions. A foreign body in the eye causes activation of nerves in the cavernous body causing vasodilation of the blood vessels and a narrowing of the lumen that results in decreased tear drainage. The third panel shows the placement of decongestant of the ocular surface causes vasoconstriction of the blood vessels of the cavernous body, and opening of the lumen of the nasolacrimal duct, and surprisingly a decrease in drainage. The final panel shows that the vasoconstriction caused by the foreign body and vasodilation by the topical congestant prevent a change in the shape of the lumen and in the drainage of tears. (Modified from Ayub, M., A. B. Thale, J. Hedderich, B. N. Tillmann and F. P. Paulsen. 2003. Invest Ophthalmol Vis Sci. 44(11), 4900–7, reproduced from the Association for Research in Vision and Ophthalmology.)

whereas MMP-7 and neutrophil elastase induced the shedding of MUC16 only.¹⁰ These compounds that caused shedding are elevated in the tears of dry eye patients and thus may cause the increase in Rose-Bengal staining found in dry eye and associated with loss of MUC16 (Box 15.1).

B. Function

The membrane-spanning mucins function to hydrate the ocular surface and serve as a barrier to pathogens. Membrane-spanning mucins are considered to be disadhesive, allowing the mucous layer to move over the ocular surface. The carbohydrate side chains hold water at the surface of the apical cell membranes. The function of individual membrane-spanning mucins remains unclear.

Membrane-spanning mucins appear to be altered in dry eye. MUC16 protein levels decreased in conjunctival epithelium and increased in tears of patients with Sjogren's

Box 15.1 Definition of Dry Eye Disease

- Dry eye is a multifactorial disease of the tears and ocular surface
- Dry eye results in symptoms of discomfort, visual disturbance, and tear film instability
- Dry eye can potentially damage the ocular surface
- Dry eye is accompanied by increased osmolarity of the tear film and inflammation of the ocular surface

Modified from 2007 Report of the International Dry Eye Workshop, The Ocular Surface, vol 5, number 2, page 27, 2007

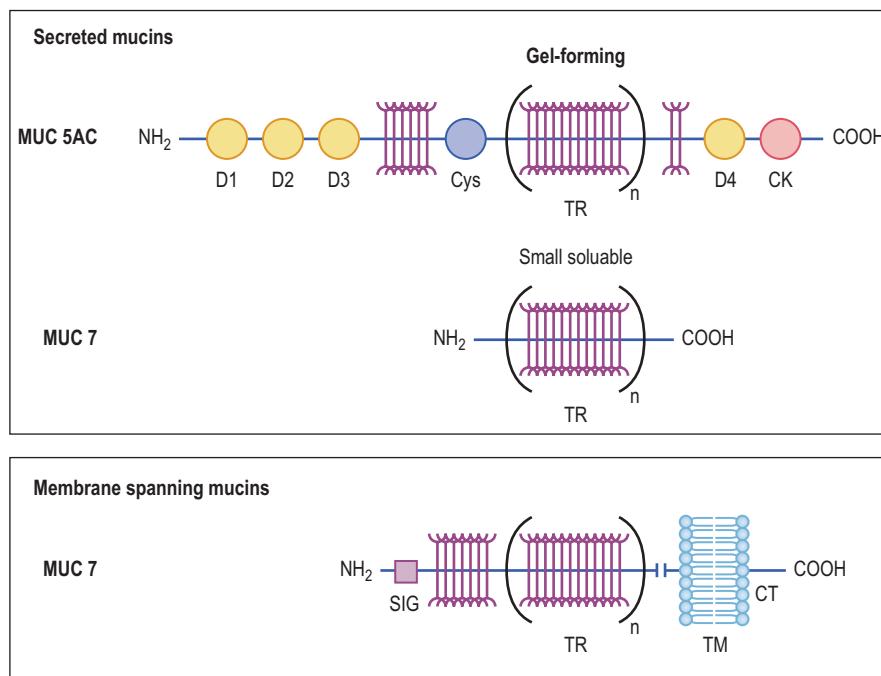

Figure 15.4 Structural motifs of the secreted and membrane-spanning mucins. MUC5AC consists of four cysteine-rich D domains for disulfide cross-linking and flank a region of variable number tandem repeats (TR). MUC7 is monomeric, has a variable number of tandem repeats. The membrane-spanning mucins have an SIG domain, a variable number of tandem repeats, a site for cleavage of the extracellular domain, a transmembrane domain (TM) for insertion of the molecule into membranes, and a carboxyterminus (CT) that is the intracellular domain. SIG: peptide signal sequence; CK: cysteine knot. (Modified from Gipson IK and Argueso P. 2003. Role of mucins in the function of the corneal and conjunctival epithelia. Int Rev Cytol. 231, 1–49. Copyright Elsevier 2003.)

Box 15.2 Conditions Associated with Aqueous Deficiency Dry Eye

- Primary lacrimal gland deficiencies including age-related dry eye, congenital alacrima, and familial dysautonomia
- Secondary lacrimal gland deficiencies including Sjogren's syndrome, lacrimal gland infiltration, lymphoma, AIDS, graft vs host disease, lacrimal gland ablation, and lacrimal gland denervation
- Obstruction of the lacrimal gland ducts from trachoma; cicatricial pemphigoid and mucous membrane pemphigoid; erythema multiforme; and chemical and thermal burns
- Reflex hyposecretion from reflex sensory block during contact lens wear, diabetes and neurotrophic keratitis
- Reflex hyposecretion from reflex motor block after VII cranial nerve damage, multiple neuromatosis, and exposure to certain systemic drugs

Modified from 2007 Report of the International Dry Eye Workshop, The Ocular Surface, vol 5, number 2, page 80, 2007

syndrome.^{11,12} MUC1 splice variants also play a role in dry eye.¹³ Human cornea and conjunctiva contain five previously identified MUC1 splice variants and a new splice variant. These splice variants have unique changes that could affect their ectodomain shedding, signaling properties of the intracellular domain, and water retention, lubrication, and barrier properties of the extracellular domains. When the type of MUC1 splice variant was determined in dry eye patients (both evaporative dry eye and Sjogren's syndrome) compared to control patients there was a reduced frequency of MUC1/A variant and an increase in MUC1/B variant in dry eye patients.^{13,14}

3. Mucous layer

A. Structure

The mucous layer backbone is the gel-forming mucin MUC5AC, synthesized and secreted by conjunctival goblet cells. MUC5AC is encoded by one of the largest genes known, producing a protein of about 600 kDa. The protein backbone of MUC5AC consists of four D domains (cysteine-rich domains) (Fig. 15.4) that flank a tandem repeat sequence in which amino acids in the protein backbone are O-glycosylated and linked to carbohydrate side chains. The D domains provide sites for disulfide bonds cross-linking multiple MUC5AC molecules that forms the framework of the mucous layer. Also contained in the mucous layer are shed ectodomains of membrane-spanning mucins, membrane-spanning mucins secreted by a soluble pathway, other proteins synthesized and secreted by goblet cells, and electrolytes and water secreted by goblet and stratified squamous cells.

B. Conjunctival goblet cells

Goblet cells are interspersed among stratified squamous cells of the conjunctiva (see Fig. 15.1). Goblet cells occur in clusters in rat and mouse, but singly in rabbit and humans.^{15–17} In all species studied, goblet cells are unevenly distributed over the conjunctiva.

Goblet cells are identified by the large accumulation of mucin granules in the apex (see Fig. 15.1). Secretory product can be visualized using Alcian blue-periodic acid stain, the lectins *Ulex europeus* agglutinin I (UEA-I) or *Helix pomatia* agglutinin (HPA), or antibodies to MUC5AC. MUC5AC is synthesized in the endoplasmic reticulum and carbohydrate side chains added in the Golgi apparatus. The mature proteins are stored in secretory granules. Upon stimulation secretory granules fuse with each other and apical membrane releasing secretory product into the tear film. Upon cell stimulation the entire complement of granules is released, known as apocrine secretion. The amount of secretion is controlled by regulating the number of cells that are activated by a given stimulus.

C. Regulation of goblet cell mucin production

Overview

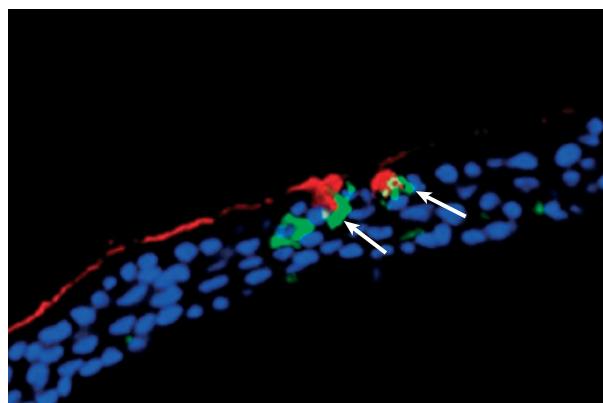

Mucin production is regulated by controlling the rate of mucin synthesis, rate of mucin secretion, and number of goblet cells present in the conjunctiva. The rate of mucin synthesis has yet to be studied in conjunctival goblet cells. Thus the remainder of this section will focus on regulation of secretion and proliferation.

Regulation of goblet cell secretion

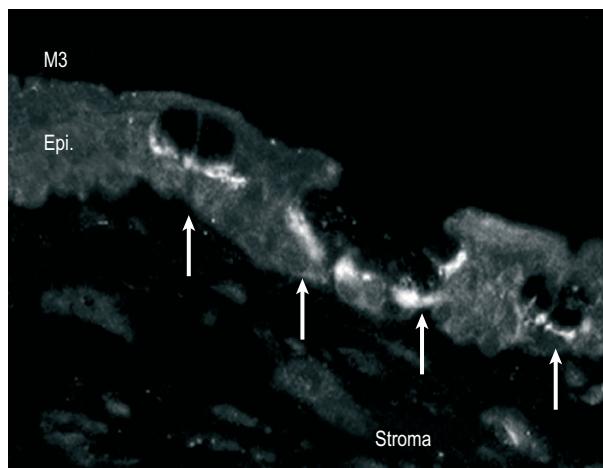

Nerves are the primary regulators of conjunctival goblet cell secretion. The conjunctiva is innervated by afferent sensory nerves and efferent sympathetic and parasympathetic nerves. Sensory nerves end as free nerve endings between the stratified squamous cells. The parasympathetic and sympathetic nerve endings also surround the goblet cells at the level of the secretory granules (Fig. 15.5). Stimulation of the sensory nerves in the cornea by a neural reflex induces goblet cell secretion via the efferent nerves. Goblet cells have receptors for neurotransmitters from both parasympathetic and sympathetic nerves. Parasympathetic nerves release both acetylcholine (Ach) and vasoactive intestinal peptide (VIP). Muscarinic receptors of the M₃AchR and M₂AchR subtypes are located similarly to the location of efferent nerves (Fig. 15.5).^{18,19} VIP receptors of the VIPAC2 receptor subtype are located in the same area as M₃AchR.¹⁹ Sympathetic nerves release norepinephrine and NPY. Several subtypes of both α₁- and β-adrenergic receptors are present on goblet cells.¹⁸ It appears that parasympathetic nerves using Ach and VIP are the primary stimuli of goblet cell secretion. The function of the sympathetic nerves remains unknown.

Components of the signaling pathways used by Ach, but not VIP, have been delineated.¹⁹ Cholinergic agonists use M₃AchR and M₂AchR to stimulate goblet cell secretion.²⁰ Cholinergic agonists presumably use the G_{αq/11} subtype of G protein that activate phospholipase C to breakdown phosphatidylinositol 4,5 bisphosphate to produce inositol 1,4,5 trisphosphate (IP₃) and diacylglycerol. IP₃ would then release intracellular Ca²⁺ by binding to its receptors on the endoplasmic reticulum. Based on a variety of experiments cholinergic agonists are known to increase the intracellular [Ca²⁺] to stimulate secretion.^{21,22}

The diacylglycerol (DAG) released with IP₃ activates protein kinase C (PKC). Nine PKC isoforms are present in

(A)

(B)

Figure 15.5 Immunofluorescence micrographs of parasympathetic nerves and M₃Ach receptors in rat conjunctiva. (A) The parasympathetic neurotransmitter VIP is shown in green. The lectin *Ulex europeus* is shown in red and indicates the location of goblet cells. The goblet cell body is subjacent to the secretory granules. The cell nuclei are shown in blue. (Reprinted with permission from Diebold, Y., J. D. Rios, R. R. Hodges, I. Rawe and D. A. Dartt. 2001. Invest Ophthalmol Vis Sci. 42(10), 2270–82.) (B) The M₃AchR is shown. The dark areas indicate the goblet cell secretory granules. Arrows indicate cell bodies of goblet cells. (Reprinted with permission from Rios, J. D., D. Zoukhi, I. M. Rawe, R. R. Hodges, J. D. Zieske and D. A. Dartt. 1999. Invest Ophthalmol Vis Sci. 40(6), 1102–11, reproduced from the Association for Research in Vision and Ophthalmology.)

conjunctival goblet cells and phorbol esters, activators of PKC isoforms, stimulate goblet cell secretion.²¹ Although a role for PKC isoforms in secretion could not be substantiated,²¹ it is likely that cholinergic agonists use PKC isoforms to stimulate secretion as PKC inhibitors block a distal step in the signaling pathway, activation of extracellular regulated kinase (ERK1/2)²³ (Fig. 15.6).

Cholinergic agonists are known to activate the epidermal growth factor (EGF) signaling pathway. In goblet cells, cholinergic agonists activate the non-receptor tyrosine kinases Pyk2 and p60Ssrc.²⁰ These kinases transactivate (phosphorylate) the EGF receptor (EGFR). This transactivation is usually mediated by ectodomain shedding by MMP causing the release of the extracellular, active domain of one member of the EGF family of growth factors. This has yet to

be tested in goblet cells. The released growth factor would bind to the EGF receptor inducing two receptors to associate and be autophosphorylated. This attracts the adapter proteins Shc and Grb2 that are phosphorylated, activating the guanine nucleotide exchange factor SOS to increase Ras activity. Ras activates MAPK kinase (Raf) that phosphorylates MAPK kinase (MEK) that phosphorylates ERK1/2. In both rat and human goblet cells, cholinergic agonists increase the intracellular [Ca²⁺] and activate PKC to stimulate goblet cell secretion by activating Pyk2 and p60Ssrc to transactivate the EGF receptor, inducing the signaling cascade that activates ERK1/2 (Fig. 15.6).^{20,23,24}

Other factors that stimulate goblet cell secretion include P2Y₂ purinergic receptors²⁵ that are activated by ATP and the neurotrophin family of growth factors. Of this family nerve growth factor and brain-derived neurotrophic factor stimulate secretion.²⁶

Regulation of goblet cell proliferation

The amount of goblet cell mucin on the ocular surface can also be modulated by controlling goblet cell proliferation. Serum, which contains a variety of growth factors, stimulates proliferation of cultured conjunctival goblet cells, both human and rat.²⁷ EGF, transforming growth factor (TGF α), and heparin binding-EGF (HB-EGF), but not heregulin stimulate proliferation.²⁷ EGF, TGF α , and HB-EGF bind to the EGF receptor (EGFR or erb-B1), HB-EGF binds to erb-B4 and heregulin binds to erb-B3 and erb-B4. That EGF, TGF α , and HB-EGF are equipotent in stimulating conjunctival goblet cell suggests that the EGFR and erb-B4 are the primary receptors used.²⁷

EGF was used as the prototype of the EGF family. EGF increases the activation of the EGFR in rat conjunctival goblet cells and activates ERK1/2 (also known as p44/p42 mitogen activated protein kinase (MAPK)) (Fig. 15.7) causing its biphasic translocation to the nucleus.²⁸ The slower sustained second peak response is responsible for cell proliferation, but the role of the rapid transient first peak is not known.

Activation of PKC isoforms also mediates EGF-stimulated goblet cell proliferation (Fig. 15.7). In rat and human goblet cells, EGF uses PKC α and PKC ϵ to stimulate conjunctival goblet cell proliferation.

D. Regulation of conjunctival electrolyte and water secretion

The electrolyte and water composition of the external environment has an important effect on release of mucins from secretory granules. Both the stratified squamous and goblet cells of the conjunctiva express ion and water transport proteins and appear to secrete electrolytes and water. Mucin and electrolyte and water secretion may not be coordinated as stimuli of mucin secretion appear to differ from those of electrolyte and water secretion.

The conjunctival epithelium secretes Cl⁻ and absorbs Na⁺ with the ratio of 1.5 to 1 causing a net secretion of fluid into the tear film.²⁹ Interestingly, both absorption and secretion occur within the same cell in the conjunctiva. The ion transport proteins are distributed evenly in all areas of the conjunctiva, suggesting that the entire conjunctiva participates in fluid secretion.

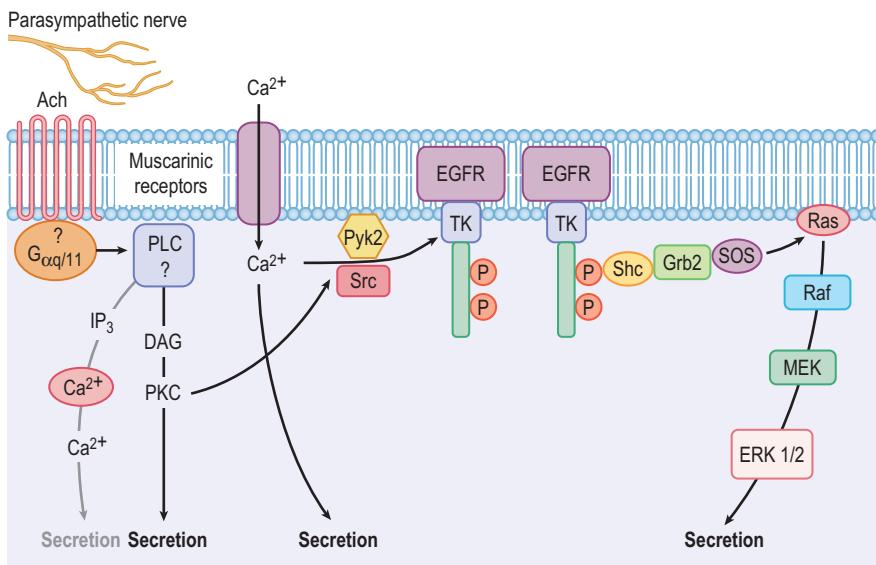

Figure 15.6 Signaling pathways used by cholinergic agonists to stimulate conjunctival goblet cell secretion – the pathway is described in the text. TK-tyrosine kinase, P-phosphorylation site. (Modified from Dartt DA. Prog Ret Eye Res 2002; 21:555–76.)

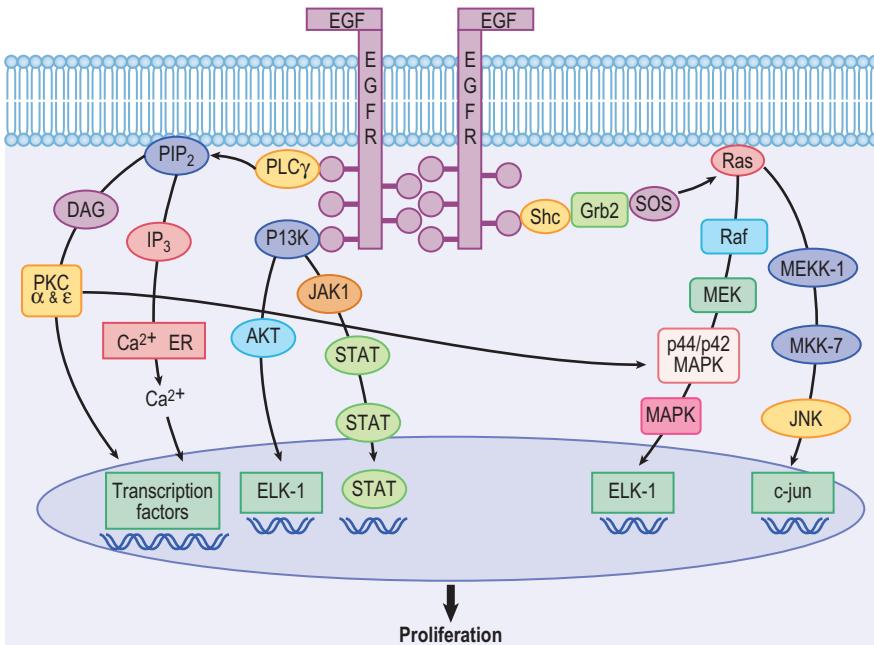

Figure 15.7 Schematic of EGF-dependent signaling pathways.

The driving force for conjunctival fluid secretion is the basolaterally located Na⁺,K⁺-ATPase that extrudes 3 Na⁺ ions for the influx of 2 K⁺ ions and generates a negative intracellular voltage (Fig. 15.8). Also on the basolateral side is the Na⁺-K⁺-2Cl⁻ cotransporter (NKCC1). The Cl⁻/HCO₃⁻ exchanger takes up Cl⁻ into the cell. Cl⁻ is secreted from the apical side of the cell through a variety of Cl⁻ channels. K⁺ is also secreted from the apical side with Na⁺ moving through the paracellular pathway to the apical side. The net effect is isotonic secretion of Na⁺, K⁺, and Cl⁻ into the tears.³⁰

Na⁺ is absorbed across the apical membrane into the cell by the Na⁺-dependent glucose cotransporter. The Na⁺ that enters the cell on the apical side is extruded on the basolateral side by the Na⁺,K⁺-ATPase. The Na⁺ influx mechanism can also be used to transport amino acids (AA) into the cell.³¹

Fluid secretion by the conjunctiva can be stimulated and contribute a substantial amount to the tear film. Increasing the intracellular [Ca²⁺] or the cellular level of cAMP causes Cl⁻ secretion.^{32,33} The β-adrenergic agonist epinephrine stimulates secretion via cAMP. Increasing cellular cAMP levels activate protein kinase A (PKA) that stimulates both Cl⁻ secretion and Na⁺ absorption by activating K⁺ channels in the basolateral membrane to hyperpolarize the cell. Hyperpolarization stimulates Na⁺ influx (into the cell) and Cl⁻ efflux (into tears) across the apical membrane. PKA also stimulates apical Cl⁻ channels. Because there is a higher rate of Cl⁻ secretion relative to Na⁺ absorption, water moves into tears in the basolateral to apical direction. In addition Na⁺ moves paracellularly to produce an isotonic NaCl secretion into tears. Water moves through water channels known as

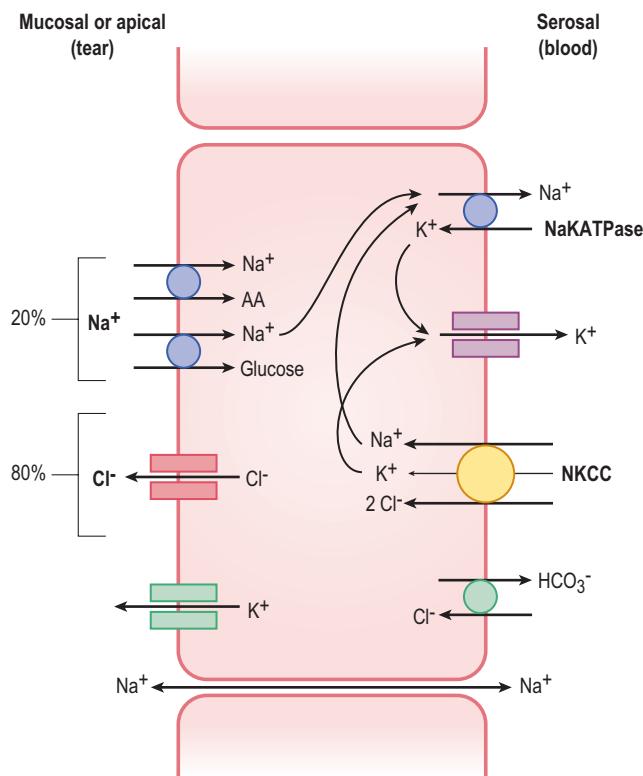

Figure 15.8 Schematic of the mechanism of electrolyte and water secretion by conjunctival epithelial cells – a description of the process is found in the text. (Modified from Darr DA. Prog Ret Eye Res 2002; 21:555–76.)

aquaporins (AQP). AQP 5 is expressed in the apical membrane and AQP 3 in the lateral membrane.

Activation of the purinergic receptor P2Y₂ by UTP and ATP also stimulates electrolyte and water secretion from the conjunctiva. P2Y₂ receptors increase intracellular [Ca²⁺].³⁴

E. Mucous layer function

The major roles of the conjunctiva are to contribute to tear production by secreting electrolytes and water, modify composition of the tear film by secreting mucins, absorb various organic compounds found in tears (including ophthalmic therapeutics), and contribute to resistance of the eye to infection by providing protection against microorganisms.³⁵ Mucins serve as wetting agents that keep the apical epithelia hydrated. Finally, conjunctival cells release paracrine signaling agents such as growth factors that affect ocular surface properties.

4. Aqueous layer

A. Overview

The main lacrimal gland is the major producer of the aqueous layer. Other ocular surface epithelia also contribute to the aqueous layer, most notably the conjunctiva, accessory lacrimal glands, and to a small extent corneal epithelium. Accessory lacrimal glands, which are similar to the main gland, are embedded in the conjunctiva. Function of the accessory lacrimal glands has not been determined as they

are difficult to study in isolation. Thus, this section will focus on the main lacrimal gland, which will be referred to as the lacrimal gland.

B. Lacrimal gland structure

The lacrimal gland is comprised of acini that drain into progressively larger tubules or ducts that coalesce into one or more excretory ducts. Acini are made up of basal myoepithelial cells that surround an inner layer of columnar secretory cells known as acinar cells (see Fig. 15.1). Stellate-shaped myoepithelial cells are known to contract, but their role in lacrimal gland secretion is still unknown. Acinar cells comprise about 80 percent of the gland and are organized in clusters. In cross-section an acinus contains a ring of pyramidal-shaped acinar cells that are joined at the junction of the apical and lateral membranes by tight junctions. The tight junctions polarize the cells and ensure unidirectional secretion of electrolytes, water, and protein, the secretory product of the lacrimal gland.

The lacrimal gland ducts are lined with one to two layers of cuboidal duct cells that make up 10–12 percent of the gland. Similarly to acinar cells, duct cells are joined at the apical side by tight junctions and secrete water, electrolytes, and protein modifying the primary lacrimal gland fluid secreted by the acinar cells.

The lacrimal gland also contains a small population of lymphocytes, plasma cells, mast cells, and macrophages. The plasma cells express immunoglobulins, especially IgA that along with secretory component forms secretory IgA, an important component of the mucosal immune system.

C. Lacrimal gland innervation

The lacrimal branch of the trigeminal nerves carries sensory stimuli from the lacrimal gland and forms the afferent innervation of the gland. The efferent innervation of the gland consists of parasympathetic and sympathetic nerves. The parasympathetic nerve endings predominate, surrounding most acini (Fig. 15.9). Sympathetic innervation is less dense, although this is species-dependent. Sensory nerves are the most sparsely located.

Afferent sensory nerves from the ocular surface activate the efferent parasympathetic nerves to stimulate lacrimal gland secretion. This neural reflex forms the predominant stimulus of lacrimal gland secretion and allows the gland to protect the ocular surface by responding to environmental stimuli.

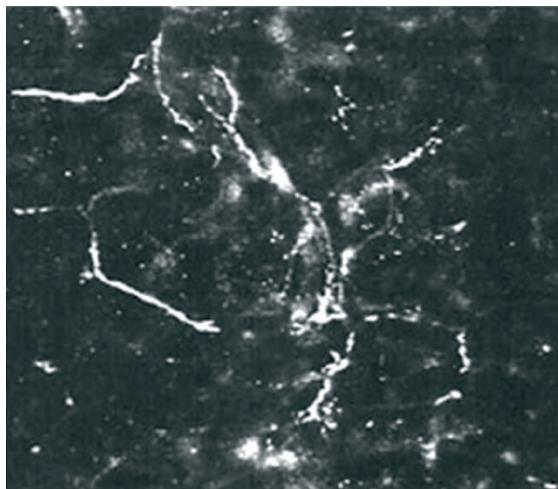

Parasympathetic nerves release the neurotransmitters Ach and VIP that activate receptors on the myoepithelial, acinar, and duct cells. The M₃AchR is the only cholinergic, muscarinic receptor in the lacrimal gland. The VIP receptor VIPAC1 is on acinar cells and VIPAC2 on myoepithelial cells. Sympathetic nerves release the neurotransmitters norepinephrine and neuropeptide Y (NPY). Norepinephrine activates α_{1D}-adrenergic and β-adrenergic receptors located on acinar cells.

D. Protein secretion regulation

Types of protein secretion

The majority of lacrimal gland secretory proteins are secreted by exocytosis. Secretory proteins are stored in secretory granules. Upon the appropriate stimulus secretory granule

Parasympathetic nerves

Sympathetic nerves

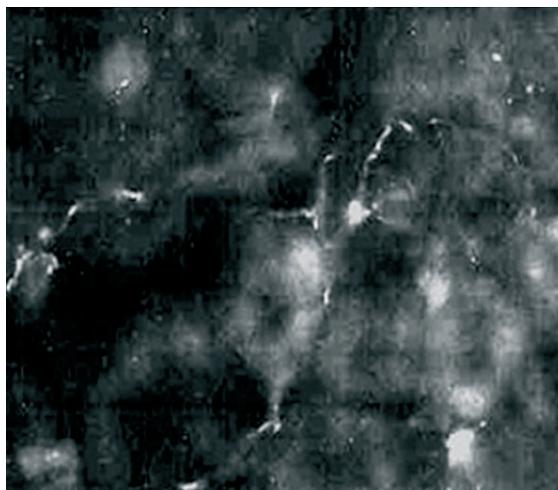

Figure 15.9 Immunofluorescence micrographs of the distribution of parasympathetic and sympathetic nerves in the lacrimal gland. Top panel: anti-VIP demonstrates location of parasympathetic nerves. Bottom panel: anti-tyrosine hydroxylase (TH) indicates sympathetic nerves.

membranes fuse with apical plasma membranes, releasing the contents into the lumen. This secretion is known as merocrine as only a small percentage of granules are released. The exocytic process is controlled by trafficking effectors that include targeting and specificity factors such as SNAREs (soluble N-ethylmaleimide (NEM) sensitive factor (NSF) attachment protein receptors (SNAPs) that function in bringing the secretory granules and apical membrane together for release of cargo secretory proteins) and Rabs (small Ras-like GTPases that regulate membrane trafficking and are active when bound to GTP and recruit proteins necessary for membrane fusion and vesicle maturity) as well as transport factors such as microtubules, actin filaments, and motor proteins.³⁶

Proteins such as secretory IgA are secreted by a combination of transcytosis and ectodomain shedding.³⁷ Transcytosis is a complex trafficking process in which the compound is endocytosed at the basolateral membrane, transported across the cell in a series of endomembrane components, and

secreted at the apical membrane. Secretory component and the EGF family of growth factors are secreted by ectodomain shedding.

The signaling pathways used by neurotransmitters to stimulate lacrimal gland secretion were correlated to exocytosis, not to transcytosis or ectodomain shedding. Thus the next section on signaling pathways will focus on exocytosis.

Cholinergic agonists

The cholinergic agonist Ach binds to M₃AchR on lacrimal gland acinar cells stimulating the G_{αq/11} subtype of G protein that activates phospholipase Cβ (Fig. 15.10). Phospholipase Cβ breaks down the membrane phospholipid phosphatidylinositol bisphosphate into IP₃ and diacylglycerol. IP₃ binds to its receptor on the endoplasmic reticulum and releases Ca²⁺, increasing the intracellular [Ca²⁺]. The depletion of intracellular Ca²⁺ stores causes Ca²⁺ influx across the plasma membrane, known as capacitative Ca²⁺ influx, to sustain the Ca²⁺ increase and replenish the stores. Intracellular Ca²⁺ stimulates exocytosis by activating target proteins involved in the release process.

The diacylglycerol produced with IP₃ activates the PKC isoforms PKC α , PKC δ , and PKC ϵ to stimulate protein secretion. PKC stimulates secretion by phosphorylating unknown substrate proteins involved in exocytosis.³⁸

Cholinergic agonists also activate inhibitory pathways that attenuate secretion. Cholinergic agonists activate Pyk2 and p60Src that cause a Ca²⁺-dependent activation of ERK1/2 (also known as MAPK) (Fig. 15.10). The step in the pathway that activates Ras is unknown. However, the Ras, Raf, MEK pathway leads to activation of ERK1/2. ERK1/2 decreases cholinergic agonist stimulated secretion.

A second pathway activated by cholinergic agonists is the phospholipase D pathway that breaks down phosphatidylcholine to phosphatidic acid and choline. Phosphatidic acid can be metabolized to diacylglycerol that through PKC stimulates ERK1/2 to attenuate secretion. Even though cholinergic agonists activate inhibitory pathways, their ultimate effect is to stimulate secretion.³⁹

VIP

VIP released from parasympathetic nerves activates a separate pathway from cholinergic agonists. VIP binds to VPAC1 and VPAC2 to activate the G protein G_{αs} that stimulates adenylyl cyclase (Fig. 15.11).⁴⁰ Adenylyl cyclase produces cAMP from ATP and cAMP activates PKA that phosphorylates target proteins in the exocytotic machinery. VIP also increases the intracellular [Ca²⁺].⁴⁰ Together cAMP and Ca²⁺ induce protein secretion.

VIP also interacts with ERK1/2. Unlike cholinergic agonists, VIP inhibits ERK1/2. VIP inhibition of ERK1/2 plays a critical role in the interaction of the VIP pathway with those stimulated by cholinergic and α₁-adrenergic agonists.⁴¹

α₁-Adrenergic agonists

The sympathetic neurotransmitter norepinephrine binds to α_{1D}-AR on the acinar cells (Fig. 15.12). To stimulate protein secretion α₁-adrenergic agonists activate endothelial nitric oxide synthase (eNOS) co-localized with caveolin on the basolateral membranes of acinar cells. eNOS produces nitric oxide (NO) that activates soluble guanylate cyclase.⁴²

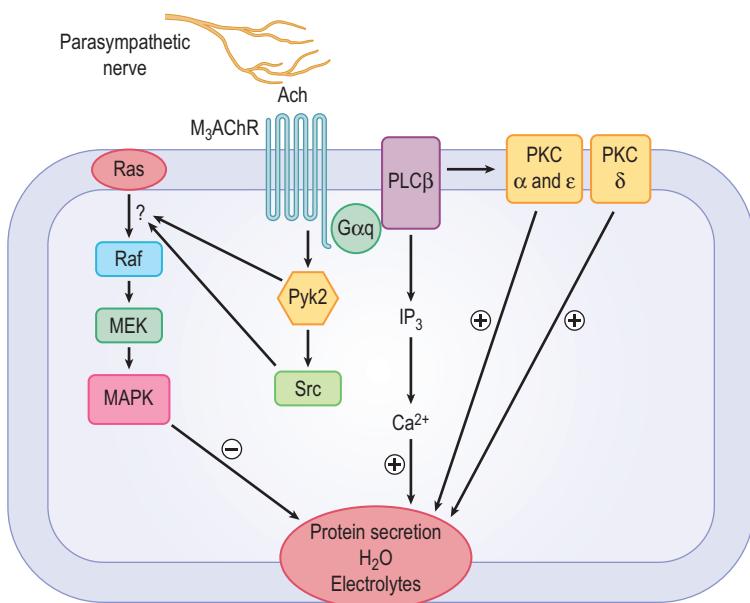

Figure 15.10 Schematic of parasympathetic signaling pathway – the pathway is described in the text.

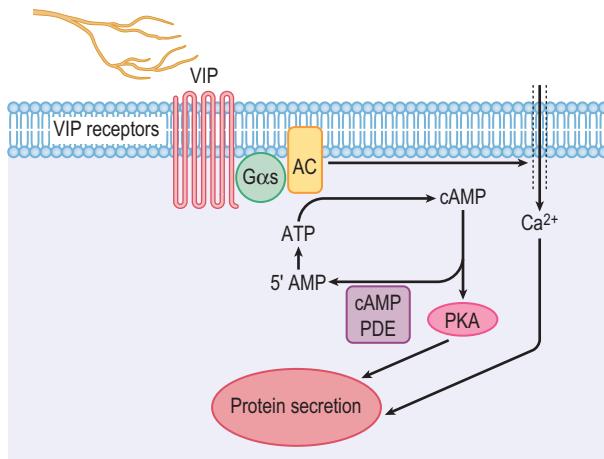

Figure 15.11 Schematic of VIP signaling pathway – the pathway is described in the text.

Guanylate cyclase (GC) produces cGMP from GTP. cGMP stimulates secretion by phosphorylating target proteins in the exocytotic machinery.

α_1 -Adrenergic agonists also give a small increase in intracellular Ca^{2+} that could interact with cGMP to stimulate secretion.⁴³ The mechanism by which α_1 -adrenergic agonists activate eNOS in the lacrimal gland is not known.

α_1 -Adrenergic agonists also activate PKC isoforms. The effector enzyme that produces diacylglycerol is not known, but is not phospholipase C or D. Diacylglycerol activates PKC ϵ to stimulate secretion.⁴³ Unlike cholinergic agonists that activate PKC α and PKC δ to stimulate secretion, α_1 -adrenergic agonists activate these PKC isoforms to inhibit secretion.⁴⁴

α_1 -Adrenergic agonists also activate the ERK1/2 inhibitory pathway (Fig. 15.12).⁴⁵ The mechanism by which α_1 -adrenergic agonists activate ERK1/2 (also known as MAPK) is different from that used by cholinergic agonists.

α_1 -Adrenergic agonists activate a matrix metalloproteinase (MMP) ADAM17, which cleaves the membrane-spanning growth factor EGF, releasing its extracellular domain.⁴⁶ The extracellular domain contains the active EGF, binding domain that binds to the EGFR causing it to dimerize. The EGFR dimer autophosphorylates through the signaling pathway described in section 3.C and activates ERK1/2 to attenuate secretion. Even though α_1 -adrenergic agonists activate inhibitory pathways, the overall action of these agonists is to stimulate secretion.

EGF

Addition of exogenous EGF (the 6 kDa EGF) gives a small stimulation of protein secretion. EGF uses IP_3 , PKC α , and PKC δ to stimulate lacrimal gland secretion.⁴⁷

Interaction of pathways

Activation of parasympathetic nerves alone or both parasympathetic and sympathetic nerves releases two or more neurotransmitters that cause secretion different than one agonist alone. Release of cholinergic and α_1 -adrenergic agonists stimulates secretion that is additive as these agonists activate separate and different signaling pathways.⁴³ Release of VIP with cholinergic or α_1 -adrenergic agonists causes secretion that is synergistic or potentiated.⁴⁸ The potentiation is caused by VIP inhibition of ERK1/2 that prevents activation of ERK1/2 by cholinergic and α_1 -adrenergic agonists (Fig. 15.13). When ERK1/2 activation is blocked, it cannot inhibit secretion and the secretory response is increased.⁴¹

E. Regulation of electrolyte and water secretion

Mechanism of acinar electrolyte and water secretion

Electrolyte and water secretion is driven by the basolateral Na^+/K^+ -ATPase (NKA) that produces the energy to drive the

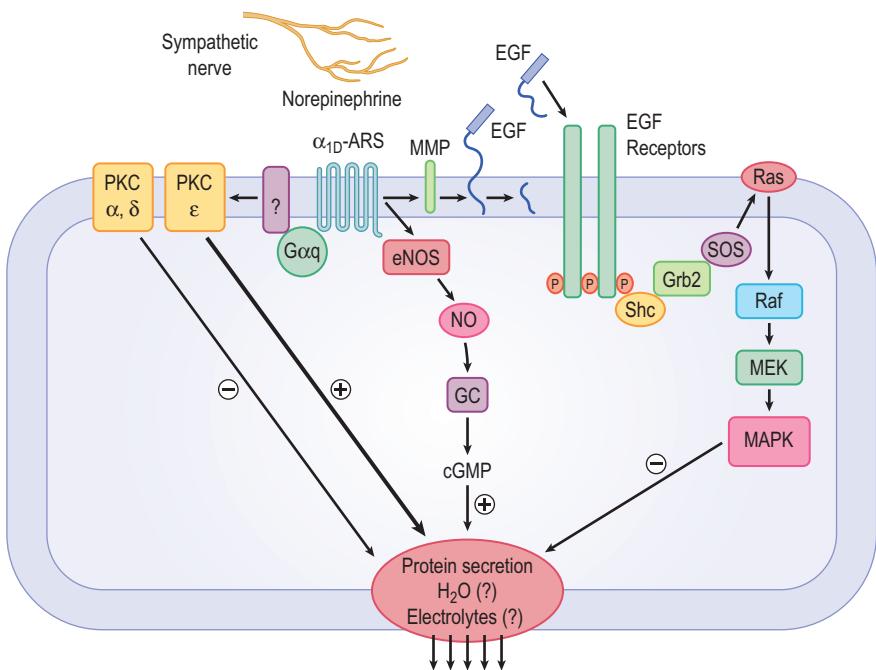

Figure 15.12 Schematic of α_{1D}-adrenergic signaling pathway – the pathway is described in the text.

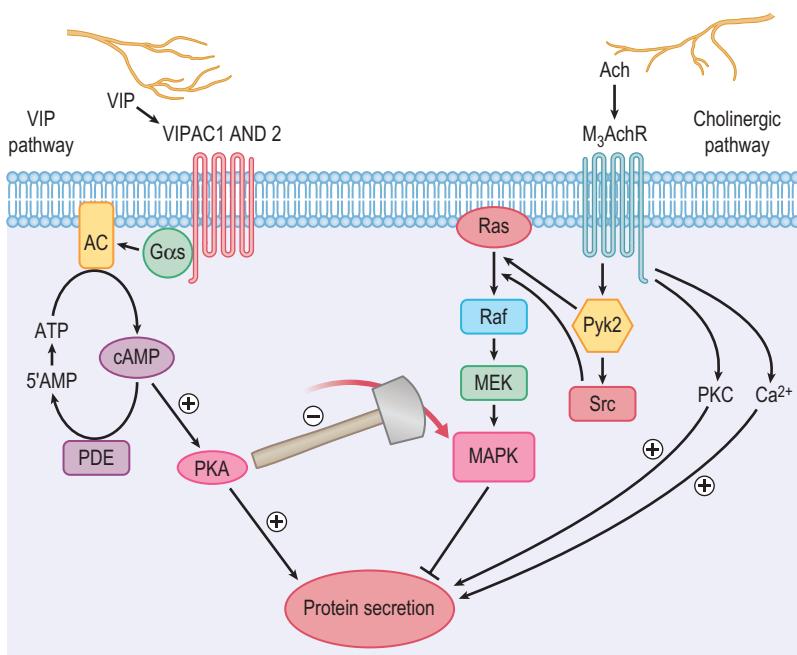

Figure 15.13 Schematic of the interaction between Ca²⁺/protein kinase C and cAMP-dependent signaling pathways.

efflux of Na⁺ and influx of K⁺ across the basolateral membrane into the cell against their electrochemical gradients (Fig. 15.14). The Na⁺/H⁺ (NHE) and Cl⁻/HCO₃⁻ (AE) exchangers and the Na⁺-K⁺-2Cl⁻ symporter (NKCC1) use the energy of the favorable inward Na⁺ gradient to drive Cl⁻ influx across the basolateral membrane. This Cl⁻ influx establishes a favorable gradient for Cl⁻ efflux across the apical membrane through Cl⁻ selective channels into the acinar lumen generating a lumen negative transepithelial potential difference. This potential difference drives the flux of Na⁺ from the basal to apical side of the cell through the paracellular pathway. K⁺ selective channels allow the K⁺ to recycle

across the basolateral membrane so that acini can produce a Na⁺-Cl⁻ rich fluid.

Mechanism of ductal electrolyte and water secretion

Duct cells use mechanisms similar to those used by acini to secrete fluid with a few exceptions. First the K⁺ channels are placed in the apical rather than basolateral membranes with the Cl⁻ channels producing a K⁺-Cl⁻ rich fluid. Those channels include the K⁺-Cl⁻ symporter KCC1, intermediate conductance calcium-activated K⁺ channel (IK_{Ca}1), CFTR channel, and CIC3 Cl⁻ channel.

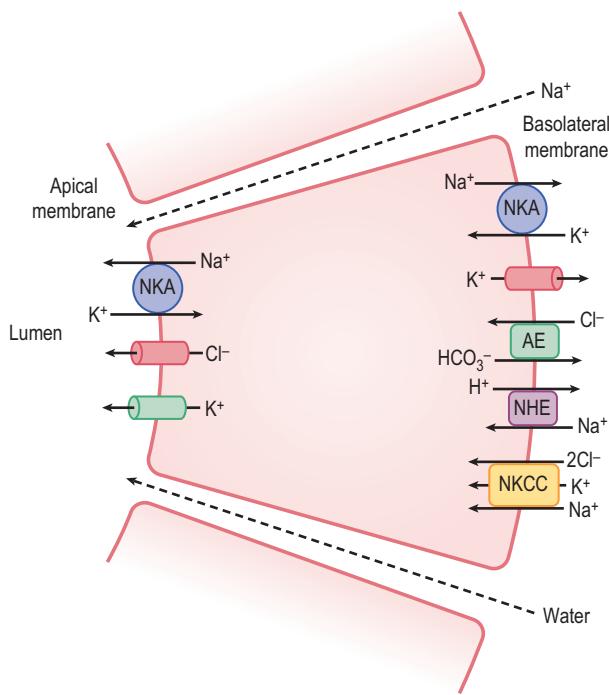

Figure 15.14 Mechanism of electrolyte and water secretion by lacrimal gland acinar cells – see text for description. (Modified from Selvam et al. Am J Cell Physiol 2007; 293:C1412–9. Used with permission.)

Neural activation of electrolyte and water secretion

The parasympathetic agonists Ach and VIP each stimulate electrolyte and water secretion.⁴⁹ Cholinergic agonists cause fluid secretion by activating apical Cl^- and K^+ channels, basolateral Na^+/H^+ exchangers, and increase the translocation of the Na^+/K^+ -ATPase from the cytoplasm to the basolateral membranes. VIP stimulates fluid secretion by cAMP activating the Ca^{2+} -dependent large conductance (BK) K^+ channel in the basolateral membrane. The mechanisms by which cholinergic agonists and VIP stimulate fluid secretion are not yet completely investigated.

F. Lacrimal gland fluid composition

Lacrimal gland fluid is isotonic, and in human and rabbit it is 300 mOsm. The electrolyte composition is similar to plasma except that it has a decreased $[\text{Na}^+]$ and increased $[\text{Cl}^-]$ and $[\text{K}^+]$. The lacrimal gland also secretes a myriad of proteins.⁵⁰ The most extensively studied are lysozyme, lactoferrin, secretory IgA, and lipocalin. Other minor proteins secreted include EGF and other growth factors, lacritin a protein unique to the lacrimal gland, and surfactant proteins A–D.⁵¹ Many proteins are antibacterial and function in the defense of the ocular surface.

G. Aqueous layer function

The aqueous layer has multiple functions critical to the health and defense of the ocular surface from the environment. The electrolyte composition of the aqueous layer is critical to the health of the ocular surface as small changes in osmolarity or electrolyte composition leads to aqueous

deficiency dry eye. Multiple causes can alter lacrimal gland secretion leading to aqueous deficiency dry eye and damage to the ocular surface (see Box 15.2). The proteins in the aqueous layer protect the ocular surface from bacterial infection and alter corneal and conjunctival function. Reflex secretion of the aqueous layers helps to wash away noxious substances and particulates into the drainage duct. The buffer system of the fluid helps to protect against changes in pH.

5. Lipid layer

A. Structure of meibomian glands and mechanism of lipid production

The lipid layer is secreted by the meibomian glands, modified sebaceous glands, that line the upper and lower eyelids in a single row.^{52,53} A single meibomian gland consists of multiple acini that secrete into ducts that converge to form a common duct that exits onto the eyelid near the mucocutaneous junction (see Fig. 15.1). The acini are surrounded by nerves and blood vessels. The cells in the acini are arranged in a specific order that reflects their function such that the outer cell layer consists of undifferentiated, flattened basal cells. As these cells mature they move inward to the center of the acinus and concomitant with this inward migration is continuing synthesis of lipids. Meibomian gland lipids are stored in vesicles. As the cells move closer to the center they contain increasingly more lipid secretory vesicles reflecting continued lipid synthesis. Upon the appropriate stimulus (unknown), the cells in the acinus center burst, releasing the entire cell contents in their secretory granule lipids and the other components of the cell into the duct system. This releases the entire cell contents and is known as holocrine secretion. The secreted cells are replaced by proliferation of the basal cells.⁵⁴ Thus the secretory product contains a complex mixture of lipids and proteins and is termed meibum. The synthesized lipids are the major component of meibum, with the minor lipid classes probably reflecting the cellular membrane lipids. Meibomian fluid is a mixture of non-polar lipids (wax esters, cholesterol, and cholesterol esters) and polar lipids (mainly phospholipids). Meibum is liquid at lid temperature.

The secreted lipid is stored in the duct system that terminates in orifices, with a muscular cuff, that open onto the lid.⁵³ Meibum is released onto the ocular surface in small amounts with each blink forming a casual reservoir with about 30 times more lipid than needed for each blink. With the up-phase of each blink the upper lid draws oil from the lid reservoir and spreads it over the anterior tear film surface. With the down phase the lipid film is returned to the marginal reservoir as the lid closes.⁵³ The lipids mix only slightly with the lipid reservoir as it folds up as an intact sheet providing a gradual turnover of the lipids in the tear film.

Butovich et al⁵⁵ have proposed that proteins and mucins contribute to the lipid layer so that the proteins, which contain hydrophobic, hydrophilic, and charged portions, can unfold and form a variety of shapes depending upon the local milieu (Fig. 15.15). The proteins could extend across the lipid layer suggesting a complex mixture of

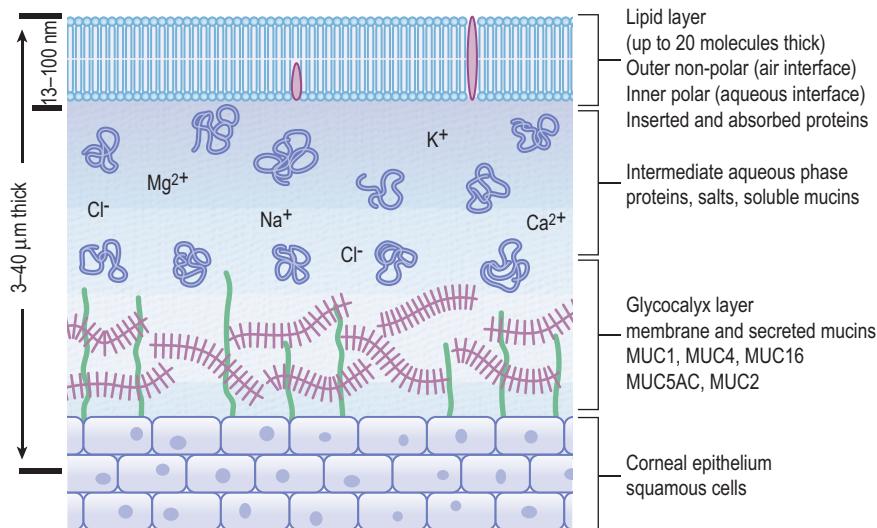

Figure 15.15 Schematic diagram of the tear film showing a new concept for the structure of the lipid layer. (Modified from Butovich IA et al. *Curr Eye Res* 2008; 33(5):405–20.)

islands of proteins, mucins, and lipids, similar to that of lung surfactant. This model would be a non-collapsible, viscoelastic gel and allow for the lowest free energy states of the proteins in contact with lipids. Changes in the osmolarity of tears would affect the ability of the proteins to unfold and interact with the lipids. This model also accounts for the lack of change of interference patterns after each blink.

B. Regulation of meibum secretion

Neural regulation

Meibomian glands are richly innervated by sensory, sympathetic, and parasympathetic nerves.⁵⁶ The sensory nerves contain substance P and calcitonin gene-related peptide (CGRP). The sympathetic fibers use catecholamines and NPY as neurotransmitters. Parasympathetic nerves are immunopositive for cholinergic neurotransmitters, VIP and NO. However, the role of nerves in meibomian gland function is unknown.

Hormonal regulation

The meibomian glands have both androgen and estrogen receptors. Androgens regulate lipid secretion by controlling lipid synthesis. Meibomian acinar cells have nuclear androgen receptors⁵⁷ and the ratio of androgens and estrogens is critical for controlling lipid synthesis.⁵⁸ Stimulating androgen receptors increases gene transcription for enzymes associated with fatty acid and cholesterol synthetic pathways and hence stimulate lipid production. Androgen deficiency is associated with meibomian gland dysfunction.

C. Function

The meibomian gland secretion forms a hydrophobic barrier to prevent tear overflow onto the lids and sebum from the skin from entering the tear film.⁵⁹ The mucocutaneous junction itself separates the tear-wettable conjunctiva from the oil-wettable eyelid skin preventing overgrowth in both directions.⁶⁰ The meibom forms a water-tight seal of the apposed lid margins during sleep.^{52,53} The tear lipids also reduce tear evaporation during eyelid opening and aid in lubrication for

Box 15.3 Meibomian Gland Diseases Causing Evaporative Dry Eye

- Reduced number of glands in congenital deficiency and acquired disease
- Replacement of glands in distichiasis and distichiasis lymphedema syndrome
- Hypersecretory gland dysfunction in meibomian seborrhea
- Hyposecretory gland dysfunction in retinoid therapy
- Obstructive disease from primary or secondary causes, of focal or diffuse nature, that is simple or cicatricial or can be atrophic or inflammatory
- Primary or secondary due to the local diseases anterior blepharitis
- Primary or secondary due to systemic disease such as acne rosacea, seborrhoeic dermatitis, and atopy
- Primary or secondary due to systemic toxicity from 13-cis retinoic acid, polychlorinated biphenyls, and epinephrine
- Cicatricial disease from chemical burns, trachoma, pemphigoid, erythema multiforme, acne rosacea, vernal keratoconjunctivitis, or atopic keratoconjunctivitis

Modified from 2007 Report of the International Dry Eye Workshop, The Ocular Surface, vol 5, number 2, page 82, 2007

the eyelids during blinking. Lipids enhance the stability of the tear film and provide a smooth optical surface for the cornea at the air/lipid interface. A decrease or an alteration in meibomian gland secretion leads to evaporative dry eye. There are multiple ways in which meibomian gland function can be altered to cause evaporative dry eye (Box 15.3) and damage the ocular surface.

Sensory Innervation of the Eye

Carlos Belmonte, Timo T. Tervo & Juana Gallar

Introduction

The sensory innervation of the eye is provided by the peripheral axons of primary sensory neurons located in the trigeminal ganglion. The sensory nerves enter the eyeball mainly through the ciliary nerves and reach all ocular tissues with the exception of the lens and the retina. Ocular innervation is particularly rich in the cornea but all tissues of the anterior segment of the eye have an abundant sensory supply. Ocular sensory fibers are functionally heterogeneous and include mechanoreceptor, polymodal nociceptor, and cold receptor types of sensory units. Consequently, the nerves respond to a variety of physical and chemical stimuli. Impulse activity originated at peripheral sensory nerve fibers of the eye reaches second-order neurons located at the trigeminal nucleus caudalis in the lower brainstem. Sensory information travels subsequently to relay stations in the contralateral posterior thalamic nucleus and finally reaches the cortex.
